11 **Abstract**

12 Notwithstanding the importance of eggplant in global horticulture, doubled haploid production in  
13 this species is still far from being efficient. Although acknowledged to have a role in the efficiency  
14 of androgenesis induction, factors such as the growth conditions of donor plant or the *in vitro*  
15 culture environment have not been deeply explored or not explored at all in eggplant, which leaves  
16 room for further improvement. In this work, we investigated the effects of different *in vivo* and *in*  
17 *vitro* parameters on the androgenic performance of different eggplant genotypes, including two  
18 hybrids and a DH line. The *in vivo* parameters included the exposure of donor plants to different  
19 temperature and light conditions and to increased levels of boron. The *in vitro* parameters included  
20 the use of different concentrations of NLN medium components, sucrose and growth regulators, and  
21 the suspension of microspores at different densities. Our results showed that whereas greenhouse  
22 temperature variations or boron application did not to have a positive influence, greenhouse lighting  
23 influenced their viability, thereby conditioning the embryogenic response. Changes in different  
24 sucrose, salts and hormone levels had different effects in the genotypes studied, which correlated  
25 with their genetic constitution. Finally, we determined the best microspore density, different from  
26 that previously proposed. Our work shed light on the role of different factors involved in eggplant  
27 microspore cultures, some of them not yet studied, contributing to make microspore culture a more  
28 efficient tool in eggplant breeding.

## 33 **Introduction**

34

35 In microspore embryogenesis, microspores are switched from microsporogenesis towards an  
36 alternative *in vitro* pathway where they develop as haploid or doubled haploid (DH) individuals.  
37 After specific *in vitro* stress treatments, some microspores are insensitive to it and follow a  
38 gametophytic-like developmental program (Satpute et al. 2005), but other microspores are  
39 successfully induced to divide sporophytically, becoming haploid or DH embryos. DH technology  
40 is a convenient tool in plant breeding, since it produces fully homozygous plants (pure lines) in a  
41 reduced period of time and with fewer resources. It is also useful for fundamental cell and  
42 molecular biology research, as well as for plant genetics (Abdollahi et al. 2009; Bueno et al. 2003;  
43 Jouannic et al. 2001). Compared to other DH technologies, microspore embryogenesis has the  
44 advantage of the thousands of microspores, potentially embryogenic, contained in a single anther.  
45 However, a still limited knowledge of the factors involved in the induction of this experimental  
46 process precludes a wider use of this technique. The low embryogenic response of many crops still  
47 precludes the massive use of DH technology, which can only be successfully exploited in few high  
48 responding species and genotypes. Among the different factors involved in the embryogenic  
49 response, the genotype is very well known and perhaps the most important one (Dunwell 2010;  
50 Seguí-Simarro and Nuez 2008). Although yet poorly studied, culture conditions of the plants used  
51 as donors of microspores have also been proposed as having an important role in the eventual  
52 response of microspores to embryogenesis (Dunwell 1976; Dunwell 2010). During anther  
53 development, the developmental window within which microspores can be deviated towards  
54 embryogenesis is also an important parameter. For most species, this window has been established  
55 around the first pollen mitosis (Seguí-Simarro 2010). Other factors as the type and duration of the  
56 stress-based inductive treatment, the composition of the culture medium and the density at which  
57 microspores are plated are also parameters to be studied and adjusted in order to optimize this  
58 process (Seguí-Simarro et al. 2011).

59 There are different technical alternatives to generate DHs. Among them, microspore culture is the  
60 method of choice in the species where possible, since it is the method where conditions are most  
61 controlled, thus providing the highest efficiency. In eggplant, however, the most widely used  
62 method is still anther culture (Salas et al. 2011; Salas et al. 2012). Microspore culture in eggplant  
63 has still a short history (reviewed in Seguí-Simarro 2016). Miyoshi (1996) was the first to develop a  
64 well-documented and working protocol of isolated eggplant microspore culture to induce  
65 embryogenesis, produce callus and regenerate DHs. He established the basis of the conditions for  
66 induction and the composition of the culture medium used in further studies. Since then, a number

67 of works have reported on the evaluation of different modifications of the medium to try to improve  
68 the efficiency of the technique and to promote progression of the microspore-derived embryo. For  
69 example, the addition of polyethylene glycol was proposed to improve the rate of callus induction  
70 and its proliferation (Corral-Martínez and Seguí-Simarro 2012). The addition of epibrassinolide was  
71 proposed to improve callus induction, although callus proliferation was negatively affected (Corral-  
72 Martínez and Seguí-Simarro 2014). The use of abscisic acid was assessed in order to prevent the  
73 undifferentiated callus growth observed soon after the formation of globular embryos. However,  
74 abscisic acid was not able to completely avoid embryo disorganization (Corral-Martínez and Seguí-  
75 Simarro 2014). Gum arabic, a mix of arabinogalactans and arabinogalactan proteins, was the only  
76 compound able to promote embryo development beyond the globular stage, but the MDEs formed  
77 presented an aberrant morphology, being defective in shoot apices (Corral-Martínez and Seguí-  
78 Simarro 2014). In general, the efforts to improve this technique focused on the *in vitro* environment,  
79 and while there are still *in vitro* conditions to refine, to date not much attention has been devoted to  
80 greenhouse/growth chamber environments to which donor plants are exposed, and to their  
81 consequences on the androgenic response.

