ALS (airborne laser scanning); TLS (terrestrial laser scanning); ALS_{FW} (full-waveform ALS); ALS_D (discrete ALS); Nh (number of hits); Nh^{ALS} (number of hits from ALS) Nh^{ALSFW} (number of hits from ALS_{FW}); Nh^{ALSD} (number of hits from ALS_D); Nt (number of theoretical laser beams passing through a voxel); Nb (number of theoretical beams that were occluded prior to reaching a voxel); PAD (plant area density); PAD^{TLS} (plant area density for TLS); NF (Newfoundland); SP (Spain).

Abstract

Laser scanning has the potential to accurately detect the vertical distribution of forest vegetative components. However, limitations are present and vary according to the system's platform (i.e., terrestrial or airborne) and recording method (i.e., discrete return or full waveform). Terrestrial configurations detect close objects (i.e., lower vegetation strata) in more detail while airborne configurations detect a more detailed upper strata, with weak backscattered signals from lower strata. Moreover, discrete lidar systems record single or multiple hits from a given pulse at intercepted features in contrast to full-waveform systems, which register the pulse's complete backscattered signal providing complete vertical profiles. In this study, we examine for a Boreal and a Mediterranean forest with contrasted conifer canopy densities: (*i*) the characterization of the vertical distribution and signal occlusion from three laser scanning configurations: full-waveform airborne (ALS$_{FW}$), discrete airborne (ALS$_D$), and discrete terrestrial (TLS); (*ii*) the comparison in the detection of understory vegetation by ALS$_{FW}$ and ALS$_D$ using TLS as reference; and (*iii*) the use of a methodological procedure based on the Gini index concept to group understory vegetation in density classes from both ALS$_{FW}$ and ALS$_D$ configurations. Our results demonstrate, firstly, that signal occlusion can be quantified by the rate of pulse reduction independently for data from all three laser scanning configurations. The ALS$_D$ configuration was the most affected by signal occlusion, leading to weak signal returns at the lower strata ($z < 4$ m) where the rate of pulse reduction was highest as a result of dense canopy covers. Secondly, we demonstrated the capabilities for both airborne laser scanning configurations to detect understory vegetation, albeit significantly more accurately with ALS$_{FW}$. Lastly, we demonstrated the use of the Gini index as an indicator to determine understory vegetation density classes, particularly for ALS$_{FW}$ data in dense canopy cover. We proceed to explain the limitations in detecting the

2

39   vertical distribution from different configurations, and indicate that understory vegetation density

40   classes may be successfully assigned with ALS$_{FW}$ in contrasted conifer canopy densities.

41

1. Introduction

Signal occlusion is the main limitation in acquiring fully comprehensive laser scanning datasets in forested environments. Signal occlusion occurs when the object to sample is partially or completely obscured by an intervening object. The presence and amount of signal occlusion found in a laser scanning dataset depends greatly on the scanning configuration (i.e., above-canopy for aerial or near-ground for terrestrial), vegetation cover and density, and its complexity (Watt and Donoghue, 2005). Signal occlusion can therefore limit the detection of a forest's horizontal and vertical distribution of vegetation, particularly in dense forested environments. It is important to note that signal occlusion is not to be confounded with forest cover. While forest cover refers to the proportion of forest covered by the vertical projection of tree crowns, signal occlusion refers to the shadow (lack of laser signal) caused by canopy elements. Several strategies have been tested to reduce signal occlusion such as increasing the number of flyovers for airborne laser scanning (ALS) (Kükenbrink et al., 2017), combining data from multiple sensors (Giannetti et al., 2018), or sampling the plot with multiple scans from varying viewpoints with a terrestrial laser scanning (TLS) (Martin-Ducup et al., 2017). Another way to deal with signal occlusion in TLS data is to divide the point cloud space into voxels and compute the Plant Area Density (PAD) for each voxel (Béland et al., 2014; Pimont et al., 2018). Analyzing signal occlusion and its effects on the estimation of forest structural attributes is essential in understanding the limitations of different laser scanning and sampling configurations, and therefore sampling designs to best minimize signal occlusion.

Although signal occlusion is present in all laser scanning datasets, ALS and TLS systems have nonetheless demonstrated their capability to characterize forest attributes with great precision

4

65   and accuracy. Among ALS sensors, traditional or discrete ALS (ALS_D) is now used

66   operationally to estimate stand attributes for a wide range of forest ecosystems (Kankare et al.,

67   2013a; Hevia et al., 2016; Bottalico et al., 2017), and to classify tree species and forest canopy

68   fuels (Vaughn et al., 2012; Ruiz et al., 2018; Torralba et al., 2018). On the other hand, less

69   attention has been attributed to full-waveform ALS (ALS_{FW}) sensors due to the data's greater

70   complexity and the current lack of processing tools (Crespo-Peremarch et al., 2018a). ALS_{FW}

71   data provides the complete signal emitted by the sensor as opposed to discrete hits. The data is

72   processed as a continuous return signal providing information within the forest vertical

73   components. Some studies have demonstrated the success of ALS_{FW} to estimate forest stand

74   variables (Cao et al., 2014a; Cao et al., 2014b; Hermosilla et al., 2014a; Crespo-Peremarch et al.,

75   2016) and classify tree species (Heinzel and Koch, 2011; Cao et al., 2016; Torralba et al., 2018).

76   In comparison with ALS data, TLS data can provide a more detailed point cloud of a forest

77   structure, albeit from a different viewpoint. For applications in forested environments, the useful

78   portion of the TLS point cloud extent is often limited (10 – 30 m) with a hemispherical view

79   around the sensor. Withstanding that, many studies have demonstrated the capabilities of TLS to

80   estimate and extract forest stand variables (Srinivasan et al., 2015; Liang et al., 2016; Ravaglia et

81   al., 2019), and fewer on the classification of tree species (Lin and Herold, 2016; Torralba et al.,

82   2018).

83

84   Since ALS and TLS sensors acquire data from differing positions relative to the forests canopy,

85   different occluded forest strata can be observed in their point clouds. Consequently, it is of

86   interest to compare their independent effectiveness to detect the forests horizontal and vertical

87   distribution, and estimate forest structural attributes. Several studies provide a base for

comparison between three laser scanning configurations: ALS_D, ALS_{FW} and TLS. These studies generally show that canopy height estimations are more accurate using ALS than TLS (Hilker et al., 2012; Crespo-Peremarch and Ruiz, 2017), while characterization of the foliage profile is estimated with more accuracy by TLS, especially in the lower strata (Chasmer et al., 2006; Hilker et al., 2010), where understory vegetation is found. On the other hand, other studies concur on a more accurate estimation of forest structural attributes from ALS_{FW} than ALS_D for canopy height (Anderson et al., 2016), aboveground biomass (Nie et al., 2017), stand volume (Lindberg et al., 2012), and the classification of species composition (Torralba et al., 2018).

A common challenge in predicting forest structure from ALS data is finding associated reference data from which reliable error estimation is possible. Most studies on forest structure variables use a combination of field measurements and allometric relationships as reference data (González-Ferreiro et al., 2012; Treitz et al., 2012; Ruiz et al., 2014). However, in cases where 3D assessments of vegetative material are required, it can be beneficial to use TLS data as a reference as these can be difficult and often logistically challenging to quantify directly from field activities. TLS data often represent the best available information to describe forest elements (Martin-Ducup et al., 2016; Crespo-Peremarch et al., 2018b; Ravaglia et al., 2019), being sampled in much more detail when compared with ALS. However, there are important discrepancies between ALS and TLS point clouds that need to be acknowledged. Looking at a vertical profile of data points in relative terms, ALS_D point clouds have far more hits within the upper canopy and on the ground, while most of the hits for TLS point clouds are located at the lower crown, trunks-stems, understory, and ground (Crespo-Peremarch and Ruiz, 2017). These differences in sampling capabilities lead to estimation divergences (Chasmer et al., 2006). In

111   general, ALS_D point clouds tend to under-represent the lower strata. While correlation between

112   ALS_D and TLS point clouds has been found to be 0.48 for heights below 20 m, it reached 0.87

113   when only the upper canopy (z > 20 m) was considered (Hilker et al., 2010). As for canopy

114   height, estimation from ALS_D and TLS were generally similar: (*i*) an underestimation of 1 m by

115   the TLS in a mixed forest in Ontario, Canada (Chasmer et al., 2006), (*ii*) a correlation of 0.94

116   between estimations from both datasets in a pine-dominated forest in South-Korea (Jung et al.,

117   2011), and (*iii*) a correlation near 1 in a coniferous forest on Vancouver Island, BC, Canada

118   (Hilker et al., 2010). Conversely, other studies found ALS_D more suited to estimate canopy

119   height than TLS: (*i*) with an R^2 of 0.96 and 0.86, respectively in a lodgepole pine forest in

120   Alberta, Canada (Hilker et al., 2012), and (*ii*) with an underestimation of 2.1 m by the TLS in a

121   Mediterranean forest (Crespo-Peremarch and Ruiz, 2017). Therefore, there are situations where

122   ALS and TLS may not accurately estimate the entire vertical forest structure, primarily due to

123   signal occlusion. This signal occlusion problem is more severe for ALS than it is for the TLS

124   because of the much smaller number of laser pulses. Fortunately, the beam width and the

125   multiple return configuration mitigate this problem. Consequently, sampling understory

126   vegetation is comparably far more comprehensive from TLS than it is from ALS. TLS data are

127   therefore suitable reference data for the estimation of understory structural attributes and

128   preferred over using traditional field sampling techniques, which can be laborious and time

129   consuming (Crespo-Peremarch et al., 2018b).

130

131   Within the vertical distribution of the forest, detection of the lower strata can be challenging

132   from ALS sensors, especially from ALS_D as a result of signal occlusion from the overstory

133   (Anderson et al., 2016; Crespo-Peremarch and Ruiz, 2017). Nonetheless, ALS_D has proven to

134 discriminate presence and absence of understory vegetation with promising accuracy (e.g., R^2's

135 of 0.83 (Martinuzzi et al., 2009), 0.77 (Hill and Broughton, 2009), 0.74 (Wing et al., 2012), and

136 0.48 (Morsdorf et al., 2010)) and has been demonstrated to be more accurately estimated by

137 ALSFW than ALSD (Hancock et al., 2017; Torralba et al., 2018). In contrast, point clouds from

138 TLS provide a large amount of detail on understory vegetation due to the position of the sensor

139 (Liu et al., 2017). However, most studies have focused on the ability of TLS to characterize

140 shrubs in ecosystems absent of overstory (e.g., Vierling et al., 2013; Olsoy et al., 2014; Greaves

141 et al., 2015); few have focused on characterizing the understory vegetation from forested

142 ecosystems (e.g., Chen et al., 2016). Furthermore, studies have estimated understory cover with

143 ALS_{FW} using TLS as reference data and obtained a normalized root-mean-square error of 24%

144 (Hancock et al., 2017) and 9% (Crespo-Peremarch et al., 2018b). Nevertheless, a limited amount

145 of studies have compared the ability to estimate understory vegetation presence or distribution

146 from these three different laser scanning datasets (i.e., ALS_{FW}, ALS_D and TLS) (e.g., Hancock et

147 al., 2017; Torralba et al., 2018). These studies confirmed that ALS_{FW} and TLS are both capable

148 of estimating the spatial distribution of understory vegetation in more detail than using ALS_D

149 data, e.g., with overall accuracies of 86.4% and 77.3%, respectively (Torralba et al., 2018).

