Abstract

The problem of controlling a liquid–gas separation process is approached by using LPV control techniques. An LPV model is derived from a nonlinear model of the process using differential inclusion techniques. Once an LPV model is available, an LPV controller can be synthesized. The authors present a predictive LPV controller based on the GPC controller [Clarke D, Mohtadi C, Tuffs P. Generalized predictive control – Part I. Automatica 1987;23(2):137–48; Clarke D, Mohtadi C, Tuffs P. Generalized predictive control – Part II. Extensions and interpretations. Automatica 1987;23(2):149–60]. The resulting controller is denoted as GPC–LPV. This one shows the same structure as a general LPV controller [El Ghaoui L, Scorletti G. Control of rational systems using linear-fractional representations and linear matrix inequalities. Automatica 1996;32(9):1273–84; Scorletti G, El Ghaoui L. Improved LMI conditions for gain scheduling and related control problems. International Journal of Robust Nonlinear Control 1998;8:845–77; Apkarian P, Tuan HD. Parametrized LMIs in control theory. In: Proceedings of the 37th IEEE conference on decision and control; 1998. p. 152–7; Scherer CW. LPV control and full block multipliers. Automatica 2001;37:361–75], which presents a linear fractional dependence on the process signal measurements. Therefore, this controller has the ability of modifying its dynamics depending on measurements leading to a possibly nonlinear controller. That controller is designed in two steps. First, for a given steady state point is obtained a linear GPC using a linear local model of the nonlinear system around that operating point. And second, using bilinear and linear matrix inequalities (BMIs/LMIs) the remaining matrices of GPC–LPV are selected in order to achieve some closed loop properties: stability in some operation zone, norm bounding of some input/output channels, maximum settling time, maximum overshoot, etc., given some LPV model for the nonlinear system. As an application, a GPC–LPV is designed for the derived LPV model of the liquid–gas separation process. This methodology can be applied to any nonlinear system which can be embedded in an LPV system using differential inclusion techniques.

Keywords: LPV controllers; LPV systems; Nonlinear systems; BMIs; LMIs; Predictive control

1. Introduction

The generalized predictive controller (GPC) originally was developed by Clarke [1,2]. This linear controller is a particular case of model based predictive controllers, which uses a controlled autoregressive integral moving average (CARIMA) model for the process. GPC has some interesting properties [7]:

- It can be applied to unstable and nonminimum-phase processes.
- It can be used as an adaptive controller.
- It has a more complex noise model than dynamic matrix control (DMC) [8] and identification command controller (IDCOM) [9].

Moreover, it has been validated in a wide spectrum of real-life applications [10].

Starting from this point, the authors have developed a reformulation of this controller in state-space [11], since
of >. A bilinear matrix inequality is a generalization of it is possible to consider nonstrict LMIs using matrix. By definition, the previous LMI is strict, although the inequality symbol > means that  

\[ F(x(k+1)) = A^r x(k) + B_r r(k) + B_y y(k), \]

\[ u(k) = C^r x(k) + D_f r(k) + D_y y(k), \]

being \( y \) the output vector of size \( n \), \( r \) the reference vector, \( u \) the control action vector of size \( m \), and \( x^i \) the controller state vector of size \( n_c \).

### 1.1. Matrix inequalities

A linear matrix inequality (LMI) is an expression of the form [13,14]:

\[ F(x) = F_0 + \sum_{i=1}^m x_i F_i > 0, \]

where \( x \in \mathbb{R}^m \) is the unknowns vector and the symmetric matrices \( F_i = F^T_i \in \mathbb{R}^{m \times m} \), \( i = 0, \ldots, m \) are given. The inequality symbol \( > \) means that \( F(x) \) is a positive definite matrix. By definition, the previous LMI is strict, although it is possible to consider nonstrict LMIs using \( \geq \) instead of \( > \). A bilinear matrix inequality is a generalization of an LMI incorporating products between unknowns:

\[ F(x) = F_0 + \sum_{i=1}^m x_i F_i + \sum_{i=1}^m \sum_{j=1}^m x_i x_j F_{i,j} > 0. \]

Following these lines, a nonlinear matrix inequality (NMI) is a matrix inequality where the dependence with respect to unknowns is a general nonlinear function. A special case that frequently occurs in practice consists of a polynomial dependence, which gives polynomial matrix inequalities (PMI).

