Incorrectly accounting for preference heterogeneity in choice experiments: Implications for welfare measurement

Catalina M. Torres, Sergio Colombo and Nick Hanley

ABSTRACT: The impact of the approach used to describe preference heterogeneity on welfare measures has been widely studied by the academic community. However, the question as to the degree of error in welfare estimation from an inappropriate choice of empirical approach has not been addressed yet. In this paper, we use Monte Carlo analysis to investigate this issue. Our overall conclusion is that, when analysts have difficulties in choosing the best approach relying on available statistical tests, smaller errors in welfare measures are likely to come from use of a latent class model.

Modelización incorrecta de la heterogeneidad de las preferencias en los experimentos de elección: implicaciones en las medidas de bienestar

RESUMEN: El impacto de enfoques alternativos de representación de heterogeneidad de preferencias en las medidas de bienestar es un área que ha recibido especial atención por parte de la comunidad académica. No obstante, la magnitud del error cometido en las estimaciones debido al uso del enfoque incorrecto todavía no ha sido objeto de análisis. En este artículo, se utiliza la simulación Monte Carlo para investigar esta cuestión. La conclusión principal es que, a falta de resultados claros en los test estadísticos disponibles, los errores en las estimaciones de bienestar son menores cuando se opta por un modelo de clases latentes.

1. Introduction

Choice modelling (CM) has emerged as a flexible and informative method for estimating non-market values in a range of fields of application, including agricultural, environmental, transport and health economics (Hensher et al., 2005a; Louviere et al., 2000). The method can be applied to both stated preference (SP) and revealed preference (RP) data. Its advantages are now well-known: The ability to estimate values for the characteristics or attributes of a range of goods, services and policy designs; to produce estimates of compensating or equivalent surplus for a range of outcomes specified in terms of changes in multiple attribute levels; and to measure both use and non-use values if an SP approach is employed. Dating from Train (1998), choice modellers have become increasingly interested in how to represent heterogeneity in preferences, a research direction foreseen by Ben-Akiva and Lerman (1985; p. 367) in one of the earliest works on discrete choice analysis. A range of empirical approaches to representing preference heterogeneity have emerged in CM, and we review these in the following section. Researchers have been able to explore the differences that selection of a particular approach makes to welfare measures in a particular dataset, and indeed have been able to implement a number of tests for which approach best fits a particular set of data (Colombo et al., 2009; Hynes et al., 2008).

However, the question as to the degree of error in welfare estimation which results from an inappropriate choice of empirical approach to represent preference heterogeneity in a particular empirical setting—in terms of the difference between estimates of the money metric measure of welfare change and the true, underlying money metric welfare change—has not been addressed. This is because, of course, in most situations we are unable to observe this underlying, true measure of welfare change for non-market goods (Johansson, 1993). Any systematic over- or under-estimation of benefits due to an inappropriate selection of modelling approach is of particular relevance for many environmental applications of CM, where the main goal is to inform benefit-cost analysis (Hanley and Barbier, 2009).

In this article, we use Monte Carlo (MC) analysis to address this question. MC analysis allows the researcher to start with a particular “true” utility function and a particular distribution of preferences across a population of consumers, and then to simulate choices to a set of choice alternatives based on these preferences. A variety of models with alternative treatments of preference heterogeneity can be estimated based on these simulated choices, and welfare estimates calculated. Since the true utility functions underlying these choices are known to the researcher, including the true, underlying pattern of preference heterogeneity which generates the data, we can then quantify both the relative and absolute magnitudes of errors in welfare estimates in relation to the true, underlying money metric measure of compensating or equivalent surplus. Thus, welfare error quantification enables us to comment on the likely consequences for benefit-cost analysis of incorrect assumptions about how to model preference heterogeneity in survey-based applications of the method.

The structure of the rest of this article is as follows. The next section provides a review of how heterogeneity has been modelled in stated choice data. It shows little
Attention has been paid to the implications for the accuracy and efficiency of welfare measures of mistaken assumptions about preference heterogeneity. Section 3 discusses the methodology used and the data employed for the MC experiments. Results are reported in section 4, where the sensitivity of welfare measures to mistaken assumptions about the nature of preference heterogeneity is analysed. Discussion and conclusions follow in section 5.

2. Modelling heterogeneity in stated choice data

The random parameter logit (RPL) and latent class (LC) model have emerged as popular approaches to preference heterogeneity (Claassen et al., 2013; Hensher and Greene, 2003; Milon and Scrogin, 2006; Scarpa and Thiene, 2005). A range of papers in transport, leisure and environmental economics compare the performance of RPL and LC approaches to determine which fits the data better and to examine differences in welfare estimates (Birol et al., 2006; Boxall and Adamowicz, 2002; Broch and Vedel, 2012; Greene and Hensher, 2003; Hynes et al., 2008; Ouma et al., 2007; Provencher and Bishop, 2004; Strazzera et al., 2013). In the RPL or “mixed logit” model, the utility function for respondent \( n \) choosing over \( J \) alternatives is augmented with a vector of parameters that incorporate individual preference deviations with respect to the mean. In LC models, heterogeneity is captured by assuming that the underlying distribution of tastes can be represented by a discrete distribution, with a small number of mass points that can be interpreted as different groups or segments of individuals. Preferences in each “latent” (that is, unobserved) class are assumed homogeneous; but preferences, and hence utility functions, can vary between segments. The two approaches can also be combined, as shown by Bujosa et al. (2010). Empirical results show that there is no clear pattern of which approach (RPL, LC) is superior to the other (Greene and Hensher, 2003; Scarpa and Thiene, 2005), with the “best” choice of approach seeming to depend on the nature of the underlying data generating process, as would be expected.