150 These results demonstrate the potential of combining ALS_{FW} and TLS data in a workflow that

151 estimates the spatial distribution of the understory vegetation beyond what can be estimated from

152 ALS_D data. However, these results were limited in their application as they were assessed in a

153 fragmented urban forest and an open Mediterranean forest.

154

155 The overarching goal of this study was to assess the ability of different laser scanning

156 configurations to estimate vertical forest structure in natural forest environments. Specifically,

157   we investigated the independent capability of ALS_D, ALS_{FW} and TLS to estimate the amount and

158   spatial distribution of understory vegetation from the lower strata (z < 4 m) for two structurally

159   contrasting conifer dominated forests: a dense Boreal forest and an open Mediterranean forest.

160   Three specific objectives were defined to reach the overarching goal: (*i*) characterize the vertical

161   distribution and signal occlusion caused by vegetation in these two ecosystems from each

162   scanning configuration; (*ii*) determine whether ALS_{FW} allows detecting the distribution of

163   understory vegetation to a level of detail beyond ALS_D capability; and (*iii*) adapt a

164   methodological procedure to determine understory vegetation density from ALS_{FW} and ALS_D

165   point clouds.

166   2. Material and methods

167   2.1.   Study areas

168   Two study areas were selected based on their contrasting canopy densities and understory

169   vegetation presence. Both sites are conifer dominated, albeit, structurally very different. Our first

170   study area (111,257 ha) is located in a Boreal Shield Ecozone in western Newfoundland and

171   Labrador, Canada and centered around 49.04°N and 57.93°W (Fig. 1a). The ecoregion is

172   dominated (~70%) by forest land and is located within the most eastern boreal forest region of

173   North America. Balsam fir (*Abies balsamea* (L.) Mill)) is the dominant tree species of the region

174   followed by Black spruce (*Picea mariana* (Mill.) Britton, Sterns & Poggenb.). White birch

175   (*Betula papyrifera* Marsh.), yellow birch (*Betula alleghaniensis* Britton), white spruce (*Picea*

176   *glauca* (Moench) Voss) and eastern larch (*Larix laricina* (Du Roi) K. Koch) are present to a

177   much lesser extent. The relief is gently undulating to hilly with elevation ranges between ~30 m

178   and 640 m. Forest understory is extremely variable depending on stand density and age, soil

179   conditions, status of regeneration and silvicultural treatments such as precommercial thinning

180   (e.g., Fig. 2 – Newfoundland, sparse understory). Understory vegetation can be composed of tree

181   saplings and seedlings, ferns (e.g., *Dryopteris carthusiana* (Vill.) HP Fuchs) and to a lesser

182   extent ericaceous shrubs (e.g., *Kalmia angustifolia* L., *Rhododendron groenlandicum* (Oeder)

183   Kron & Judd, *Vaccinium* spp.).

184

185   The second study area (3,742 ha) is located in a Mediterranean forest located in the Natural Park

186   of Sierra de Espadán, in the eastern Spanish province of Castellón centered around 39.96°N and

187   0.41°W (Fig. 1b). The study area is dominated by Aleppo pine (*Pinus halepensis* Mill.),

188   maritime pine (*Pinus pinaster* Ait.) and cork oak (*Quercus suber* L.). This province is the most

189   mountainous in Spain with altitudes ranging from sea level to 1,813 m. The presence of

190   understory in the study area is very variable, mainly depending on the dominant species and soil

191   properties. Understory vegetation is dominated by the following shrubs and flowering plants:

192   rosemary (*Rosmarinus officinalis* L.), tree heath (*Erica arborea* L.), brezo (*Erica multiflora* L.),

193   Mediterranean buckthorn (*Rhamnus alaternus* L.), kermes oak (*Quercus coccifera* L.) and mastic

194   (*Pistacia lentiscus* L.). Fig. 2 illustrates examples of different understory scenarios.
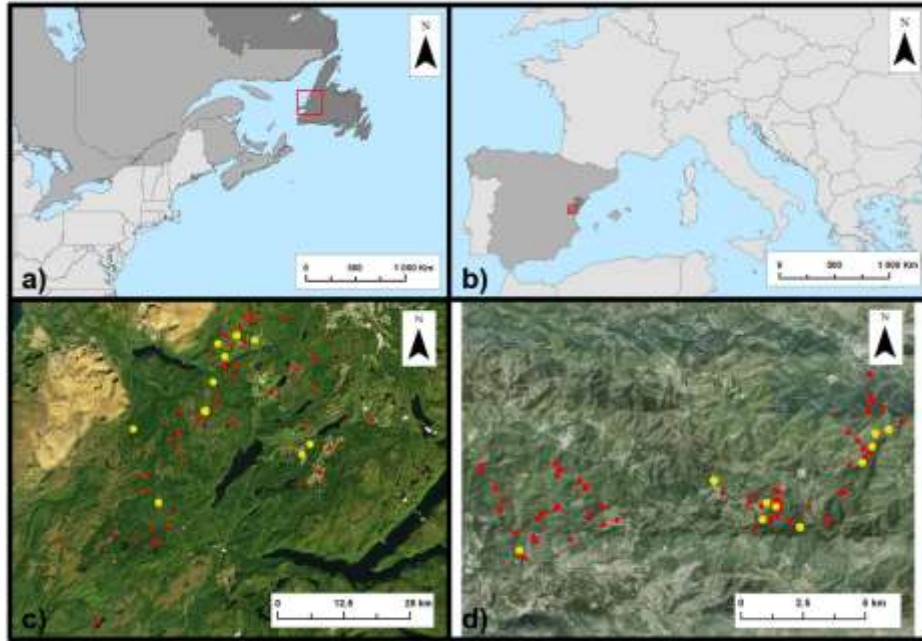

195
196
197   **Fig. 1.** Location of plots registered (red) and plots used in the current study (yellow) within each
198   study area: (a, c) in western Newfoundland, Canada, and (b, d) in the Castellón province, Spain
199   (Background imagery: PNOA andWorldView-2).
200
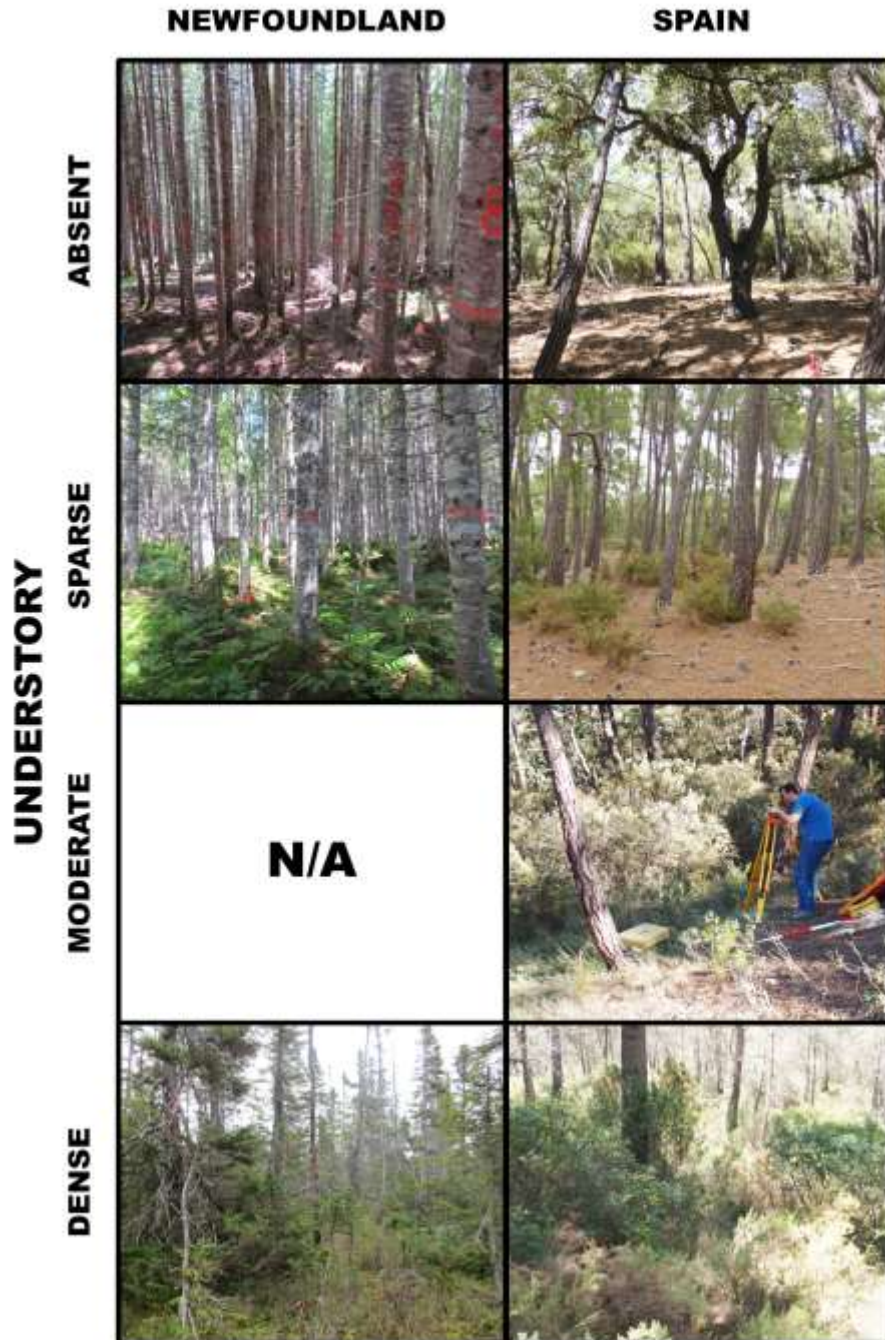

Fig. 2. Field photographs from the Newfoundland and Spain sites illustrating the varying densities of understory vegetation.