### 1.2. LPV controllers

For last years many authors [3–6,15–20] have developed linear parameter varying (LPV) controllers for nonlinear systems. The key idea consists in modifying the controller matrices to adapt the controller to the nonlinear system depending on signal measurements. The most general dependence of controller matrices with respect to measurements is linear fractional (LF) [3], and in particular for discrete-time systems the controller structure is [21]:

\[
\begin{pmatrix}
x^i(k+1) \\
y^i(k) \\
u(k)
\end{pmatrix} =
\begin{bmatrix}
A & B_A & B_r & B_y \\
C^\Delta & D^\Delta_A & D_r^\Delta_A & D_y^\Delta_A \\
C^c & D^c_A & D_r^c_A & D_y^c_A
\end{bmatrix}
\begin{pmatrix}
x^i(k) \\
u^i_A(k) \\
r(k) \\
y(k)
\end{pmatrix}
K(z)
\]

\[ u^i_A(k) = \Delta^i_A y^i(k), \]

\[ \Delta^i_A(k) \] is a matrix which affinely depends on signal measurements. In Fig. 1 this structure is represented, which is essentially composed of an upper linear fractional transformation between a linear time invariant controller and the time varying matrix \( \Delta^i_A \).

The synthesis of such controllers is based on solving a feasibility problem with LMIs and/or BMIs [13], or based on solving a linear optimization subject to LMIs and/or BMIs. The problems with LMIs are always convex and can be efficiently solved in polynomial time using, for example, interior points algorithms [13]. As opposite, the problems with BMIs are nonconvex, and there do not exist algorithms to solve them in polynomial time.

### 1.3. LPV models for nonlinear systems

All the references presented in the previous section require an LPV model for the nonlinear system in order to design the LPV controller. Usually the available information about a certain nonlinear system is a nonlinear model. Therefore, the first step for these methods is to obtain an LPV model whose dynamical trajectories contain the nonlinear model ones, using techniques of linear differential inclusion [13]. The key idea used in differential inclusion consists in replacing the nonlinear part of the system model by an expression which has a linear fractional (LF) dependence with respect to the signals present in this nonlinear part [3,13]. Other references obtain a identified LPV model [19,20,22–27] using an experimental data or a given nonlinear model for the nonlinear system.

The result of this operation is a linear time varying model which depends LF on that signals, as Fig. 2 shows. In particular, its mathematical representation is:

\[
\begin{pmatrix}
x(k+1) \\
y_A(k) \\
e(k) \\
y(k)
\end{pmatrix} =
\begin{bmatrix}
A & B_A & B_r & B_y \\
C & D_A & D_r & D_y \\
C & D_{r,v} & D_r & D_y \\
C & D_{r,v} & D_r & D_y
\end{bmatrix}
M(z)
\begin{pmatrix}
x(k) \\
u_A(k) \\
r(k) \\
y(k)
\end{pmatrix}
\]

\[ u_A(k) = \Delta(k)y_A(k), \]

\[ \Delta(k) \] is a matrix which affinely depends on signal measurements. In Fig. 2 this structure is represented, which is essentially composed of a linear fractional transformation between a linear time invariant controller and the time varying matrix \( \Delta(k) \).
where $\Delta$ depends affinely on some system signals, $p$ is a vector containing any input signal different from control actions, and $e$ is a vector containing all the output signals which can give a system performance measure.

This linear time varying system can be viewed as a linear parameter varying one since the signals present in $\Delta$ can be interpreted as parameters that are time varying. Therefore, this is an LPV model for the nonlinear system.

In general, not all the signals present in $\Delta$ will be measurable, and so the LPV controllers designed for this LPV model only will can use measured ones $\Delta_m$:

$$\Delta = \begin{bmatrix} \Delta_m & 0 \\ 0 & \Delta_{nm} \end{bmatrix}$$

and so, $\Delta_{nm}$ only will depend on $\Delta_m$.

In these cases the designed LPV controllers are called robust, since, at least, they must stabilize the LPV model with time varying parameters that cannot be measured on line.