The fact that RPL and LC models assume that the variance of the error term of utility is constant, and consequently that the scale parameter is also constant, has led to the emergence of alternative approaches which focus on modelling scale heterogeneity. The main reason is pointed out by Louviere et al. (1999; 2002; 2008), Louviere and Eagle (2006) and Meyer (2007): All statistical models in which the dependent variable is latent are likely to confound estimates of the model’s parameters with error variability, and as such the parameter estimates do not represent mean tastes but the means multiplied by a scale factor. One of the approaches for dealing with scale heterogeneity is the covariance heterogeneity (Cov-Het) model, which includes heterogeneity in the stochastic part of utility by allowing the scale parameter to be a function of choice attributes and respondents’ socioeconomics characteristics. Colombo et al. (2009) compare the performance of the RPL, LC and the Cov-Het models and conclude the LC approach best fits the data although the three models perform equally well in terms of out-of-sample predictions.
More recently, there has been an emerging literature which aims to combine the modelling of taste and scale heterogeneity. Fiebig et al. (2010) compare a RPL model with a scale heterogeneity multinomial logit model (S-MNL) where only scale heterogeneity is allowed, and a generalized multinomial logit (G-MNL) model which considers both taste and scale heterogeneity. They conclude that the S-MNL and G-MNL models outperform the RPL model especially in datasets that involve more complex choices. Greene and Hensher (2010) find however that accommodating only scale heterogeneity (i.e. neglecting taste heterogeneity) may be of limited empirical interest, resulting in a statistically inferior model, whereas the inclusion of both scale and taste heterogeneity results in an improvement over the standard RPL model. Importantly, they observe that compared to failure to include for taste heterogeneity, failure to account for scale heterogeneity may not be of such great empirical consequence especially when WTP measures are of primary interest. The reason is that the effect of confounding between scale and taste cancels out in the estimation of the WTP, because this is calculated by dividing the estimated coefficients by the price parameter (i.e. making the estimation of WTP scale-free). Although this is not always generally applicable\(^1\), most CM applications in environmental valuation aim primarily at providing information to decisions makers about non-market values of environmental goods, and in particular to produce estimates of compensating or equivalent surplus for a range of outcomes specified in terms of changes in attribute levels for public goods. When the analyst is primarily interested in WTP measures, the more parsimonious model approach which considers taste heterogeneity alone can thus be adequate\(^2\).

As can be seen then, research on heterogeneity in choice modelling is extensive. However, little attention has been paid to examine the effects on welfare estimates of mistaken assumptions about the nature of preference heterogeneity. As pointed out by Torres et al. (2011), the interest in analysing the bias and efficiency of welfare estimates within non-market valuation has been mainly centered on investigating, through MC analysis, issues such as the i) specification of the recreation demand function in travel cost models, ii) WTP elicitation in the contingent valuation approach, and iii) experimental design under different utility specifications in choice experiments (Kling, 1987; 1988; 1989; Adamowicz et al., 1989). Investigations of the effects of decisions over appropriate nesting structures in multiple site recreation demand models represent a related area of concern (Herriges and Kling, 1997; Kling and Thomson, 1996), which also makes use of MC analysis. In the contingent

---

\(^1\) Flynn et al. (2010) point out that such normalization is not always possible, as for instance in the medical field where often there is not a monetary attribute used in the design. In this case, it is paramount to take into account both taste and scale heterogeneity to obtain unbiased estimates of the parameter of interest. At the same time they warn that there may be different variance-scale factors by attribute and the traditional solution of dividing the attribute coefficients by the price coefficient may be wrong.

\(^2\) Hess and Rose (2012) argue that gains in fit obtained in models accounting for scale heterogeneity are the results of using more flexible distributions, rather than an ability to capture scale heterogeneity. Indeed, they argue that recent work aimed at providing separate and uncorrelated stochastic treatments of ‘scale’ and ‘taste’ sensitiveness, such as Fiebig et al. (2010) and Greene and Hensher (2010), ignores the existence of scale/taste sensitivity confound and hence interpretation from their results is wrong.
valuation field, papers focusing on the analysis of welfare bias and variance through the MC approach mostly deal with the advantages of combining RP and SP data (Kling, 1997), and the efficiency gains from using double-bounded discrete choice model relative to a bivariate probit model (Alberini, 1995) and different elicitation formats and bid designs (Scarpa and Bateman, 2000). In choice experiments (CE), the main concern of analysts has been directed towards examining through the use of MC methods the implications for welfare measurement of different experimental design strategies (Carlsson and Martinsson, 2003; Ferrini and Scarpa, 2007; Lusk and Norwood, 2005; Scarpa and Rose, 2008).