2.2. Forest plots

Circular plots were established with a radius of 11.28 m and 15 m for the Newfoundland and

Spain sites, respectively. Plot center locations for both sites were measured with a GPS RTK

209   with an average accuracy of ~0.40 m. Tree species, living status, diameter at breast height, height

210   and canopy base height were measured at all plot locations. For the Newfoundland site, 59

211   established experimental plots from Luther et al. (2019) were made available with associated

212   ALS_D and ALS_{FW} data, while 70 established experimental plots were made available with similar

213   data for the Spain site (Fig. 1c and d). Among these experimental plots, a structurally

214   representative sample of ten plots was selected per site for TLS sampling by maximizing the

215   variability of canopy cover and understory vegetation for analysis in this study. Regarding

216   canopy cover, we estimated it at plot locations from the proportion of ALS_D first hits to total hits

217   above 2 m per McGaughey (2014). Then, plots with a percentage of first hits above 70% were

218   classified as having a dense canopy cover, between 40% and 70% as having a sparse canopy

219   cover, and below 40%, as having a very sparse canopy cover. Furthermore, we assigned

220   understory vegetation density classes at plot locations through field interpretations and classified

221   plots as having dense, moderate, sparse, or absence of, understory vegetation (Fig. 2). Fig. 3

222   illustrates the variability in structure from all conifer dominated plots and the structural

223   representativeness of the retained sample plots.
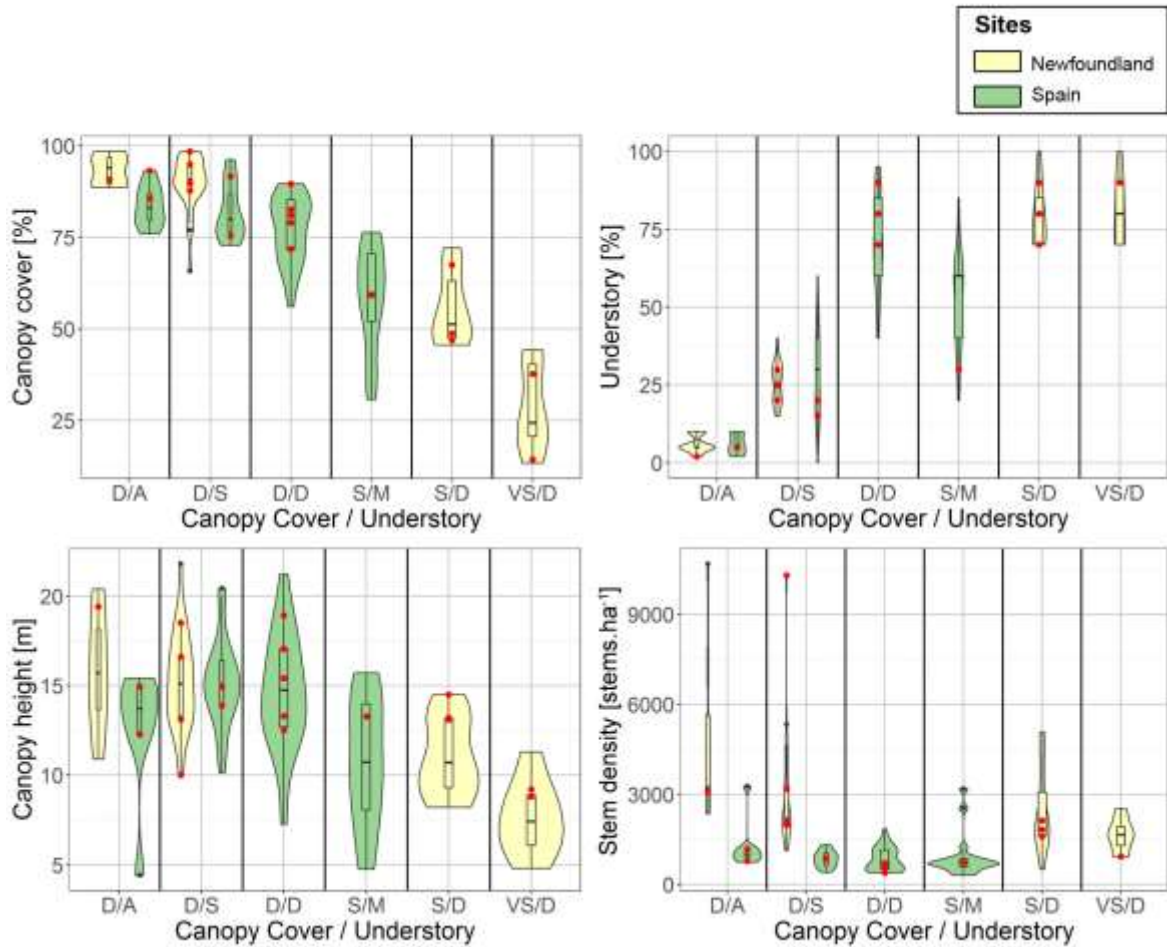

Fig. 3. Violin plots representing four structural attributes (canopy cover, understory, canopy height and stem density) from all available plots. Attribute values for plots retained for analysis are in red. Abbreviations: D-dense; M-moderate; S-sparse; VS-very sparse; A-absent.

2.3. Laser scanning data

In our study, we analyzed laser scanning data obtained from three differing configurations, namely ALS_D, ALS_{FW}, and TLS. The ALS data obtained for the Newfoundland site were acquired between August 15th and September 24th 2016 with a Riegl LMS-Q680i. The approximate flight altitude was 1000 m above ground level. Data were acquired with a pulse frequency of 330 kHz and a scan angle range of $\pm$ 30º. Not excluding waterbodies, the overall average laser scanning pulse density was 7.34 pulses·m^{-2}. ALS_{FW} data was discretized by the service provider (Leading Edge Geomatics, Canada) using the Gaussian pulse estimation

14

238   computation method to extract ALS_D data. Average point densities of 16 points·m^{-2} were

239   observed at plot locations for ALS_D.

240

241   ALS data acquisition at the Spain site was undertaken on September 16th 2015 using an IGI

242   LiteMapper 6800. Flight altitude ranged between 600 and 820 m above ground level. Data were

243   acquired with a pulse frequency of 300 kHz and a scan angle range of $\pm$ 30º. The overall average

244   pulse density was 14 pulses·m^{-2}. Again, ALS_{FW} data was discretized by the service provider

245   (IMAO, France) using the Gaussian pulse estimation computation method to extract ALS_D data.

246   Average point densities of 36 points·m^{-2} were observed at plot locations for the Spain site for

247   ALS_D.

248

249   The TLS data were collected using a FARO FOCUS 3D 120 phase-based laser scanner using a

250   multi-scan configuration on both sites, recording only the first hit with an angular density

251   between pulses of 0.0036 degree. TLS data for the Newfoundland site were acquired between

252   June and August 2017 while the TLS data for the Spain site were acquired between September

253   29th and October 23rd, 2015. To minimize signal occlusion, each plot was scanned from nine

254   positions: one at plot center, four at ~15 m from the center in each cardinal direction (i.e., N, W,

255   S, E), and four at ~ 7.5 m and ~ 6 m from the center in each primary intercardinal direction (i.e.,

256   NW, SW, SE, NE) for the Spain and Newfoundland sites, respectively. Each scan identified a

257   minimum of three co-registration spherical targets common with adjacent scans. Co-registration

258   of the 9 scans was performed using FARO SCENE software version 6.2 (FARO, Lake Mary,

259   FL). The resulting co-registered point cloud comprised, on average, 392×10^6 hits.

260

261   2.4.   Overview of the methods

262   An overview of the methodological approach and associated procedures is presented in Fig. 4.

263   First, ALS_{FW} data were denoised and georeferenced in order to create an ALS_{FW} point cloud

264   compatible with the ALS_D and TLS point clouds (Procedure 1). We then proceeded with the

265   co-registration of the three laser scanning datasets: ALS_{FW}, ALS_D and TLS (Procedure 2). Once

266   co-registered, all the point clouds were represented independently in voxel grids (Procedure 3a).

267   Sampling of each voxel by the laser beams depends primarily on three variables: (*i*) the number

268   of theoretical laser beams passing through the voxel (Nt), (*ii*) the number of these theoretical

269   beams that were occluded prior to reaching the voxel (Nb), and (*iii*), the number of hits returned

270   from these theoretical beams within the voxel (Nh). We then estimated these variables for each

271   voxel of the three datasets (Procedure 3b) in order to derive the vertical distribution profiles from

272   ALS (Nh^{ALS} for both discrete (Nh^{ALSD}) and full waveform (Nh^{ALSFW}) datasets) (Procedure 3c) as

273   well as the Plant Area Density from TLS (PAD^{TLS}) (Procedure 3d), which is the projected

274   surface of the vegetated materials (wood and leaves). In order to quantify and compare signal

275   occlusion within the three laser scanning datasets, we computed for each the rate of pulse

276   reduction of Nt as the proportion of beams blocked prior to reaching the voxel (Nb/Nt)

277   (Procedure 3e). A height normalization was then applied to Nh^{ALS}, PAD^{TLS}, and the rate of pulse

278   reduction from ALS_{FW}, ALS_D and TLS (Procedure 4). This created a coherent vertical leveling

279   between these estimated variables from which we produced vertical profiles of Nh^{ALS}, PAD^{TLS}

280   and the rate of pulse reduction (Procedures 5a and 5b). These vertical profiles were used to

281   analyze the relationship between the detection of vegetative material in different strata from

282   airborne and terrestrial laser scanning configurations and the rate of pulse reduction. We

283   computed the coefficient of correlation at lower strata ($0.5\ m \leq z \leq 4\ m$) to quantify the similarity

16

284   of vertical profiles of Nh^{ALSFW} and Nh^{ALSD} with PAD^{TLS}. Afterwards, the lower strata of the

285   Nh^{ALS} vertical profiles were compared to determine which ALS configuration (i.e., ALS_{FW} or

286   ALS_D) depicts the understory vegetation in more detail. An application of the Lorenz curve

287   (Lorenz, 1905) and the Gini index (Gini, 1912) calculated from the Nh^{ALSFW} and Nh^{ALSD} vertical

288   profiles of the lower strata determined the density of understory vegetation, which we compared

289   with field observations. Data processing and analysis was carried out in Python (van Rossum,

290   1995) and R programming languages (Team, 2013). PAD^{TLS} was computed with the L-Vox

291   algorithm (available in the Computree open source framework (Piboule et al., 2015)).
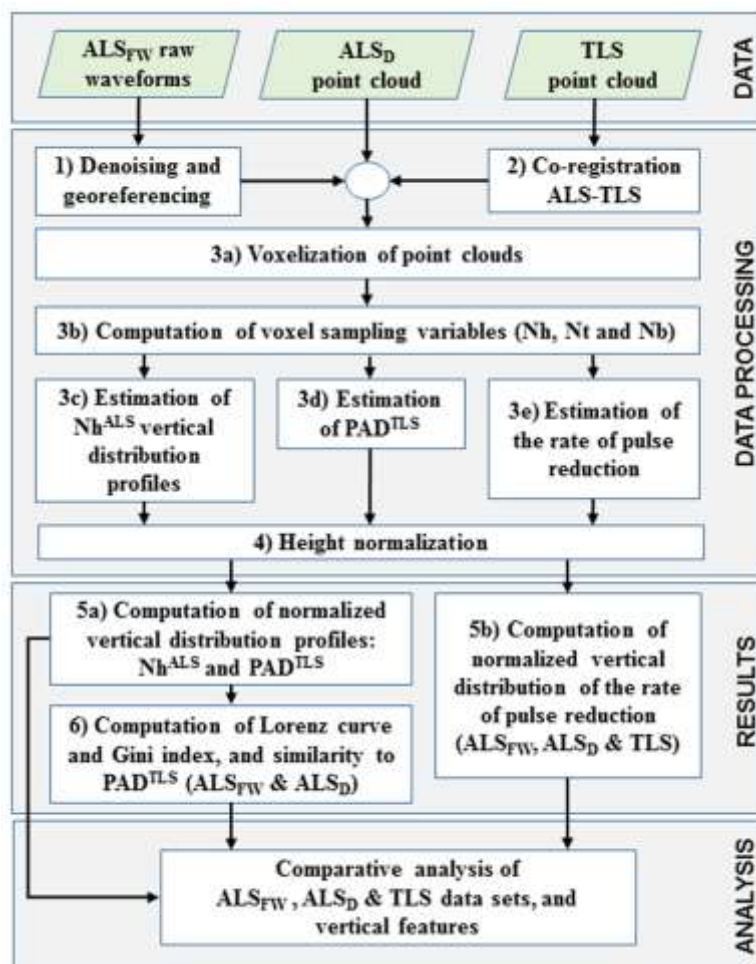