2. GPC–LPV

The GPC–LPV controller is an LPV controller based on the linear state-space GPC (1) presented in Section 1. The key idea consists in adding to a designed GPC a linear fractional dependence with respect the signals present in the matrix $\Delta_m$, and therefore, this gives the LPV controller (4) (Fig. 3), but in this particular case the matrices $A^c$, $B^c$, $C^c$, $D^c$ are known since the linear GPC is designed in a first step. The remaining matrices must be designed in a second step: $B_{\Delta \Delta}$, $C_{\Delta \Delta}$, $D_{\Delta \Delta}$, $D_{\Delta y}$ and $D_{\Delta y}$, which can be referred as delta matrices.

The initial linear GPC is designed by using a linear local model of the LPV model around an operating point, which belongs to the nonlinear system operation zone. This local model is obtained from LPV model assuming the signals of matrix $\Delta$ a constant and equal to the signal values at that operating point. The LTI GPC has a number of integrators equal to the number of output controlled signals.

The second step of the design consists in obtaining the delta matrices. However, there is an initial problem which must be solved: the resulting GPC–LPV may not have, in general, the integral behaviour of LTI GPC. The state matrix of GPC–LPV (4) is:

$$A^c + B^c \Delta_c (I - D^c \Delta_c)^{-1} C^c.$$

It must be assured that this matrix has exactly a number of eigenvalues at one equal to the number of controlled outputs. By design, $A^c$ satisfies this condition, and so there exists a linear state transformation $T$ such that:

$$T^{-1} A^c T = \begin{pmatrix} A^{c'} & Z \\ 0 & I_n \end{pmatrix},$$

using this transformation in (7) the number of integrators will be exactly $n$ if:

$$\Delta_c (I - D^c \Delta_c)^{-1} C^c = \Delta_c (I - D^c \Delta_c)^{-1} C^c,$$

where $\Delta_c$ is the size of $\Delta_c$, and some of the delta matrices have changed to new values as a result of this linear transformation: $B_{\Delta \Delta}$ and $C_{\Delta \Delta}$. Besides, some matrices of LTI GPC have also changed by this transformation: $B^c$, $B^c$ and $C^c$.

The design of delta matrices is done by solving feasibility problems with LMIs and/or BMIs, or optimizing linear functions subject to LMIs and/or BMIs. These matrix inequalities were obtained starting from previous results found in the literature, usually for continuous-time systems, and adapting them to the particular case of GPC–LPV. The resulting controller at off-nominal points verifies all the specifications demanded: stability, norm bounding, etc.; since delta matrices are obtained satisfying the corresponding matrix inequalities for all the possible values of $\Delta$ matrix.

2.1. Matrix inequalities conditions for closed loop stability

The main result which enables the most part of matrix inequalities obtained in the last years is the Lyapunov condition of stability. If it exists a positive definite matrix $Q$ such that:

$$A^T Q A - Q < 0,$$

then the linear autonomous system $x(k + 1) = A x(k)$ is asymptotically stable. This condition is used in [6,13,28–31]. The main difference between these results consists of the dependence with respect to matrix $\Delta$: affine, quadratic or LF. In this work the authors have used the most general dependence, that is to say, LF.

Following, mainly, the ideas of [6,31] it is possible to obtain a set of LMIs and a PMI which provides a sufficient condition for the stability of the closed loop formed by GPC–LPV and the LPV model (5):
where $A$ and $B$ are unknown matrices. As a particular case, it is possible to take $A_p = A_m$ providing a simpler and more conservative condition.

PMI (11) can be recast as a BMI by using Schur complement lemma [13] and adding the condition $V_{22} > 0$:

$$M^T \begin{pmatrix} -Q & 0 & 0 \\ 0 & -Q & 0 \\ 0 & 0 & V \\ 0 & 0 & 0 \end{pmatrix} M - M_1^T \begin{pmatrix} Q & 0 & 0 \\ 0 & 0 & V_{22} \end{pmatrix} M_1 < 0,$$

$$M = \begin{pmatrix} A_{CL} & B_{CL,A} \\ C_{CL,A} & D_{CL,A} \end{pmatrix}, \quad M_1 = \begin{pmatrix} 0 & B_{CL,A} \\ C_{CL,A} & D_{CL,A} \end{pmatrix}. \quad (14)$$

2.2. Matrix inequalities conditions for norm bounding

In the literature there are also conditions to ensure bounds for different norms: $\infty$, 2 and 1. For $\infty$-norm it is applied, for example, the bounded real lemma [32], for 2-norm the grammians can be used [33], and for 1-norm the star norm (*-norm) which is an upper bound [34,35] can be recast as matrix inequalities.