It is thus easy to see that most of the literature concerned about the analysis of welfare bias and efficiency through the use of MC analysis has paid little attention to the question of how important the way in which preference heterogeneity is modelled in CM is for welfare measurement. To our knowledge, only Torres et al. (2011) attempt to examine the errors from mistaking the way of explaining heterogeneity in CEs. In particular, and with a focus on different attribute specifications, they analyze the effects on welfare estimates from i) correctly assuming RPL taste heterogeneity but mistaking parameter distributional assumptions, and ii) incorrectly assuming RPL taste heterogeneity when it is driven by the scale factor. However, Torres et al. (2011) do not investigate the significance of analytical errors resulting from differences between latent class (finite mixture) and random parameter (continuous mixture) utility functions.

In this paper, we contribute to the literature by examining the errors from mistaken empirical approaches to account for the nature of underlying preference heterogeneity, when choice is only affected by variations in tastes across people and not by variations in the scale of the error. In other words, we focus on the implications of mistaken assumptions about the underlying utility function capturing taste heterogeneity in CEs. The feature of preference heterogeneity on which we focus is this distinction between finite- and continuous-mixing models. As discussed, there are indeed more options for the researcher focusing on preference heterogeneity to choose from now than just RPL or LC, but we exclude them from our analysis for two reasons. First, our focus is on the two most widely-used approaches to date in modeling preference heterogeneity in the environmental valuation literature, namely RPL and LC models (Beharry-Borg et al., 2009; Bujosa et al., 2010; Colombo et al., 2009; Hess and Beharry-Borg, 2012; Hynes et al., 2008; Provencher et al., 2002). Second, the debate around how best to model scale heterogeneity is still inconclusive. In this context, we think it is of considerable interest for cost-benefit analysts to know how much of an error can be made in estimating welfare measures by specifying the “wrong” model under either of these two simple model specifications.
3. Methods

3.1. The experimental design

We base our Monte Carlo analysis on an actual CE study of recreational beach use in Santa Ponça Bay, a small Mallorcan tourism area\(^3\). We consider three site quality attributes, two representing measures of water quality (\(X_1, X_2\)), an indicator of congestion at the beach (\(X_3\)) and a cost attribute (\(X_4\)). Each attribute takes three possible levels. The features of the experimental design used in this paper are explained in Torres et al. (2011), who base their MC analysis on the same recreational study. We use a D-efficient design allowing for main effects only\(^4\). The main features of the design are shown in Table 1.

3.2. Underlying taste heterogeneity and true compensating surplus

Given preference heterogeneity in the systematic part of utility has been commonly understood on the basis of RPL and LC models in environmental valuation, we focus on representations of these two types of taste heterogeneity at the first stage of our MC analysis. Thus, for both types of taste heterogeneity we consider two underlying linear-in-attributes utility functions with the same explanatory variables (\(X_1, X_2, X_3,\) and \(X_4\)).

---

\(^3\) See Torres et al. (2009) for more details on the study.

\(^4\) Although one could argue that a WTP efficient design would be better when the focus is on welfare estimates, using a D-efficient design allows us to relate the simulations to real data collected using the same design.
For simplicity reasons, differences in preferences across individuals have only been assumed for the two environmental attributes $X_1$ and $X_2$. Thus, when true preferences are best described using a RPL model, each individual has been assigned their own parameters for $X_1$ and $X_2$, which represent mean attribute weights plus person-specific deviations from those means, as shown in equation [1]:

$$U_{jit} = (\alpha + \eta_i) X_{1jt} + (\beta + \psi_i) X_{2jt} + \gamma X_{3jt} + \omega X_{4jt} + \epsilon_{jit}$$  \[1\]

where $U_{jit}$ is the indirect utility of alternative $j$ for individual $i$ and choice occasion $t$, $\alpha$, $\beta$, $\gamma$ and $\omega$ are the known parameters of the attributes (i.e. mean attribute weights), $\eta_i$ and $\psi_i$ are individual-specific standard deviation parameters for $\alpha$ and $\beta$, respectively, and $\epsilon_{jit}$ is the error term associated with alternative $j$ and individual $i$ and choice occasion $t$ (Train, 1998; 2009).

We recognize that assuming a non-random coefficient for the cost attribute is a strong assumption as it implies the assumption of a constant marginal utility of income (Lanz and Provins, 2013) which has implications for WTP estimates (Daly et al., 2012). However, there is still a debate in the literature about the relative advantages of using a random or a non-random cost coefficient. Indeed, many authors state that a random cost parameter is associated with problems of identification of WTP values (Colombo et al., 2007; Hensher et al. 2005b; Olsen, 2009; Rigby et al., 2009). Besides, the development of modeling approaches intended to overcome those problems, such as the WTP space estimation, is still yielding mixed results (Balcombe et al., 2009). According to this, and especially considering that in this paper we focus on mistaken assumptions about taste heterogeneity in a context where we control for the true underlying utility specification, we opt for specifying a non-random cost parameter to make our results clearer. However, we recognize that assuming constant the marginal utility of income is unrealistic and represents a limitation of this work for the use of the welfare estimations in real policy settings.