292
293
294   **Fig. 4.** Overview of the methodological approach. Abbreviations: ALS_{FW}: full-waveform
295   airborne laser scanning, ALS_D: discrete airborne laser scanning, TLS: terrestrial laser scanning,
296   Nh: number of hits, Nt: number of theoretical laser beams, Nb: number of theoretical laser beams

297   blocked before reaching a given voxel, Nh^{ALS}: number of hits extracted from airborne laser
298   scanning (i.e., full-waveform and discrete), PAD^{TLS}: plant area density extracted from terrestrial
299   laser scanning.
300

301   ## 2.5.   Data preprocessing

302   ### 2.5.1.   Denoising and georeferencing the waves from ALS_{FW}

303   Initial data were available in point cloud format for the ALS_D and TLS configurations. Unlike

304   discrete return lidar sensors which record backscattered energy at precisely referenced points in

305   time and space, ALS_{FW} sensors record backscattered energy as a nearly continuous signal in a

306   full-waveform indexed bin. We therefore needed to create an ALS_{FW} point cloud compatible

307   with the ALS_D and TLS point clouds. To do so, we removed the noise contained in the raw

308   ALS_{FW} waveforms and georeferenced the remaining bins (Procedure 1). We adopted the process

309   proposed by Lefsky et al. (2005), and further described by Hermosilla et al. (2014b), which first

310   defines a noise threshold as the mean of the waveform's amplitude summed with four times its

311   standard deviation. All the waveforms whose amplitudes were below this threshold were

312   discarded as noise. After removing noisy waveforms, background noise was suppressed from the

313   remaining waveforms by subtracting a noise value (133% of the mode of the amplitudes) from

314   each amplitude value of the waveform. We then computed each bin's XYZ coordinates from: (*i*)

315   the coordinates of at least one hit belonging to the waveform, (*ii*) the elapsed time between the

316   known hit and the anchor point (i.e., the beginning) of the waveform, (*iii*) the distance between

317   two consecutive bins, and (*iv*) the waveform line parameters Xt, Yt and Zt. The coordinates and

318   orientation of the waveform were derived from the known hit coordinates and waveform line

319   parameters. The coordinates of the anchor point were derived from the known hit coordinates,

320   orientation of the waveform, and elapsed time between the known hit and anchor point. Each

321   bin's XYZ coordinates were then defined by the coordinates of the anchor point, the orientation

18

322 of the waveform, and the distance between two consecutive bins. The resulting ALS_{FW} data

323 contained only significant waveforms with the noise removed from which we were able to create

324 a georeferenced point cloud compatible with those from the two other configurations: ALS_D and

325 TLS.

326

327   2.5.2. XY co-registration of ALS and TLS datasets

328 Considering that the main goal of this research is to compare the data obtained from three

329 different laser scanning configurations, it was necessary that all point clouds were co-registered

330 in the same coordinate system (Procedure 2). Co-registration is a critical step to ensure that the

331 three point clouds can be compared in our analysis. Georeferencing of the ALS data followed

332 common practice and was done by registering the flight trajectory coordinates from the airborne

333 GPS to a set of ground control points. These ground control points allowed for an accurate

334 georeferencing of the flight lines, and therefore the resulting waveforms and point clouds. Given

335 that the ALS_D is derived from the ALS_{FW} data, co-registration between these two datasets was

336 not necessary.

337

338 Co-registration of the TLS data to the ALS data was performed using the latter as reference.

339 These data were co-registered on a plot-level basis. For each plot, Canopy Height Surfaces

340 (CHS) were generated independently from both ALS_D and TLS data. The geometric distribution

341 of tree crowns and canopy gaps guided the selection of homologous points from both CHS. A 2D

342 affine matrix transformation was then computed from the homologous point coordinates and

343 applied to the TLS point clouds. Only translation in the horizontal plane and rotation around the

344 vertical axis were applied since the distance values from both laser scanner systems needed to be

19

345 maintained, therefore not altering the scale. The root-mean-square error (RMSE) of the 2D affine

346 transformation was 9 cm ± 4 cm and 7 cm ± 7 cm for the Newfoundland and Spain data,

347 respectively. The co-registration process was carried out by extracting the coordinates with

348 QGIS open source software (QGIS, 2016) and computing the 2D affine transformation.

349

350   2.6.   Estimating voxel sampling variables and the rate of pulse reduction

351 The 3D space of the point clouds was discretized in voxels to produce vertical profiles

352 (Procedure 3a). The point density from the TLS point clouds was sufficiently high to allow the

353 adoption of very small voxels (e.g., ~5cm). However, assessing the capacity of each laser

354 scanning configuration to detect understory vegetation required adopting a common voxel size: a

355 trade-off between the fine vertical features of vegetation density and the availability of sufficient

356 hits from laser scanning signal within a voxel. We therefore adopted a voxel size for all three

357 datasets according to (*i*) the pulse spacing of ALS in XY plane, (*ii*) the temporal sample spacing

358 of ALS_{FW} in the Z axis, and (*iii*), avoiding empty voxels in either datasets (Crespo-Peremarch et

359 al., 2018a). The most suitable voxel size was determined to be 0.5 m in X, 0.5 m in Y and 0.15 m

360 in Z (vertical).

361

362 We first computed for all datasets the number of beams crossing the voxel (Nt), the number of

363 hits within the voxel (Nh), and the number of beams blocked prior to reaching the voxel (Nb)

364 (Procedure 3b). The computation approach of these three sampling variables differed between

365 the TLS and ALS datasets due to their distinct sensor-signal-scene configurations. The approach

366 taken for the TLS data used the one (first) hit per pulse of the TLS phase-shift technology. The

367 approach taken for the ALS data assumed that all recorded hits were associated with an

368 independent laser pulse having no cross-section (i.e., a vector with no divergence). This,

369 however, is an abstraction. In fact, multiple hits originate from the same beam. Hence, the

370 sampling variables derived from TLS data are not directly comparable with those derived from

371 ALS data. We therefore assumed the number of hits in each voxel to be a representation of the

372 forest vertical distribution only from ALS for both Nh^{ALSD} and Nh^{ALSFW} (Procedure 3c) while the

373 forest vertical distribution from TLS was represented by the cumulative PAD^{TLS} (Procedure 3d).

374 In addition to Nt, Nh and Nb, the path length of all pulses crossing the voxel was estimated from

375 the TLS data. The three voxel sampling variables and the path length of all pulses crossing the

376 voxel allowed calculating PAD^{TLS}, in $m^2 \cdot m^{-3}$, for each voxel according to the mathematical

377 framework proposed by Pimont et al. (2018). We used a minimum of five pulses reaching a

378 voxel (Nt-Nb $\geq$ 5) as a threshold for calculating PAD^{TLS}, otherwise the voxel was assigned as

379 being occluded. A negligible number of TLS voxels were tagged as occluded due to the large

380 voxel size relative to point density.

381

382 In order to quantify signal occlusion caused by vegetation, we computed the rate of pulse

383 reduction as the proportion of beams blocked prior to reaching the current voxel (Nb/Nt)

384 (Procedure 3e). Knowing the rate of pulse reduction provides insight on the potential or

385 drawbacks of the different laser scanning configurations.

386

387   2.7.   Extracting forest vertical distribution and rate of pulse reduction profiles

388 In Section 2.5, through the 2nd procedure, TLS data were co-registered only in XY (not in Z) to

389 the ALS$_D$ data. Absolute heights of the canopy needed to be maintained in order to define the

390 original laser pulse trajectories, which was critical in computing Nh^{ALSD}, Nh^{ALSFW}, PAD^{TLS}, and

391 the rate of pulse reduction. However, in order to extract and make meaningful plot-level

392 comparisons of the vertical profiles of these attributes (stored as 3D matrices of voxels), a co-

393 registration in the Z-axis was necessary (Procedure 4). Co-registration ensured that the base of

394 each column of voxels was set to a common Z reference system where all ground voxels were set

395 to a height of 0 m. Both the ALS and TLS datasets had their respective DTMs created with a cell

396 size of 0.5 m. The DTMs for ALS data were generated from ALS_D data. Classification of ground

397 points was done using the Axelsson algorithm (Axelsson, 2000) implemented in LAStools

398 (Isenburg, 2017). The DTMs for the TLS data were produced for every plot using an open source

399 ground classification algorithm in Computree (Piboule et al., 2015). Height normalization of the

400 3D matrices was therefore done with their respective DTM; e.g., Nh^{ALSD} and Nh^{ALSFW} were

401 normalized to its respective ALS-derived DTM as PAD^{TLS} was normalized to its respective

402 TLS-derived DTM.

403

404 Next, we extracted vertical profiles of these 3D matrices to represent the vertical distribution of

405 forest elements for each horizontal layer of voxels (i.e., a vertical bin with a height of 0.15 m).

406 The value of each vertical bin was calculated as the sum of the voxel values of the corresponding

407 horizontal layer for Nh^{ALSD}, Nh^{ALSFW} and PAD^{TLS} (Procedure 5a). The rate of pulse reduction

408 was calculated as the average of the voxel values for that horizontal layer (Procedure 5b). Only

409 information 0.5 m above the ground was considered therefore removing values associated to an

410 understory zone strongly influenced by soil micro-relief and very low vegetation. This procedure

411 provided the normalized vertical profiles of Nh^{ALSD}, Nh^{ALSFW} and PAD^{TLS}, and the rate of pulse

412 reduction.

413

414   In order to assess how well we captured the vertical distribution profiles at different heights from

415   ALS, we assessed the relationships between Nh^{ALS} and PAD^{TLS} by means of ratios. To do so, we

416   computed, plotted and compared the ratios between Nh^{ALS} and PAD^{TLS} (i.e., Nh^{ALSD}/PAD^{TLS} and

417   Nh^{ALSFW}/PAD^{TLS}). The resulting vertical profiles highlighted limitations in detecting the

418   different vertical strata based on a unitless indicator. Higher values imply a higher detection of

419   the vegetation, while lower values imply a more limited detection.

420

421   2.8.   Classifying the vertical distribution of understory vegetation from ALS data

422   Once the forest vertical profiles were generated for Nh^{ALS}, both ALS configurations (ALS_D and

423   ALS_{FW}) were compared to detect the understory vegetation. The height range for this comparison

424   was set between 0.5 m and 4 m to detect the lower strata through Nh^{ALS} vertical profiles. The

425   upper limit of 4 m was deemed appropriate to capture high shrubs within our study sites.