Following the same lines as previous subsection the authors have developed BMIs for these three norms by using LF dependence. For example, a sufficient condition that ensures that $\infty$-norm of channel $p/e$ is bounded by $< 0$ is:

$$L^T \begin{pmatrix} -Q & 0 & 0 \\ 0 & -I & 0 \\ 0 & 0 & -I \end{pmatrix} L - L^T \begin{pmatrix} Q & 0 & 0 \\ 0 & I & 0 \\ 0 & 0 & I \end{pmatrix} L_1 - L_1^T \begin{pmatrix} Q & 0 & 0 \\ 0 & I & 0 \\ 0 & 0 & I \end{pmatrix} L < 0$$

$$L = \begin{pmatrix} A_{CL} & B_{CL,A} & B_{CL,P} \\ C_{CL,A} & D_{CL,A} & D_{CL,A} \\ C_{CL,P} & D_{CL,A} & D_{CL,A} \end{pmatrix}, \quad L_1 = \begin{pmatrix} 0 & 0 & B_{CL,P} \\ 0 & 0 & D_{CL,A} \\ 0 & 0 & D_{CL,A} \end{pmatrix},$$

$$B_{CL,P} = (B + B_D D_{CL,P} E_D') C_{CL,A} = (C + D_{CL} D_{CL,P} C_{CL,A}) C_{CL,A} D_{CL,A} D_{CL,P},$$

$$D_{CL,P} = D_{CL} D_{CL,P} C_{CL,A} D_{CL,A}.$$

2.3. Matrix inequalities conditions for closed loop specifications

Specifications such as settling time, overshoot, etc., can be guaranteed by using sufficient conditions based on BMIs and LMIs [32,36]. Basically, the procedure is the same as in previous sections, although in this case the matrix inequalities are developed by employing closed loop pole clustering techniques. For example, Lyapunov stability condition for discrete-time systems imposes pole clustering on the open unit disk. Pole clustering in other complex plane subsets guarantees other specifications, for example:

- Maximum settling time: disk centered at origin with radius smaller than one.
- Maximum transient oscillation frequency $w_p$: sector with vertex at the origin and angle $w_p \cdot T$, being $T$ the sampling period.

For these and other more complex subsets BMIs and/or LMIs sufficient conditions for pole clustering of closed loop poles are developed. They are omitted due to limited space.
2.4. Other matrix inequalities conditions

It is possible to obtain sufficient conditions in order to guarantee other properties:

- Time domain constraint satisfaction: saturation of actuators, safety limits in some signals, etc.
- Generalized 2-norm [33].
- etc.

2.5. Analysis of matrix inequalities conditions

In all the matrix inequalities obtained previously for the GPC–LPV (14) and (15), there is at least one BMI, being the remaining ones LMIs. These BMIs cannot be recast as LMIs, and so the design of GPC–LPV controller presented here requires an algorithm capable of dealing with kind of matrix inequalities.

2.6. Numerical resolution of problems with BMIs

As previously stated, for problems with LMIs there are efficient algorithms that obtain the solution in polynomial time. However, the problems with BMIs [37]:

- In the actual literature of robust control based on matrix inequalities they have a great importance [38,39].
- They can be NP-hard problems [40].
- They are nonconvex and so may exist local solutions that can be considered as suboptimal one.
- There do not exist, in general, algorithms which can obtain in polynomial time their global solution.
- There exist algorithms based on branch and bound techniques which can solve problems of small size (low number of variables and small BMIs) in exponential time [38,39,41,42].
- By other side, there exist algorithms that obtain only local solutions but they can solve problems of medium and large size [43–45].

The algorithm proposed in [45] has been implemented in the commercial software PENBMI from PENOPT. PENBMI has been used in this work to obtain local solutions to the problems with BMIs. The main reason to use this software is that the BMI problems presented in this work have large size. In particular this software can be used in Matlab through the free toolbox YALMIP.