When true preferences are best described using a LC model, we consider heterogeneity for $X_1$ and $X_2$ is explained by the fact that individuals are assigned to two behavioural groups or latent (i.e. unobserved) segments on the basis of three LC covariates. The covariates considered to probabilistically determine membership of the two segments are two continuous variables, namely Age ($Z_1$) and Education ($Z_2$), and one dummy variable indicating if the individual belongs or not to some environmental organization ($Z_3$). Although it is not uncommon that only two latent classes in a given population best explain preferences (Beharry-Borg and Scarpa, 2010; Birol et al., 2006), our main motivation for using a simple set up with only two segments is to consider in comparison the most extreme case between the discrete and conti-

---

5 This helps to explain why many of the papers using RPL models that have been published in top journals over the last years still opt to use a fixed parameter for the price term both in the RP (Frondel and Vance, 2013; Massey et al., 2006; Moeltner and Shonkwiler, 2005; Murdock, 2006; Provencher and Bishop, 2004) and the SP fields (Birol et al., 2006; Beharry-Borg et al., 2009; Boxall and Adamowicz, 2002; Burton and Rigby, 2009; Colombo et al., 2007; Foster and Mourato, 2003; Hensher et al., 2005b; Kipperberg and Larson, 2012; Olsen, 2009; Olsen et al., 2011; Rigby et al., 2009; Rolfe and Windle, 2013).
nuous distribution of the preferences. Indeed, the higher the number of latent classes, the closer the discrete and continuous distributions become. LC taste heterogeneity is then driven by the individual probability of membership in a latent class \( s \) (equation [2]) in such a way that preferences are assumed homogeneous within each class (equation [3]) but heterogeneous between segments (Train, 2009).

\[
P_{is} = \frac{\exp(\lambda_{1s}Z_{is} + \lambda_{2s}Z_{2is} + \lambda_{3s}Z_{3is} + \xi_{is})}{\sum_{s=1}^{S} \exp(\lambda_{1s}Z_{is} + \lambda_{2s}Z_{2is} + \lambda_{3s}Z_{3is} + \xi_{is})} \tag{2}
\]

where \( P_{is} \) is the probability for individual \( i \) of membership in segment \( s \), \( Z_{is}, Z_{2is}, \) and \( Z_{3is} \) are the covariates for individual \( i \), \( \lambda_{1s}, \lambda_{2s}, \) and \( \lambda_{3s} \) are the known parameters of the covariates for segment \( s \), and \( \xi_{is} \) is a Gumbel distributed error term associated to individual \( i \) and segment \( s \) (Bhat, 1997). Although a semi-parametric form based only on a constant term can be used to specify the membership probability (Scarpa and Thiene, 2005), the most common specification is implemented with a set of socio-economic covariates (Bujosa et al., 2010).

Conditional on belonging to segment \( s \), the utility of individual \( i \) for alternative \( j \) is specified as:

\[
U_{jits} = \alpha \ X_{1jt} + \beta \ X_{2jt} + \gamma \ X_{3jt} + \omega \ X_{4jt} + \epsilon_{jits} \tag{3}
\]

where \( U_{jits} \) is the indirect utility of alternative \( j \) for individual \( i \), choice occasion \( t \) and segment \( s \), \( \alpha \) and \( \beta \) are the known parameters of \( X_1 \) and \( X_2 \) for segment \( s \), \( \gamma \) and \( \omega \) are known parameters of \( X_3 \) and \( X_4 \) being constant for both segments, and \( \epsilon_{jits} \) is the error term associated with alternative \( j \), individual \( i \), choice occasion \( t \) and segment \( s \).

Note that when generating RPL simulated choices, we have not made the random parameters of \( X_1 \) and \( X_2 \) to depend on the LC socio-demographics. Comparing RPL and LC models in such a way is not an uncommon practice in the literature (Boxall and Adamowicz, 2002; Broch and Vedel, 2012; Ouma et al., 2007). In fact, as stated by Broch and Vedel (2012), the LC model is believed to be able to provide a different dimension for describing taste heterogeneity, where individuals are expected to have different motivations and aims for their choices, and therefore potentially belong to discrete groups based on latent variables. In the case of RPL, the heterogeneity is described by allowing the preference to vary according to a random distribution. We want to keep this difference in the data generation process.

With the purpose of measuring the difference between estimated and true compensating surplus (CS), we perform a simulation exercise using an experimental design based on a real empirical application involving an improvement in the good being valued (beach quality) described by changes in three of its attributes, namely water quality \( (X_1) \), the duration of an algal bloom \( (X_2) \) and crowding at the beach \( (X_3) \). Following Hanemann (1984), the CS at the individual level, defined as the WTP for a change in the attributes from the business-as-usual (BAU) scenario, has been calculated for the RPL and LC heterogeneity contexts as shown in equations [4] and [5], respectively:
Incorrectly accounting for preference heterogeneity in choice experiments...

\[ CS_i = -(1/\omega)(\alpha_i \Delta X_1 + \beta_i \Delta X_2 + \gamma \Delta X_3) \]  

[4]

\[ CS_i = P_{ij/s} CS_s + P_{ij/s*} CS_{s*} \]  

[5]

\[ P_{ij/s*} = 1 - P_{ij/s} \]  

[5a]

\[ CS_{\text{class}} = -(1/\omega)(\alpha_{\text{class}} \Delta X_1 + \beta_{\text{class}} \Delta X_2 + \gamma \Delta X_3), \text{class} = s, s^* \]  

[5b]

where \( \Delta X_1, \Delta X_2, \Delta X_3 \) represent the changes in \( X_1, X_2, \) and \( X_3, \) respectively, from the policy-off to the policy-on context, \( CS_s \) and \( CS_{s*} \) are the CS corresponding to segment 1 and segment 2, respectively, being constant across individuals within each segment, and \( \omega \) is the parameter for the cost attribute \( X_4 \) (or the marginal utility of income).