426   Detection of the understory vegetation was addressed through the characteristics of the Nh^{ALS}

427   vertical profiles, whose curvature depends on the presence of understory vegetation. To quantify

428   the curvature of the Nh^{ALS} vertical profiles, we combined the fitting of the Lorenz curve (Lorenz,

429   1905) with the Gini index (Gini, 1912) (Procedure 6). The Gini index is a measure of statistical

430   dispersion initially created to measure inequality of countries' wealth. It is computed as the area

431   between the curve and the equality line (i.e., 1:1 line) (see area A in Fig. 5a) divided by the area

432   below the equality line and delimited by the main axes (see area B in Fig. 5a). Fig. 5b and 5c

433   show the two extreme cases, i.e., complete equality (i.e., Gini index = 0) and complete inequality

434   (i.e., Gini index = 1), respectively. Consequently, the Gini index quantifies the curvature of a

435   distribution, or in our application, a vertical profile. The Lorenz curve and Gini index have been

436   widely used in economics, but also in some forestry applications. For instance, Valbuena et al.

437   (2013) and Valbuena et al. (2014) proposed several indicators describing tree size inequality

438   related to forest vertical structure. These indicators were based on the combined analysis of the

439   Lorenz curve from ALS_D data, including the Gini index. In addition, the Gini index obtained

440   from ALS_D was proposed to identify differences in structural complexity of forests (Valbuena et

441   al., 2016).
442
443

444   **Fig. 5.** Description of the Gini index for (a) a general case, and two examples showing (b)
445   equality (i.e., Gini index = 0) and (c) inequality cases (i.e., Gini index = 1), respectively.
446

447   In our study, each Nh^{ALS} vertical profile (Nh^{ALSD} and Nh^{ALSFW}) is represented by a Lorenz curve.

448   The Gini index was estimated from this Lorenz curve through the ratio A / (A + B) (Fig. 5a, 6b).

449   To do so, we applied the following three steps:

450

451   1. Nh^{ALS} vertical profiles were first filtered to exclude overstory following the same

452   procedure for ALS_{FW} and ALS_D. We discarded the Nh^{ALS} values in the vertical profiles

453   that had a height greater than the first relative minimum of Nh^{ALS} (see Fig. 6b).

454   Consequently, high shrubs were included in the analysis but lower crowns were excluded

455   from the computation of the Gini index (see Fig. 6a).

456

24

457   2. Nh^{ALS} values were then normalized between 0 and 1 using Eq. (1) (see Fig. 6c). The

458   normalization facilitated the comparison between plots since Nh^{ALS} values are variable

459   according to the different plots and acquisition configurations.

460
$$Nh^{ALS}{}_{norm} = \frac{Nh^{ALS} - min\ (Nh^{ALS})}{max\ (Nh^{ALS}) - min\ (Nh^{ALS})}$$
(1)

461   where $Nh^{ALS}{}_{norm}$ refers to the normalization (between 0 and 1) of Nh^{ALS}. Also, $min(Nh^{ALS})$

462   and $max(Nh^{ALS})$ are the minimum and maximum values, respectively, of Nh^{ALS} for the

463   current   plot   between   0.5   and   4   m.

464

465   3. Finally, the Gini index was computed as the area between the curve and the equality line

466   divided by the area below the equality line and delimited by the main axes (see Fig. 6c).

467   Application of the Gini index was performed using the *ineq* package (Zeileis et al., 2009)

468   in the R programming language (Team, 2013).

469

470   The PAD estimation of the lower strata from the TLS data is a far less affected by signal

471   occlusion because of the position of the scanner. Therefore the PAD^{TLS} vertical profile was used

472   as a reference to compare the ability of ALS_{FW} and ALS_D to detect understory vegetation. Nh^{ALS}

473   vertical profiles were compared with PAD^{TLS} by calculating the correlation coefficient at lower

474   strata (0.5 m $\leq$ z $\leq$ 4 m) and its significance using the Student's t-test (Gosset, 1908). This

475   coefficient is a unitless quantity, and therefore allows comparing different datasets with different

476   units and orders of magnitude, such as Nh^{ALSFW}, Nh^{ALSD} and PAD^{TLS} vertical profiles.
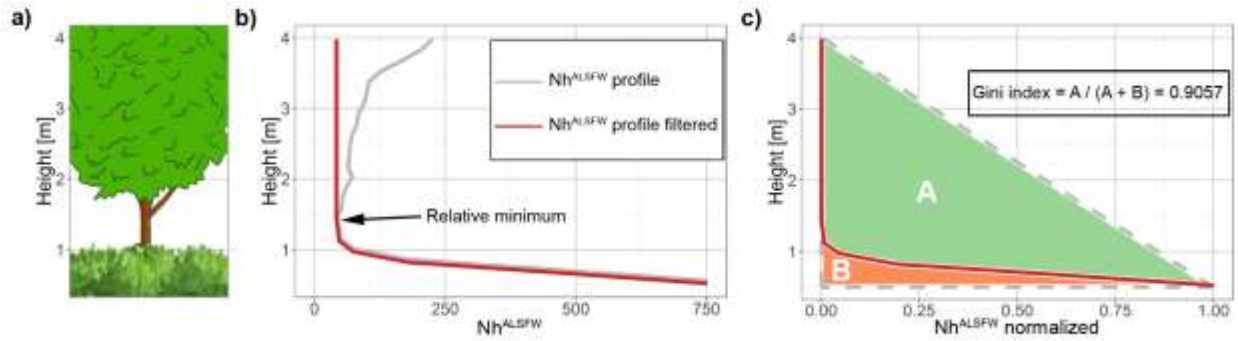

Fig. 6. Depiction of (a) separation between understory vegetation and overstory, (b) the filtering of Nh^{ALSFW} vertical profile corresponding to the lower strata from plot P3-NF and Nh^{ALSFW} vertical profile, and (b) estimation of the Gini index from the resulting Nh^{ALS} vertical profile.

3. Results

3.1. Forest vertical distribution and rate of pulse reduction profiles

The data processing steps led to a representation of the vertical distribution and rate of pulse reduction profiles from the three laser scanning configurations, shown for a sample of plots from the Newfoundland and Spain sites in Fig. 7 and 8, respectively. Overall, results show that ALS, viewing the forest from the top-down, was more limited to sample the lower strata, while TLS, viewing the forest from bottom-up, was more limited to sample the top of the canopy. Despite these limitations, the vertical distribution profiles generally represented the forest's vertical structure, capturing components of the different vertical strata. For instance, plot P5-SP (Fig. 8b) has a mixed presence of maritime pines and cork oaks. This heterogeneous vertical structure was represented by different peaks in associated PAD^{TLS} vertical profiles. Conversely, plots with a homogeneous vertical structure (e.g., plot P7-SP, Fig. 8c) were represented by a single and well-defined peak in their associated vertical distribution profiles. A visual comparison between vertical distribution profiles (i.e., PAD^{TLS}, Nh^{ALSD} and Nh^{ALSFW}) and associated rated of pulse reduction with the one meter wide point cloud transects reveals an obvious correlation: both

26

498 vertical profiles of element distribution and point cloud density decreased as the rate of pulse

499 reduction increased. The rate of pulse reduction profiles generally followed a distribution in the

500 form of a sigmoid function or "S"-shaped curve, whose form, or increment of slope of the rate of

501 pulse reduction, depended on the laser scanning configuration as well as the density of the upper

502 canopy. For example, all plots with dense canopy cover (e.g., Fig. 7a, 7b, 8a, 8b, and 8d) had rate

503 of pulse reduction profiles following a clearly defined sigmoid distribution. However, converse

504 trends were observed in the rate of pulse reduction from ALS and TLS: increasing rates of pulse

505 reduction were associated with decreasing heights from ALS and increasing heights from TLS.

506 Furthermore, in some instances, observed high values in the rate of pulse reduction were

507 associated with very low values from the vertical distribution profiles (i.e., where PAD^{TLS} and/or

508 Nh^{ALS} reached or approached 0). This occurred more frequently for Newfoundland plots where

509 conifer species on this site grow dense, creating a dense upper canopy (e.g., P2-NF and P4-NF in

510 Fig. 7a and 7b, respectively). For these plots, the rate of pulse reduction profiles transition to

511 high values (i.e., 35-40% for TLS; 80-90% for ALS) at heights of ~10-13 m. Conversely, for

512 plots with sparsely distributed vegetation, the rate of pulse reduction was very low. In conditions

513 of sparse vegetation, the rate of pulse reduction curve followed the typical sigmoid distribution,

514 however did not reach the high values observed from denser plots (e.g., P7-SP in Fig. 8c). Sparse

515 and very sparse sites often displayed a relatively flat vertical line, terminating near the ground by

516 a steep high value (e.g., P6-NF and P10-NF in Fig. 7c and 7d). Overall, but more specifically in

517 dense canopy covers, an offset in the x-values from the midstory strata of PAD^{TLS} was observed

518 relative to Nh^{ALS}. This offset coincides with the large discrepancy in the number of hits returned

519 by ALS and TLS systems from the midstory strata, where ALS did not detect tree stems to the

520 same degree as TLS. On the other hand, little variability was observed in Nh^{ALSD} vertical profiles

521   in the lower strata, except in some cases where canopy cover was very sparse (e.g., P10-NF).

522   The analysis of vertical distribution profiles from the lower strata generally showed lower

523   Nh^{ALSD} when compared to Nh^{ALSFW}. In addition, similarity in overall shape, quantified and

524   reported in section 3.2 by means of the coefficient of correlation, was greater between Nh^{ALSFW}

525   and PAD^{TLS} than between Nh^{ALSD} and PAD^{TLS}. Furthermore, Nh^{ALSFW} values had an exponential

526   increment as they approached the ground when understory vegetation was absent. This trend was

527   less obvious in plot P4-NF and most Newfoundland plots with higher rates of pulse reduction (>

528   80%).