3. Application: liquid–gas separation process

In this section the previous design methodology of GPC–LPV controller will be applied to a liquid–gas separation process (Fig. 4), extensively used in petrol engineering to vaporize liquefiable gases, which in this example consists of liquid propane. The system nonlinear model has been taken from [46,47]:

\[
\dot{V}_L = F_o - \frac{K}{\rho} \left( \frac{e^{a_1(T + a_2)}}{T} - T - \frac{RT}{\rho e} \right),
\]

\[
\dot{T} = \frac{1}{V_L} \left[ F_o (T_o - T) + \frac{Q}{\rho C_p} - \frac{K}{\rho C_p} \left( \frac{e^{a_1(T + a_2)}}{T} - T - \frac{RT}{\rho e} \right) \right],
\]

\[
\dot{\rho}_e = \frac{1}{V - V_L} \left[ \rho_e (F_o - F_v) \right] + K \left( 1 - \frac{\rho_e}{\rho} \right) \left( \frac{e^{a_1(T + a_2)}}{T} - T - \frac{RT}{\rho e} \right).
\]

In this state-space model the state variables are: \( T \) (°C) gas temperature equal to liquid temperature, \( V_L \) (m³) liquid volume and \( \rho_e \) (kg/m³) gas density. Input signals: \( F_o \) (m³/s) liquid propane flow, \( Q \) (kcal/s) heat power that provides the intercooler and \( F_v \) (m³/s) the upper extraction flow, which is constant and equal to 0.105 m³/s. This model supposes that liquid density is constant and equal to \( \rho = 500 \text{ kg/m}^3 \). The remaining signals are considered to be constant and their values and the model constant values are shown in Table 1.

3 Also true for many other conditions.
Next step is to sample this nonlinear model (16) by using a zero order hold (ZOH) with sampling period $T_s$ taking a first order approximation of matrix exponential [48]:

$$A_d = e^{\frac{K}{T_s}} \approx I + A \cdot T_s,$$

(17)

since with $T_s = 0.5$ s the approximate discrete matrix is a good estimate of exact one. With such approximation the discrete-time model is:

$$\begin{align*}
V_L(k+1) / T(k+1) / \rho_i(k+1) &= A_d \begin{pmatrix} V_L(k) / T(k) / \rho_i(k) \end{pmatrix} + B_d \begin{pmatrix} F_o(k) / Q(k) \end{pmatrix},
\end{align*}$$

$$A_d = T_s \begin{pmatrix}
\frac{1}{T_s} & -\frac{K_i}{\rho_i} \frac{e^{t/T_s}}{T_s} & \frac{K_{RT}}{\rho_i} \frac{1}{T_s} \\
0 & \frac{1}{T_s} & -\frac{K_i}{\rho_i} \frac{e^{t/T_s}}{T_s} \\
0 & \psi \frac{e^{t/T_s}}{T_s} & -\frac{1}{T_s} - \frac{1}{T_s} F_v - \psi \frac{K_{RT}}{\rho_i}
\end{pmatrix},
$$

$$B_d = \begin{pmatrix}
\frac{1}{T_s} (T_o - T) \cdot T_s / \rho_i \cdot \rho_i V_L / T_s \\
0 & T_s / \rho_i V_L / T_s \\
0 & 0
\end{pmatrix}.$$

(18)

As it can be seen, $A_d$ and $B_d$ matrices depend nonlinearly on state variables, so all of them must be included in time varying parameters such that an LPV model can be obtained:

$$\delta_1 = 1/V_L, \quad \delta_2 = T - T_o, \quad \delta_3 = \rho_i.$$

(19)

This selection of time varying parameters is justified by the form how the LPV model is obtained [3,49]. The obtaining of this LPV model is omitted due to its large extension.

By other side, as it is present an exponential dependence with respect temperature in $A_d$ it is necessary to use a Taylor series of degree 2 in order to obtain an LF dependence:

$$e^{a_1/T_s + a_2} \approx a_0 + a_1 \cdot (T - T_o) + a_2 \cdot (T - T_0)^2,$$

(20)

with this series a good adjust is obtained along the temperature operation range. Finally, taking $V_L$ and $T$ as measured output signals the resulting LPV model is:

$$\begin{align*}
\begin{pmatrix} x(k+1) \\ y(k) \end{pmatrix} &= \begin{pmatrix} A & B_A \\ C_A & D_A \end{pmatrix} \begin{pmatrix} x(k) \\ u_A \end{pmatrix} \\
&= \begin{pmatrix} \Delta(k) y_A(k) \\ \Delta(k) \end{pmatrix} = \text{Diag} (\delta_1(k), \delta_2(k), \delta_3(k), \delta_2(k)) I_4
\end{align*}$$

$$A = \begin{pmatrix} 1 & -\frac{K_i}{\rho_i} T_o & \frac{K_{RT}}{\rho_i} T_o \\
0 & 1 & 0 \\
0 & 0 & 1
\end{pmatrix},
$$

$$B_A = \begin{pmatrix}
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0
\end{pmatrix},
$$

$$C_A = \begin{pmatrix} 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0
\end{pmatrix}.$$
These parameters were adjusted manually after different experiments over the separator, which guarantee closed loop stability inside the operating ranges, by using LMIs conditions.