Table 2 shows the known parameters used to calibrate the utility function (equations [1] and [3] for RPL and LC model, respectively) and to calculate compensating surplus (equation [4] and [5]). The scenario considered was a hypothetical change in \( X_1, X_2, \) and \( X_3, \) from a status quo level (a value of 60, 8, and 10, respectively, as shown in Table 1) to a situation in which they take the levels 20, 6, and 20, respectively, indicating a reduction in water pollution and in the congestion level at the beach. The values for all the parameters but \( \alpha \) used in the RPL DGP are those used for the linear utility specification in Torres et al. (2011). The values for the attribute parameters of segment 1 and 2 in the LC DGP have been chosen in such a way that individuals belonging to segment 1 are more sensitive to impacts on beach quality. Besides, we consider individuals of segment 1 to be younger, have higher education levels and belong to an environmental organization. This means that younger, better educated individuals belonging to an environmental organization will be more sensitive to beach quality. The mean and standard deviation of the three covariates used in the analysis are also reported in Table 2. The values assumed for the covariates and their parameters allow us to assume that the true probability of belonging to segment 1 is 55.15 % and that of belonging to segment 2 is 44.85 %. We base the percentages on the findings by Birol et al. (2006), Beharry-Borg and Scarpa (2010) and Bujosa et al. (2010), who, after showing that a LC model with two segments best fit the data, report segment shares ranging from 40 % to 60 %.

---

6 For comparability reasons, the values for the parameters representing homogeneous preferences among individuals (\( \gamma \) and \( \omega \)) are the same in both DGPs.

7 To set the parameter values for the covariates and attributes, we undertook LC model estimations on different sets of choices generated through LC schemes built on different parameter values. We chose the values for which the LC model showed a better performance.

8 In particular, the class probabilities they find are 57.24 % vs. 42.76 % in Birol et al. (2006), 61 % vs. 39 % in Beharry-Borg and Scarpa (2010), and 38.88 % vs. 61.12 % in Bujosa et al. (2010). To set the values for the true segment shares, we run different LC models on LC choices generated under different values for the segment shares ranging from 40 % to 60 %. Again, we chose the values for which the LC model showed a better performance.

a RPL-Log represents the RPL preference scenario, where and α and β are lognormally-distributed, with 1.8 mean and 0.45 variance for α, and 0.7 mean and 0.18 variance for β. Note that we assume the variance being a 25% of the mean. LC-2 seg represents the LC preference scenario where two latent segments exist in the population with shares 0.55 and 0.45.

b The minimum and maximum values of Age are 18 and 83, respectively. Education has only 3 levels meaning low (1), medium (2) and high (3) education levels. EO takes value 1 when the individual belongs to an environmental organization. Therefore, the assumed population consists of mid-life, educated, environmentally-aware individuals.

c The true CS has been obtained by averaging the individual CS values over all the simulated individuals.

Source: Own elaboration.

3.3. MC experiments and quantification of errors in welfare estimates

At the second stage of the analysis, MC experiments have been undertaken to simulate choices for each of the two types of true taste heterogeneity when attribute values change in the way specified above. The utility of each alternative for each choice occasion has been calculated by combining the known parameters of the utility function (in Table 2) with the attribute levels and an error term. These error terms have been generated from a Gumbel distribution, and a unique error has been randomly drawn not only for each alternative but also for each observation in the sample.

This procedure generates two datasets, one for each type of underlying true taste heterogeneity or Data Generating Process (DGP). In each dataset, for each choice task the simulated choice has been assigned to the alternative providing the highest utility level. In the simulation, 240 individuals have been considered. As each hypo-
Theoretical individual faces 6 choice tasks (as might be the case in a typical empirical study), 1,440 (240x6) observations have been created by this process for each DGP. These observations represent the two underlying true forms of preference heterogeneity. Then, using these simulated samples of responses, RPL and LC models have been estimated in the usual manner, and welfare estimates calculated. By estimating different models under different DGPs it is possible to determine the errors that the analyst would incur when he/she mistakenly estimates an LC model when the true underlying preferences are distributed continuously and vice-versa.

The errors in welfare measurement from mistaken assumptions on the part of the analyst about the nature of taste heterogeneity have then been calculated for different scenarios, as shown in Table 3. First, a scenario 1 in which the analyst assumes preference heterogeneity for $X_1$ and $X_2$ is driven by the existence of two latent classes in the population when true preferences are lognormally-distributed (i.e. by erroneously estimating a LC model when the true DGP is characterised by an RPL). Second, a scenario 2 where the parameters for $X_1$ and $X_2$ are assumed to vary across individuals according to a lognormal distribution when true preference heterogeneity is driven by the existence of two latent classes (i.e. erroneously estimating a RPL model when the true DGP is characterised by a LC DGP). Third, to examine the implications of assuming a parameter distribution other than the lognormal one, scenarios 3 and 4 in which RPL models assuming triangular-distributed parameters have been estimated under the two types of DGPs stated above (LC and RPL (log-normal)), respectively. Finally, an additional analysis where the analyst assumes preference homogeneity for $X_1$ and $X_2$ (i.e. erroneously estimating a Multi-Nomial Logit model when preferences are indeed heterogeneous) has also been undertaken (scenarios 5 and 6).