529
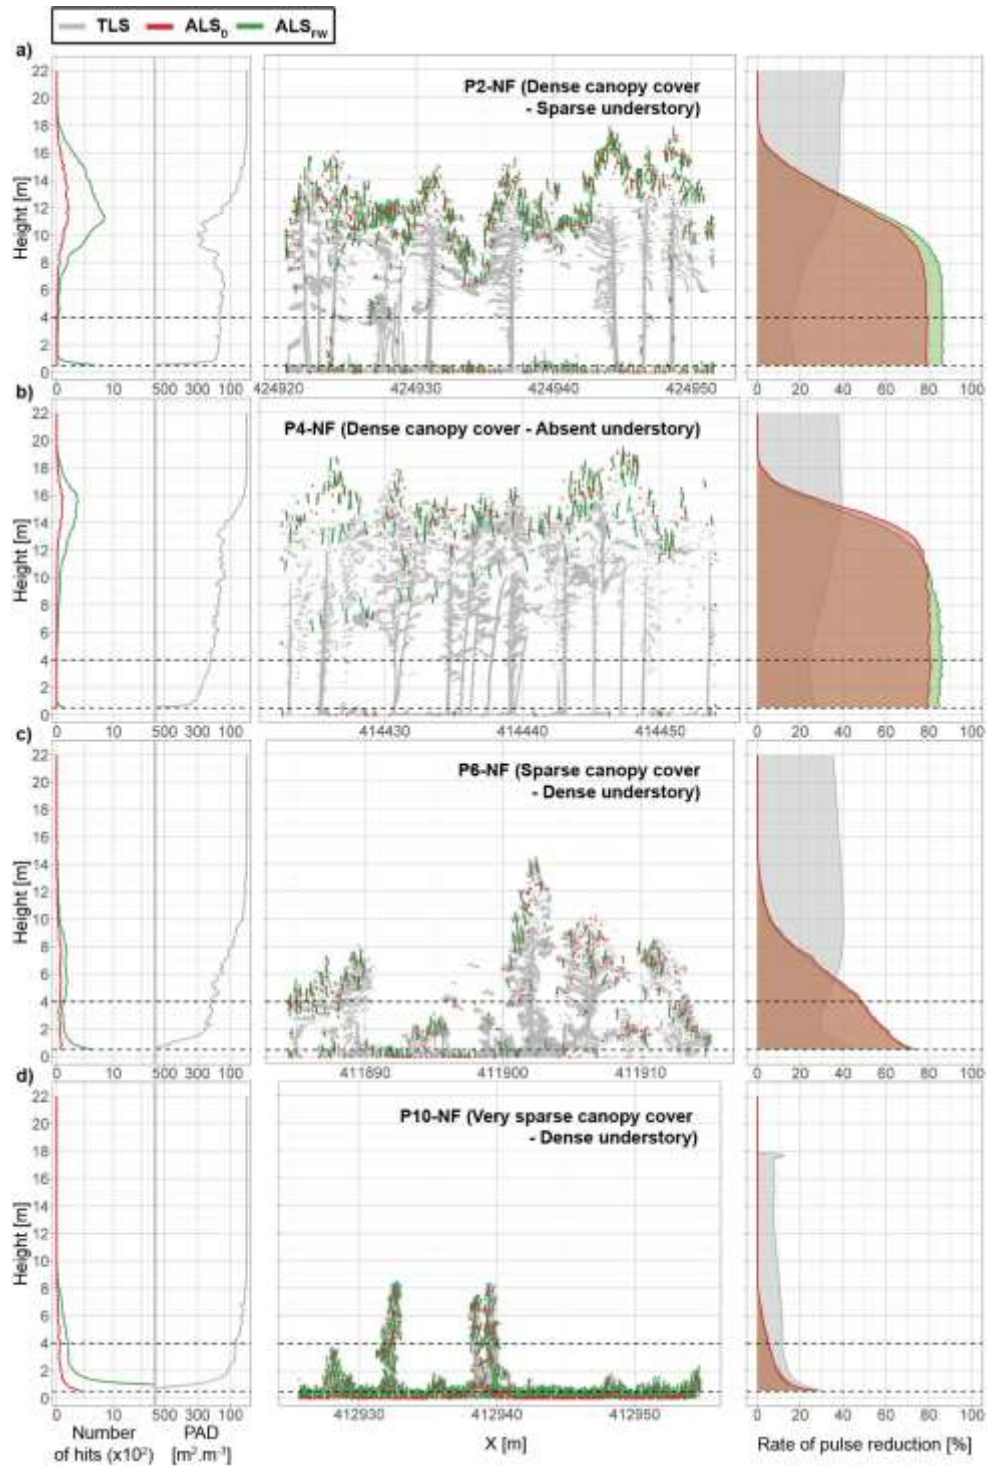

Fig. 7. Vertical profiles representing four plots of the Newfoundland site (a-d). The three figures from left to right represent: (i) the number of hits from ALS and cumulative Plant Area Density from TLS, (ii) a point cloud transect of one meter wide, and (iii) the rate of pulse reduction from the three configurations (i.e., TLS, ALS_D and ALS_{FW}). Dashed lines represent the limits of the lower strata (i.e., 0.5 and 4 m).

29
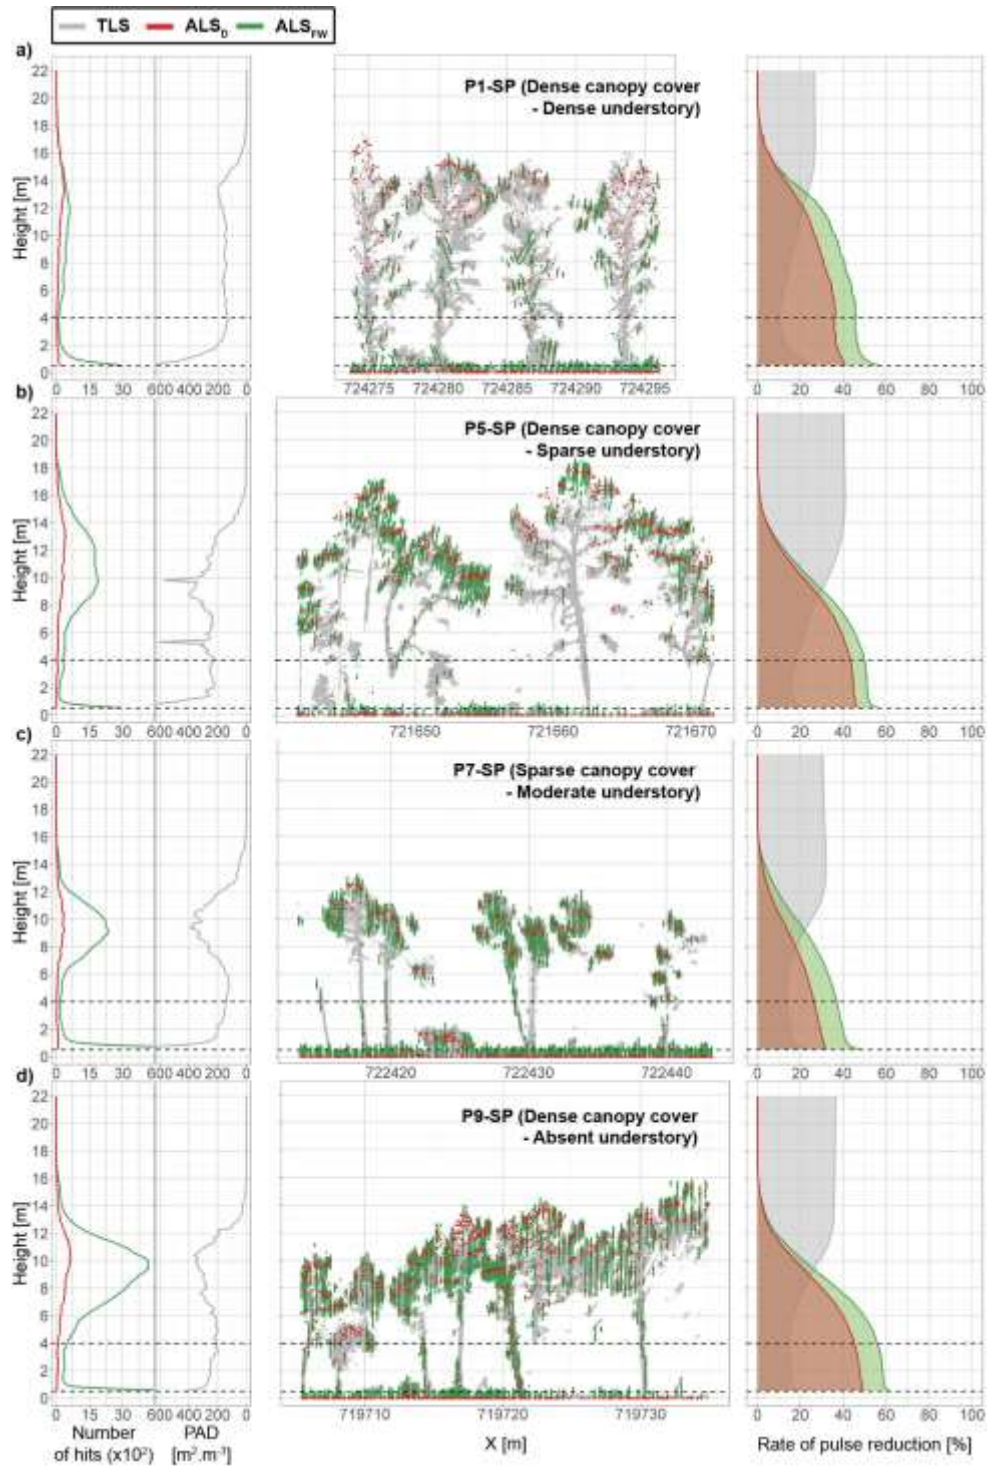

Fig. 8. Vertical profiles representing four plots of the Spain site (a-d). The figures from left to right represent: (i) the number of hits from ALS and cumulative Plant Area Density from TLS, (ii) a point cloud transect of one meter wide, and (iii) the rate of pulse reduction from the three configurations (i.e., TLS, ALS_D and ALS_{FW}). Dashed lines represent the limits of the lower strata (i.e., 0.5 and 4 m).

545   Considering TLS as reference, the ratios between Nh^{ALS} and PAD^{TLS} in Fig. 9 illustrate the

546   limitations of ALS configurations in detecting the vertical distribution profiles at different

547   heights based on a unitless indicator. Ratios were calculated as Nh^{ALS} divided by PAD^{TLS},

548   therefore implying higher detection of vegetation as this ratio value increases. The highest values

549   for the ratio calculated from Nh^{ALSD} were observed in the upper strata for all plots (Fig. 9). In

550   most cases, ALS_D incoming pulses were blocked by the dominant strata, generating signal

551   occlusion underneath. ALS_{FW} (Nh^{ALSFW}/PAD^{TLS}) and ALS_D (Nh^{ALSD}/PAD^{TLS}) ratio values were

552   most similar in the upper strata. Nevertheless, ALS_{FW} ratio values below the dominant strata

553   (i.e., intermediate and/or lower strata) remained high, while ALS_D ratio values dropped.

554   Generally, ALS_D ratios dropped below 1 m, and in some cases below 2.5 m (e.g., P10-NF in Fig.

555   9).