In Figs. 5–8 temperature, liquid volume, \( F_o \) flow and heat power are represented when the LTI GPC controls the separator, under the assumption that this one starts from the equilibrium point given by \( T = 340 \text{ K} \) and \( V_L = 1.9 \text{ m}^3 \).

In a second step, the delta matrices of GPC–LPV are designed under the condition that \( \| r/u \|_\infty \) is smaller than LTI GPC one. This design is based on the BMI (15). The optimization with PENBMI took around 30 m in a PENTIUM IV at 2.8 GHz with 512 MB of RAM under Windows XP. After the calculation, the LTI GPC provides an \( \| r/u \|_\infty \) of 514.5597 whereas the GPC–LPV 392.8146. Delta matrices corresponding to GPC–LPV designed are:

\[
B_A^c = \begin{pmatrix}
-1.7537 \times 10^{-2} & 3.0914 \times 10^{-3} \\
1.6954 \times 10^{-4} & -6.6281 \times 10^{-5} \\
-1.8793 \times 10^{-5} & 3.9026 \times 10^{-6} \\
-5.1626 \times 10^{-5} & 4.7361 \times 10^{-6} \\
-1.2388 \times 10^{-5} & -7.6908 \times 10^{-8} \\
4.1258 \times 10^{-7} & -1.9465 \times 10^{-7} \\
-5.2850 \times 10^{-7} & 6.9737 \times 10^{-8}
\end{pmatrix},
\]

\[
C_A^c = \begin{pmatrix}
2.5626 & -0.5310 \\
20.1832 & -21.4447 \\
-72.2428 & -181.1467 \\
118.1280 & 353.9015 \\
-54.0962 & -365.9777 \\
-111.2757 & -68.8352 \\
-14.0149 & -57.4931 \\
-11.8806 & -42.3621 \\
211.3161 & 36.0944
\end{pmatrix},
\]

\[
D_A^c = \begin{pmatrix}
-0.4583 & 0.0298 \\
0.0573 & 0.0185
\end{pmatrix},
\]

\[
D_{A,y}^c = \begin{pmatrix}
125.5063 & -26.0878 \\
300.6801 & -3.8997
\end{pmatrix},
\]

\[
D_{A,\Delta}^c = \begin{pmatrix}
-55.2494 & -11.6330 \\
-3.1525 & 0.8039
\end{pmatrix},
\]

\[
D_{e,\Delta}^c = 0_2.
\]

In the aforementioned figures the results obtained with GPC–LPV are also represented. Basically, the GPC–LPV provides a faster closed loop response and a bigger under-shoot in temperature.

Fig. 5. Liquid volume. Continuous line: LTI GPC. Dashed line: GPC–LPV.

Fig. 6. Temperature. Continuous line: LTI GPC. Dashed line: GPC–LPV.

Fig. 7. Liquid propane flow. Continuous line: LTI GPC. Dashed line: GPC–LPV.
4. Conclusions

- The GPC–LPV controller is presented as an LPV controller designed in two steps.
- In first step an LTI GPC is designed by using a local model of the nonlinear system.
- In a second step delta matrices are selected in order to satisfy a set of LMIs and or BMIs, which guarantees: closed loop stability, norm bounding, closed loop specifications, etc.
- The set of LMIs and or BMIs is obtained starting from the results of analyzed literature, and working with the matrix inequalities in this particular case.
- Along this work the dependence with respect to Λ matrix is always LF.
- In most cases BMIs are obtained from PMIs by applying the Schur lemma.
- For the numerical computation of solutions, the commercial software PENBMI is used to obtain local solutions.
- The design methodology of GPC–LPV is applied to a highly nonlinear model of a liquid–gas separator process.