$^a$ DGP means Data Generating Process, which can follow either a RPL-Log scheme with lognormally-distributed parameters for $X_1$ and $X_2$ or a LC-2seg scheme with 2 segments.

$^b$ LC-2seg means estimating a LC with 2 segments, whilst RPL-Log and RPL-Triang refer to a RPL with lognormally- and triangular distributed parameters for $X_1$ and $X_2$, respectively. MNL refers to the Multinomial Logit Model.

Source: Own elaboration.
Taking into account the two types of underlying true DGPs and the four analytical scenarios (LC, RPL-Log, RPL-Triang, MNL), 8 different MC experiments (2x4) have thus been undertaken. The individual CS values for the same change in $X_1$, $X_2$ and $X_3$ have been estimated for each MC experiment following equations [4] and [5] according to the type of estimated model (i.e. RPL or LC). This process has been repeated 1,000 times. Next, the importance of using the correct model to account for taste heterogeneity has been examined by quantifying the individual errors in the estimated CS values. To do this, the mean squared proportional error (MSPE) has been calculated at the individual level for each MC replication, according to equation [6]:

$$\text{MSPE}_r = (1/I) \left[ \sum_{i=1}^{I} \left( \frac{(CS^e_i - CS^t_i)^2}{CS^t_i} \right) \right]$$

where $r$ is a specific repetition of the MC experiment, $I$ is the total number of simulated individuals, $CS^e_i$ is the estimated CS of individual $i$ in repetition $r$ and $CS^t_i$ is the true CS of individual $i$. The MSPE represents the square of the ratio between bias (the difference between the estimated and true CS) and the true CS. The MSPE is the most appropriate measure relative to other accuracy measures typically used in the literature such as Bias, Relative Bias or Mean Square Error for two reasons: 1) it is a relative measure and, hence, it is independent of the magnitude of the true CS, thus making comparable the results from the MC experiments; and 2) it gives an idea of not only the accuracy but also the efficiency (the variance) of welfare estimates. At each MC repetition, the MSPE has been calculated as the average over 240 individual welfare measures. After 1,000 MC repetitions, a distribution of MSPE mean values for the change in $X_1$, $X_2$ and $X_3$ has been obtained for each experiment. The values for MSPE reported for each MC experiment have been calculated as the average of the sum of the mean values obtained in each MC replication (equation [6]) over the 1,000 repetitions.

4. Results

The results of the MSPE in the estimated CS for each MC experiment are reported in Table 4. As stated above, these values refer to a hypothetical change in the attributes $X_1$, $X_2$ and $X_3$ from the baseline levels of $X_1 = 60$, $X_2 = 8$ and $X_3 = 10$ to the levels of $X_1 = 20$, $X_2 = 6$ and $X_3 = 20$. MSPE measures are shown in terms of the two DGPs (i.e. true RPL and true LC preferences) and the estimation model (MNL, RPL and LC) used in the simulations$^9$.

$^9$ Note that, for comparability reasons, results from using the correct model to account for taste heterogeneity have also been reported.

*RPL-Log means estimating a RPL assuming lognormally-distributed parameters for \( X_1 \) and \( X_2 \), whilst RPL-Triang means estimating a RPL model assuming triangular-distributed parameters for these attributes. LC-2seg means estimating a LC model with 2 segments. DGP is Data Generating Process.*

Source: Own elaboration.

When true preferences are characterised by continuous mixing as in the RPL-Log case, mistakes about the correct distribution within the RPL model seem irrelevant; both RPL-Log and RPL-Triang provide the same MSPE. This is probably due to the high adaptability of the RPL model to fit the underlying true random distribution. A mistaken assumption of LC preferences produces a relatively small increase in the error in welfare estimation, as the MPSE increases by a factor of 1.7 (from 0.037 to 0.056). As it may be expected, mistakenly assuming homogeneous preferences by specifying a multi-nominal logit leads to much larger increase in the error, a factor of 4.7 (from 0.037 to 0.143). A different situation is observed when true preferences are characterised by finite mixing with a 2-class structure. The smallest error is achieved when analysts correctly “guess” the true underlying heterogeneity. However, a larger relative error results from mistakenly specifying the model as RPL, as the MPSE increases by a factor of 5 (from 0.026 to 0.106), relative to the previous case. Again, the distributional form of RPL model is of little consequence, and a multi-nominal logit specification leads the error to increase by a factor of 21, that is, it produces the biggest relative error (from 0.026 to 0.428).

The main result to this juncture is thus that errors in welfare estimation from getting the preference heterogeneity specification wrong are most important when true preferences result in a LC DGP. In contrast, if the analyst mistakenly assumes that the preference heterogeneity is discrete when in reality it follows a continuous distribution, then this produces a smaller error in consumers’ surplus than the opposite assumption about taste heterogeneity.