556
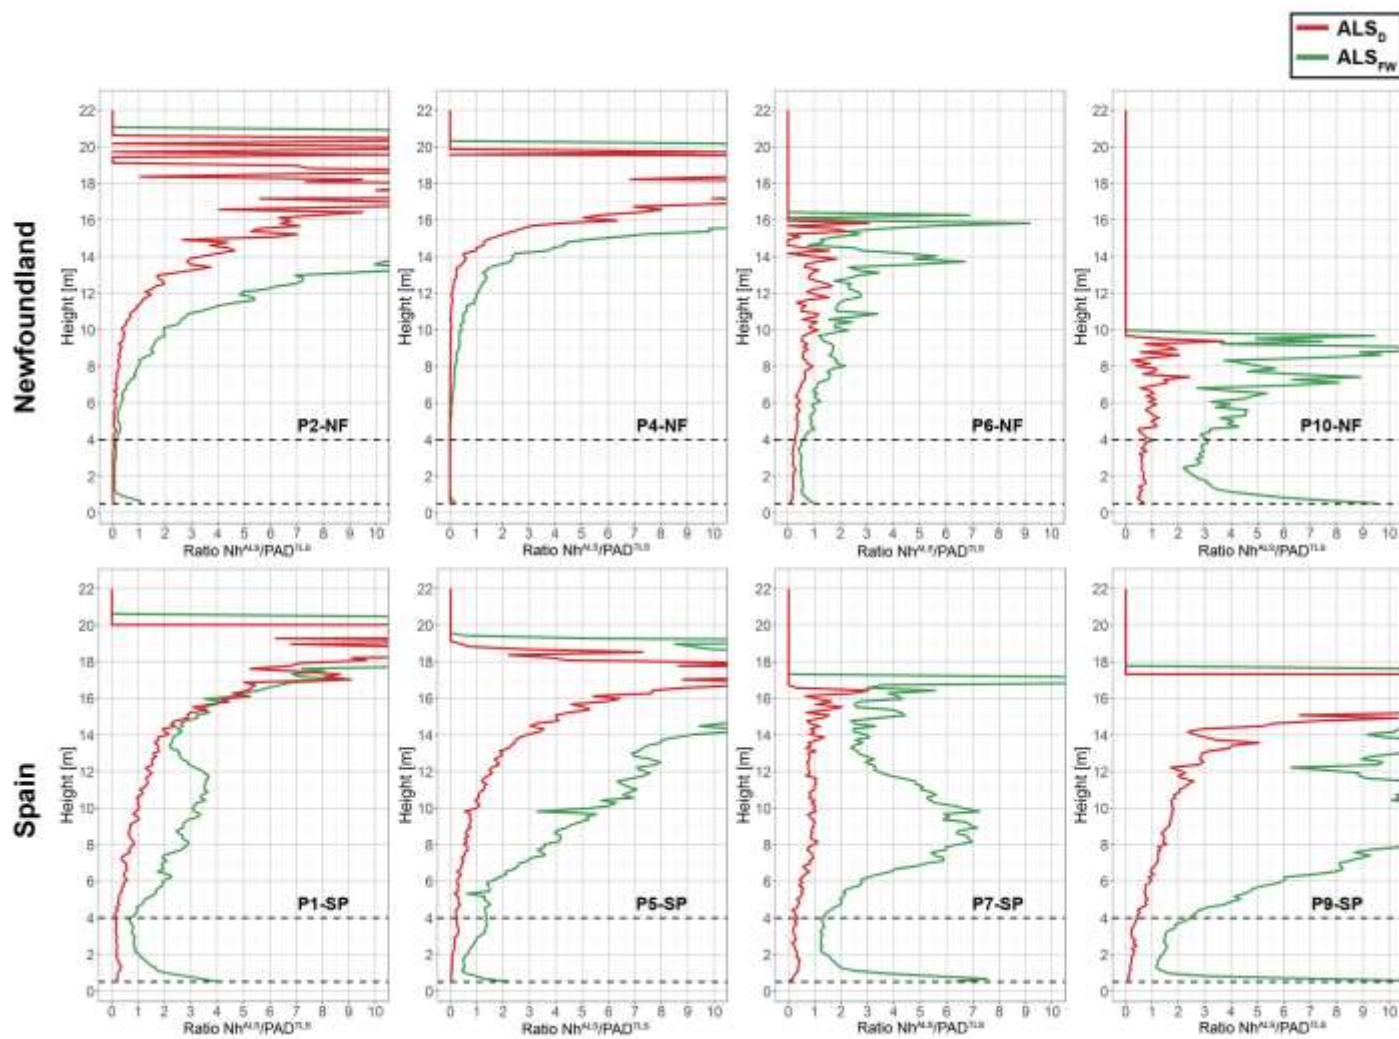

Fig. 9. Vertical profiles representing the ratio (Nh^{ALS}/PAD^{TLS}) between the Nh from ALS (i.e., ALS_{FW} in green and ALS_D in red) and cumulative PAD from TLS for a sample of plots. Dashed lines represent the limits of the lower strata (i.e., 0.5 and 4 m).

561   3.2.   Understory characterization from ALS

562   In the previous subsection it was observed that although the values of the vertical distribution

563   profiles may differ between Nh^{ALS} and PAD^{TLS}, they remained similar in terms of shape, albeit

564   with different units and order of magnitude. This similarity in terms of shape of the vertical

565   distribution profiles was quantified between Nh^{ALS} and PAD^{TLS} by using the coefficient of

566   correlation (see Table 1), which ultimately allows for determining whether understory vegetative

567   material was detected. Coefficients of correlation were calculated between Nh^{ALS} (i.e., Nh^{ALSFW}

568   and Nh^{ALSD}) and PAD^{TLS} vertical profiles from the lower strata. Null coefficient of correlation

569   values (e.g., observed from ALS_D for plots P4-NF, P5-NF and P6-SP, and for plot P6-SP from

570   ALS_{FW}) were due to the fact that no values were registered at the lower strata, and therefore the

571   standard deviations of the corresponding vertical profiles were equal to zero. Coefficients of

572   correlation between Nh^{ALSFW} and PAD^{TLS} were rarely below 90%, and all were considered to be

573   significant correlations according to the Student's t-test (Table 1). The range of coefficients of

574   correlation for ALS_{FW} was between 53.48% and 99.58%, with an average value of 90.11% and

575   an associated standard error of 3.04%. On the other hand, with the exception of plot P9-NF, all

576   coefficients of correlation between Nh^{ALSD} and PAD^{TLS} were all lower or at par, with one

577   correlation not being considered as significant (plot P7-SP). The range of coefficients of

578   correlation for ALS_D was between 30.60% and 97.36%, with an average value of 82.57% and an

579   associated standard error of 4.29%. Regarding summary statistics of the differences in

580   coefficients of correlation between ALS_{FW} and ALS_D, the range was between 22.01% and -

581   68.36% (being negative values when coefficients of correlation for ALS_{FW} were greater), with an

582   average value of -9.50% and an associated standard error of 4.62%. Hence, although ALS_{FW}

583   detected understory vegetation with a much larger number of hits than ALS_D (see Figures 7, 8

584 and 9), the latter still had a significant correlation with PAD^{TLS}. Remarkably, strong correlations

585 between Nh^{ALSFW} and PAD^{TLS} were observed for dense canopy cover plots from the

586 Newfoundland site, where the rate of pulse reduction was large in lower strata. For instance,

587 plots P2-NF and P4-NF had rates of pulse reduction ~85% for ALS_{FW} at the lower strata and an

588 associated coefficient of correlation with PAD^{TLS} equal to 98.50% and 93.39%, respectively.

589 Nh^{ALSFW} and Nh^{ALSD} were equally correlated with PAD^{TLS} (i.e., < 1% of difference) in only a

590 few plots having a dense canopy cover (plots P8-SP and P10-SP) and in a plot with very sparse

591 canopy cover (plot P10-NF).

592

597

3.3.   Understory vegetation density classification

599   Afterwards, the variation of the Nh^{ALS} vertical profiles at the lower strata was quantified by

600   means of the Gini index, whose values for ALS_D and ALS_{FW} are presented in Table 2. Generally,

601   sparse understory vegetation densities had large Gini indices (i.e., gradual increments of Nh^{ALS}),

602   while dense understory vegetation had low Gini indices (i.e., steep increments of Nh^{ALS}). Despite

603   considerable differences between the structure of Boreal and Mediterranean forests, the Gini

604   index values confirmed a coherent behaviour for both sites as a vegetation density indicator.

605   Specific Gini index ranges derived from the Nh^{ALSFW} vertical profiles were associated to

606   understory vegetation density classes as follows: absent (91.63% ± 0.13), sparse (90.59% ±

607   2.23), moderate (84.31% ± 0.00), and dense (75.45% ± 7.86). Similarly, from the Nh^{ALSD} vertical

608   profiles, Gini index ranges were associated to understory vegetation density classes as follows:

609   absent (97.69% ± 4.01), sparse (83.79% ± 12.31), moderate (53.38% ± 0.00) and dense (59.37%

610   ± 16.71). Nevertheless, the Gini index class interval thresholds computed from ALS_D were

611   fuzzier, implying more overlap between classes, than those from ALS_{FW}. Class intervals derived

612   from computed Gini index values showed larger standard deviations for ALS_D than ALS_{FW}.

613   Furthermore, misclassification between sparse and absent understory vegetation density classes

614   occurred when derived with ALS_D data. Some plots with a moderate or sparse understory had a

615   Gini index from Nh^{ALSD} lower than plots with a dense understory vegetation (e.g., P7-SP vs. P3-

616   SP), which lead to a misclassification. Similarly, plot P5-NF, with sparse understory vegetation,

617   had a Gini index from Nh^{ALSFW} larger than that observed for plots with absent understory, which

618   also lead to a misclassification.

619

Table 2. Gini index from Nh^{ALSFW} and Nh^{ALSD} vertical profiles for each plot from the Newfoundland and Spain sites. Plots are in ascending order according to the Gini index computed from Nh^{ALSFW}.

Plot ID	Understory vegetation	Canopy cover	Gini index Nh^{ALSFW} (%)	Gini index Nh^{ALSD} (%)

4. Discussion

In this study, we assessed the ability of different laser scanning configurations to estimate vertical forest structure, linking it with a new method to estimate signal occlusion in the different strata. In addition, we also assessed and compared the suitability of ALS_{FW} and ALS_D to classify in understory vegetation density classes. Key results highlighted the limitations inherent to different configurations in estimating vertical forest structure and the importance of signal occlusion. More specifically, in the lower strata, which is highly occluded by ALS configurations, understory vegetation density was successfully assessed through vertical canopy

633   density profiles. Moreover, the analysis of vertical profiles from our testing plots demonstrated

634   that ALS$_{FW}$ improved understory identification and density estimation over ALS$_D$.

635

636   Overall, our results confirmed the general trend largely accepted by the scientific community,

637   which implies that laser scanning signal occlusion prevails in sectors blocked by dense canopy

638   covers. Signal occlusion therefore depends largely on the laser scanning configuration: ALS,

639   viewing the forest from the top-down, is more limited to sample the lower strata, while TLS,

640   viewing the forest from bottom-up, is more limited to sample the top of the canopy (Hilker et al.,

641   2012; Anderson et al., 2016; Crespo-Peremarch and Ruiz, 2017). Regarding ALS configurations,

642   canopy density of the upper layer is the single most important environmental factor in defining if

643   sufficient airborne laser pulses reach the complete vertical range of the forest. Hence, signal

644   occlusion can limit exhaustive sampling of the lower vertical strata with ALS data. In this sense,

645   Maltamo et al. (2014) distinguished between signal occlusion and canopy cover as two different

646   but related phenomena, both affecting the overestimation of canopy base height when using

647   ALS. Conversely, for plots with sparsely distributed vegetation, the level of signal occlusion is

648   very low. Consequently, estimation of the distribution of vegetative material is possible

649   throughout the vertical range of the forest. In these cases, vertical distribution of forest materials

650   can be estimated with high level of accuracy. LaRue et al. (2020) also observed that estimating

651   canopy density of the lower strata is best achieved in open canopy covers for ALS

652   configurations, because of the influence of signal occlusion caused by dense canopy covers.