An interesting follow-up question which arises is: Why does the LC specification do relatively well when the true utility function is RPL-log? One possible reason concerns the way in which “errors” are considered here, that is, with respect to wel-
fare measures (CS) rather than preference parameters. In this case what matters is the similarity between the estimated and the true underlying CS distributions more than the similarity between the true and estimated preference distributions. In LC, although preferences are discrete, generating welfare estimates requires preference parameters to be combined with a continuous membership probability function. As such, even when the true CS distribution results from a set of preferences which vary continuously, the “mixing” between the utility parameters and class membership probability draws a continuous distribution of CS that approximates well to the true underlying CS distribution. Thus the MPSE error measures can be small.

These results suggest that it would be fruitful to examine the effects on welfare error magnitudes of changing the distribution of true CS when this originates from either a discrete or a continuous preference structure. Thus, starting from the assumption that the true CS distribution originates from a discrete preference structure (LC DGP), we change the distribution of variables which determine LC membership and calculate MSPE errors for the four model specifications described above (LC-2 seg, RPL-Log, RPL-Triang, MNL). Put another way, we change the true share of the two segments leading to a given true CS distribution without changing the segment covariate and attribute parameters. This allows us to consider the same two segments in terms of their environmental preferences and socioeconomic features, thus making results comparable. As the CS distribution results from the combination of discrete mixing preferences and the continuous distribution of the class membership probability function, it enables us to use a wider variety of true CS distributions facilitating the analysis of CS distribution similarities. Thus, we consider three cases which are labelled A, B and C in Table 5. In Case A, class one probabilistically contains 28% of respondents and class two, 72%, whilst in Case C the figures are 78% and 22%, respectively. Case B represents an intermediate situation whose results are described above (in Table 4). In Table 5, we show the MSPE for the three cases considering the four model specifications used above under a LC DGP.

---

10 We argue that in the empirical application of a CE aiming at disclosing the social value of a good or service, the leading measure to feed benefit-costs analysis is the compensating surplus rather than the preferences towards the attributes.

11 For example, in this application this is achieved by simply modifying the distribution of the Age, Education and “Belonging to an environmental organization” variables in the simulated sample.

12 To set the values for representative cases of low, medium and high segment shares, we tried to estimate LC models on LC choices generated under the assumptions that the true share for segment 1 was 25%, 50% and 75% (and 75%, 50% and 25% for segment 2, respectively). However, LC models collapsed for those values. Thus the values we report in Table 5 are those for which the LC model showed the best performance. We did not consider segment shares lower than 25% as this would have implied to assign a higher than 75% share to the second class, which, as earlier said, would have moved us away from common findings in the literature (Beharry-Borg and Scarpa, 2010; Birol et al., 2006; Bujosa et al., 2010).

\textsuperscript{a} RPL-Log means estimating a RPL assuming lognormally-distributed parameters for \(X_1\) and \(X_2\), whilst RPL-Triang means estimating a RPL model assuming triangular-distributed parameters for these attributes. LC-2seg means estimating a LC model with 2 segments.

\textsuperscript{b} S1 means true share for segment 1 and S2 means true share for segment 2.

Source: Own elaboration.

As expected, in all cases the LC model provides the lowest error in terms of matching the estimated model with the true underlying DGP. Comparing Case A with Case B it may be seen that the MSPE value from (erroneously) using an RPL model rather than a LC model increases solely as a result of this change in the class membership distribution. Case C gives a similar outcome for specifying RPL rather than the (correct) LC model as B, but a much smaller error from specifying a MNL model. The RPL model performs much better in Case A. The reason can be easily spotted by considering the distribution of the true CS in the three cases investigated. These are shown in Figures 1-3.

As can be seen a log-normal distribution fits better with a true distribution of CS values as in Case A, relative to Case B or Case C. Because of this, the RPL model which assumes a log-normal distribution for its parameters provides smaller errors in the MSPE of Case A relative to the other cases\textsuperscript{13}. However, for cases B and C, the RPL model performs poorly because the resulting true underlying distribution of CS differs notably from that estimated using the RPL models.

\textsuperscript{13} Clearly a RPL model with lognormally-distributed parameters and a fixed cost term generates a distribution of WTP which is lognormal.

We now further investigate the robustness of the LC model in terms of welfare measurement by assuming now that the true CS distribution comes from an RPL DGP. For this purpose, we simulate three types of RPL-Log DGP scenarios differing only in the variance of the random parameters – labelled Small Var, Medium Var and High Var. That is, we consider a true CS distribution which originates from a set of preferences which are continuously distributed according to a log-normal distribution with different variances. For the three cases, we consider the variance of the random parameters is about 13 %, 45 % and 75 % of their means according to common findings in the literature. Changing the known value for the variance of the random parameters rather than the known values for their means allows us to keep the analysis focussed on the same preferences towards the environment, thus making results more comparable. The MSPE values are described in Table 6.

Again, on average the model which provides the most accurate measures is the one which is in accordance to the true underlying DGP (RPL-Log in this case), and assuming the wrong distribution of the random parameter has little effect. However, it is worth noting that when the analyst mistakenly assumes discrete preference heterogeneity when the true underlying source of preference heterogeneity is continuous, the MSPE values are lower than in the opposite case. As a general finding here, the LC model seems to be more robust than the RPL model to mis-specification of the preference heterogeneity. The suggested reason is the large flexibility of the LC model to adapt to the true underlying distribution of CS by means of combining the utility parameter and class probability distributions.

5. Discussion and conclusions

How best to model preference heterogeneity for environmental goods has been of on-going interest to choice modellers working with both revealed and stated preference data for many years. In this paper, we have compared the two most usual approaches to date in the environmental literature, namely RPL and LC, exploring the impact on welfare measures. Our paper complements earlier work by investigating the relative errors from mis-specifying the model of preference heterogeneity when the true DGP is unknown to the researcher. This is a relevant question, since the “best” choice of econometric model to fit to a given data set of choices is often a hard question to answer: trade-offs often exist between different measures of model performance such as fit, flexibility, consistency with underlying theory, parsimony and simplicity of interpretation. We do this using a MC approach, focussing on the deterministic element of utility within a random utility set-up (that is, ignoring scale heterogeneity). This approach has the great merit that it enables us to measure the true, underlying (money-metric) utility change from a change in environmental quality, and then compare this “true” measure with the estimated welfare change under different econometric modelling assumptions.

Our main findings are that, in presence of taste heterogeneity, the smallest welfare errors are always found when the analyst estimates a model whose treatment of heterogeneity mirrors the underlying true heterogeneity. However, the form of this underlying true preference heterogeneity is typically unknown to the analyst, whilst the conventional tests based on model fitting and log-likelihood are not always conclusive due to the different nature of model specifications. When uncertainty exists about how to model preference heterogeneity and the main interest of the analyst rests in the generation of welfare measures for use in cost-benefit analysis,
we find that the LC modelling seems to be a more robust and flexible approach in the sense of generally resulting in smaller errors. This model provides CS measures which are not so distant from the true measures, even if the true DGP is described by continuous (RPL) distribution. This result has been observed for the specific case of a 2-latent class model which represents the “most extreme” case of preference difference between the assumed continuous and discrete distributions. Having more latent classes\textsuperscript{14} would offer a higher flexibility to the model and further reduce the gap between the true and estimated CS. Changes in the distribution of people across latent classes have effects on the error in welfare measurement from mis-specified models, although the LC maintains a higher degree of precision and accuracy. The performance of an RPL model is impacted by the correct selection of the distributions for the random parameters. We also find that the errors from using a LC model when the true DGP is continuous mixing depend on the variance of this distribution across the population, with the LC modelling proving to be a robust approach even in the presence of high variances\textsuperscript{15}. Our overall conclusion is then that smaller welfare errors are likely to come from use of a latent class model, which is in line with the findings by Birol et al. (2006), Colombo et al. (2009), Hynes et al. (2008), Shen and Saijo (2009) and Sagebiel (2011).

In this context, one can argue that with real (as opposed to simulated) data, the analyst never knows the true DGP and hence MC analysis plays a limited role in drawing conclusions about the most desirable empirical strategy, as its results will always be restricted to the assumptions made about the DGP. Generalising the findings from a MC study in this context can be challenging. However, assumptions about the underlying individual choice behaviour have also to be made when working with real data: the analyst has to specify a model according to her assumptions about individual preferences. Uncertain knowledge about true preferences means that any econometric model will be mis-specified to a degree. After all, models are by definition only approximations to reality (Fiebig et al., 2010). The impossibility of a “perfect” model specification—or, equivalently, the acceptance that all models are mis-specified to a degree—makes necessary the use of tools aimed at analyzing the performance of alternative models for a given data set. In this setting, MC analysis plays a crucial role. Indeed, in contrast to common tests based on model fitting and log-likelihood, it allows analysts to generate data and hence examine model performance through quantification of welfare errors from mistaken model assumptions. Findings from studies such as this can have important implications for the use of benefit-cost analysis in policy evaluation, if they point to the likely occurrence of large errors in benefits estimation from following particular empirical strategies.

In this paper, in the RPL approach we have assumed two of the most common distributions for random parameters: Lognormal and triangular\textsuperscript{16}. However, several

\textsuperscript{14} Subject to criteria such as a minimum class membership probability, for example.

\textsuperscript{15} The RPL which uses a triangular distribution drastically increases the MSPE error when the variances of the random parameters are large.

\textsuperscript{16} The triangular distribution has been used instead of the more common normal distribution to avoid the effect of the tails of the normal in the CS measures.
other distributions are available in the literature (although many are not implemented
in the standard statistical software available to analysts) and the sensitivity of results
to the use of these alternative distributions needs to be tested in future research. Ad-
ditionally, it would be interesting to examine how results change when estimating
the standard RPL or LC model when heterogeneity in true preferences is not driven
by taste heterogeneity alone but by a combination of taste and scale heterogeneity,
or only by the latter. An obvious extension of the current research is to apply the
simulation to a wider context of models accounting for preference heterogeneity,
including those that combine aspects of both finite and continuous mixing (Greene
and Hensher, 2013), and boundedly-rational decision making rules such as attribute
non-attendance (Scarpa et al., 2009).