653

654   In cases where significant signal occlusion exists, ALS configurations detection of lower strata

655   density capabilities are limited. The reliability of vertical distribution profiles is directly

656   dependent on the level of signal occlusion. In this regard, we proposed to use the rate of pulse

657   reduction as an indicator of the amount of signal occlusion occurring at various heights in the

658   forest. Inferring the ability to detect vertical distribution from our reference dataset (PAD^{TLS}) and

659   the plotted values of rate of pulse reduction profiles led us to propose a threshold of the rate of

660   pulse reduction from which the estimation of the distribution of vegetative material is no longer

661   possible. This threshold is variable and related to the density of the canopy cover, which remains

662   plot-specific. We noticed that Nh^{ALS} values between the height with a rate of pulse reduction

663   above ~80-90% and the ground do not provide reliable estimates of vegetation density. A similar

664   principle, reversed vertically, applies to TLS datasets where PAD^{TLS} between the height with a

665   rate of pulse reduction above ~35-40% and the top of the canopy. The slope of the rate of pulse

666   reduction curve, which follows a sigmoid function, depends on the laser scanning configuration

667   as well as the density of the upper canopy. Currently we suggest an approximate threshold for

668   the rate of pulse reduction. The ability to define a more specific threshold may be tied to

669   parameters of this sigma curve as a discriminating indicator of the overall signal occlusion and

670   defining the vertical area where vegetation density can be estimated.

671

672   ALS_{FW} and ALS_D data come from the same signal, however, further processing steps before

673   obtaining the final product make them different. Using the complete (i.e., ALS_{FW}) or the

674   discretized (i.e., ALS_D) signal in the detection of the top of the canopy is not significantly

675   different to assess vegetation density. Nonetheless, ALS_{FW} provided a definite advantage to

676   detect vegetation density for intermediate and lower strata than ALS_D. Lower strata are generally

677   occluded due to overstory blocking incoming laser pulses. Consequently, Nh^{ALSD} vertical

678   profiles do not show much features in the lower strata, except in some cases where signal

679   occlusion caused by overstory is low (e.g., very sparse canopy cover). Nevertheless, when using

680   PAD^{TLS} as reference, Nh^{ALS} (i.e., Nh^{ALSFW} and Nh^{ALSD}) vertical profiles correlations are

681   considered as significant, albeit Nh^{ALSFW} is more correlated. Although curve correlation is more

682   accurate, and the number of hits much larger at the lower strata with ALS_{FW}, our results

683   confirmed that understory vegetation was captured by ALS_D, albeit to a lesser extent and in plots

684   with a high rate of pulse reduction (i.e., ~85%). Other studies have also found difficulties

685   associated with ALS_D to detect the internal forest structure (Chasmer et al., 2006; Hilker et al.,

686   2010; Hilker et al., 2012). The higher potential of ALS_{FW} when compared with ALS_D to detect

687   and determine understory vegetation density classes was also found in several studies (Hancock

688   et al., 2017; Crespo-Peremarch et al., 2018b; Torralba et al., 2018). Our results confirm the

689   potential of both ALS configurations to detect non-occluded strata (i.e., top of the canopy) and

690   demonstrated the increased capability of ALS_{FW} to detect strata with signal occlusion (i.e.,

691   intermediate and lower strata). Although ALS_D may be used to estimate understory vegetation at

692   a plot-level, the signal is generally weak in dense canopies and hence limits the estimation of

693   density in the lower strata at such fine spatial scales.

694

695   Vertical profiles with Nh^{ALSFW} display a systematic artefact near the ground in the form of an

696   exponential increment, even if understory vegetation is absent. This increment depends mainly

697   on two factors: the large number of hits from the ground and the hits from the understory

698   vegetation. The histogram of hits from the ground usually follows a Gaussian curve for which

699   the upper side can be merged by the hit from understory, if present. When understory is present,

700   generally variation of the Nh^{ALSFW} values relates to the understory vegetation density classes,

701   whereas Nh^{ALSD} values are not responsive, except for open canopies with a rate of pulse

702 reduction below ~50%. Regardless, the number of hits from the ground dominates to the point of

703 masking the understory signal in most situations. Hence, although Nh^{ALSFW} vertical profiles

704 increase exponentially as they approach the ground for all the understory vegetation scenarios,

705 variation of Nh^{ALSFW} increment can be used to identify and determine understory vegetation

706 density classes.

707

708 We demonstrated the Gini index to be a useful and accurate indicator to determine understory

709 vegetation density classes from either Nh^{ALS} vertical profiles. Our results demonstrated that

710 understory vegetation density classes can be identified and further grouped by processing the

711 ALS data in both dense and porous forests. Despite strong signal at lower heights in the forest,

712 ALS and especially ALS_{FW}, the Gini index identifies understory densities. Additionally, Gini

713 index thresholds established for understory vegetation densities coincide for both sites: Boreal

714 and Mediterranean. Thus, the understory vegetation density classes are represented by the

715 following Gini value ranges from Nh^{ALSFW}: below a value of ~85% for dense understory

716 vegetation density, between ~85% and ~90% for sparse, and above ~90% for absent.

717 Fortunately, and contrary to ALS_D, misclassification from ALS_{FW} is not occurring between

718 sparse and other understory vegetation density classes. In a related study, Valbuena et al. (2012)

719 discriminated forest structural types by using an application of the Lorenz curve and the Gini

720 index based on the basal area and the number of trees. Apart from a Gini index of 0% and 100%

721 representing the complete equality and inequality, respectively, they also found that a value of

722 50% was relevant. This value represents a uniform distribution of the basal area of the trees.

723 However, with our datasets, Gini index values from Nh^{ALSFW} were all above 56%, since the

724 Lorenz curves start increasing below the height considered as upper limit of the lower strata (i.e.,

725 4 m), and therefore Gini index values are higher. Other indicators such as L-Skewness (Valbuena

726 et al., 2017) and Shannon Index (Almeida et al., 2019) are complementary to Gini index. L-

727 skewness allows for quantifying the asymmetry of the Lorenz curve. This facilitates estimating

728 mean height and absence of understory vegetation. Additionally, the Shannon Index represents

729 the diversity of the dataset using a variable as reference (e.g., species). Therefore, it would be

730 feasible to use height thresholds as a variable to determine understory vegetation density classes.

731 Nonetheless, when signal occlusion caused by overstory is important, the ability to use the

732 Shannon or Gini indices is strongly compromised. It is therefore critical to estimate the level of

733 signal occlusion by means of the rate of pulse reduction prior to carry out the analysis.

734

735 We proposed a simple way to identify the understory vegetation layer and exclude the overstory.

736 The procedures most frequently adopted in the literature apply a threshold at 2 m height

737 assuming that it covers the understory vegetation. This procedure is non-discriminant, not plot-

738 specific, and therefore it may exclude shrubs or include lower crowns. Instead, we propose

739 considering the vertical distribution of gaps in the density profiles to identify a local minimum

740 separating overstory from understory vegetation. This results in different height values

741 delimiting understory vegetation from overstory, which for our dataset varied between 0.525 and

742 3.975 m. The accuracy of this procedure depends on vegetation homogeneity. This vertical gap

743 assessment was done at a plot-level, but it can also be applied at a finer scale (e.g., at voxel-

744 column) if a minimum hit density is reached for all heights to avoid false gaps. The procedure we

745 proposed is plot-specific and allows for an automatic height division of overstory and understory

746 vegetation layers.

747

748 Some limitations in the application of the developed methodological procedure are noteworthy.

749 Currently, PAD estimates are limited to being derived from TLS data, as the estimation of PAD

750 from ALS configurations is currently not possible. The unbiased estimation of PAD from the

751 mathematical framework proposed by Pimont et al. (2018) decreases significantly the influence

752 of signal occlusion for a reliable representation of vertical profiles. Therefore, it is a useful

753 reference to represent distribution of vertical structure. PAD estimation from all the

754 configurations would have allowed for a comparison in the detection of the vertical distribution

755 profiles. Unfortunately, no methods were currently available to estimate PAD from multiple

756 returns ALS data. Nevertheless, the number of hits in the ALS data in the non occluded areas can

757 be used as a unitless indicator (i.e., coefficient of correlation) comparable with PAD^{TLS}.

758 Furthermore, we note that the Gini index was successful in determining understory vegetation

759 density classes from both airborne and terrestrial laser scanning data, but can not be implemented

760 with emerging full-waveform spaceborne laser scanning data such as GEDI (Global Ecosystem

761 Dynamics Investigation) (Dubayah et al., 2020). GEDI emits four laser beams with a large

762 footprint (~19-25 m) that do not overlap. The method proposed in this study assumes that many

763 laser beams cross a same voxel, and then the number of hits is used as a driving variable to

764 calculate the Gini index. Nevertheless, other metrics based on return amplitude (Crespo-

765 Peremarch and Ruiz, 2020) may be more suited to characterize understory vegetation on large

766 areas with GEDI.

767

768 Knowing the limitations of laser scanning configurations is fundamental to use lidar point clouds

769 for the estimation of forest canopy structure. The most severe limitation is caused by signal

770 occlusion by vegetative elements, which can be quantified with the rate of pulse reduction.

771   Despite high level of signal occlusion in the lower strata for ALS configurations, the proposed

772   method allows estimating presence and density of understory vegetation in both dense and

773   porous canopies of Boreal and Mediterranean forests through the Gini index applied to ALS_{FW}

774   data. This new indicator becomes one of the few options to characterize understory vegetation

775   for ALS configurations, which has many implications for forest ecology and wildfire mitigation.

776

777   5. Conclusions

778   This study assessed the limitations and potentials of airborne and terrestrial laser scanning

779   configurations to estimate the vertical forest structure. We conclude that understory vegetation

780   density classes can successfully be determined more accurately with ALS_{FW} than with ALS_D.

781   More specifically, three key points stand out from our study. Firstly, the rate of pulse reduction

782   profiles was demonstrated to be a good indicator to quantify signal occlusion along the vertical

783   profile. This information can be used to determine the reliability of vegetation density estimates

784   from different laser scanning configurations for specific vertical strata. Secondly, both ALS

785   configurations (discrete and full waveform) showed their capability to detect understory

786   vegetation, albeit significantly more accurately with ALS_{FW} due to the greater number of hits

787   registered in lower strata. The considerably lower number of hits registered from ALS_D in the

788   lower strata suggests that a forest plot would be the finest spatial scale (i.e. minimal mapping

789   unit) for which understory vegetation can be successfully detected, and hence, our methods could

790   be applied to. Finer scales would inevitably lack sufficient registered hits in understory

791   vegetation for accurate understory characterization. Finally, and thirdly, we demonstrated the use

792   of the Gini index as a way to determine understory vegetation density classes from both ALS

793   configurations, again, more accurately with ALS_{FW}. Understory vegetation density classes

794 (absent, sparse, moderate and dense) were defined through thresholds applied to the index for

795 both ALS$_{FW}$ and ALS$_D$. Computing the rate of pulse reduction and Gini index characterized the

796 vertical structure and understory vegetation of these structurally differing forests. The

797 applications for which this contribution may be relevant are several, such as characterizing

798 wildlife habitats, assessing timber productivity and improving silvicultural decision-making in

799 support of wildfire mitigation. Further research is needed to better understand the relationships

800 between estimates of PAD and vertical profiles of number of hits for ALS configurations,

801 vertical profiles of rate of pulse reduction and classification of forest types, and the use of the

802 Gini indicator to estimate presence and density of understory vegetation.