82 As seen, the efforts to improve this technique are still limited, and there is still a wide room for  
83 improvement in order to understand what factors influence the androgenic response in eggplant, and  
84 how to modulate them. In this work we aimed to explore some of these factors in several eggplant  
85 genotypes through isolated microspore culture. We focused on some factors relative to donor plant  
86 conditions, including the effects that greenhouse temperature and light have in the *in vivo*  
87 development of microspores within the anthers of donor plants, and how this affects their further *in*  
88 *vitro* embryogenic response. We also studied the possible effect that foliar applications of boron  
89 might have on microspore/pollen viability. Indeed, boron is essential for normal development of  
90 reproductive organs, and increased boron levels were found to increase tube growth and  
91 germination in areca (Liu et al. 2013), and pollen quality and viability in other solanaceous crops  
92 (Peñaloza and Toloza 2018). The response to alterations in several parameters of the *in vitro* culture  
93 environment such as microspore density and sucrose, salts and hormone levels was also studied.  
94 Together, our results may be useful to make isolated microspore culture a more efficient tool in  
95 eggplant breeding.

96

## 97 **Materials and methods**

98

### 99 *Plant material*

100 We used as donor plants 2 eggplant F1 hybrids and a DH line. In this work, we identified the  
101 hybrids as E1 and E2, since they were proprietary material protected under confidentiality  
102 agreements. The DH36 line is a DH line developed by us (Rivas-Sendra et al. 2017b) from cv.  
103 ‘Bandera’ a commercial hybrid from Seminis. Seeds of all materials were germinated in growth  
104 chambers in plastic dishes and transferred to seedling trays with commercial growing substrate and  
105 kept at 20°C with a photoperiod of 16/8 and light intensity of 200  $\mu\text{mol m}^{-2} \text{s}^{-1}$ . After one month,  
106 seedlings were transplanted to 30 cm pots in a pollinator-free greenhouse at the COMAV  
107 greenhouses (campus of Universitat Politècnica de València, Spain, GPS coordinates: 39°29’01” N,  
108 0°20’27” W). Pots were filled with coco peat and irrigated and fertilized using a drip irrigation  
109 system. Plants were grown under natural light in air-conditioned greenhouses where temperature  
110 was initially set up to 22°C but subjected to seasonal fluctuations (22±3°C). Plants were pruned and  
111 trained with vertical strings.

112

#### 113 *Application of boron to donor plants and evaluation of microspore viability*

114 The experiment consisted of a randomized complete block design with three concentrations of foliar  
115 fertilizer of soluble concentrated 15% (w/v) boron (Labifol). Five replicates of each treatment were  
116 done, totaling 20 pots (one plant per pot). Three concentrations were made, equivalent to 100, 150,  
117 and 200 mg/L. Boron was applied to the leaves on a weekly basis during the treatment (three  
118 weeks), at a dose of 0.16 L per plant and application. Control plants were applied the same volume  
119 of water. To evaluate microspore viability after boron application, anthers from buds containing a  
120 majority of vacuolated microspores and young pollen grains (the suitable stages for microspore  
121 embryogenesis) were sliced and washed to extract microspores/pollen. For fluorescein diacetate  
122 (FDA) staining (Rivas-Sendra et al. 2017a; Rivas-Sendra et al. 2019), two drops of  
123 microspore/pollen suspension were placed on a slide with 5  $\mu\text{l}$  of 1/100 FDA solution, incubated for  
124 10 min and observed under a epifluorescence microscope. Data collected from five different  
125 microscope fields were arcsine transformed and subjected to analysis of variance (ANOVA). Post-  
126 hoc comparisons with Duncan’s multiple range test were used to find out differences between  
127 groups ( $p \leq 0.05$ ).

128

#### 129 *Isolated microspore culture*

130 Before the *in vitro* culture of microspores, for each genotype we determined the anther length  
131 containing the appropriate microspore/pollen developmental stage. Microspores were *in vitro*  
132 cultured in liquid medium as described in Corral-Martínez and Seguí-Simarro, (2014). Briefly,

133 anthers at the right stage were dissected, surface disinfected and crushed to release the microspores.  
134 Microspores were isolated through 41  $\mu\text{m}$  filters, centrifuged three times, suspended in distilled  
135 water, inoculated in plates and incubated at 35°C in darkness during three days. Then, microspores  
136 were recovered from cultures, resuspended in NLN medium (Nitsch and Nitsch, 1967)  
137 supplemented with 2% sucrose, 0.5 mg/l of 1-naphthaleneacetic acid (NAA) and 0.5 mg/l of 6-  
138 benzylaminopurine (BAP), and cultured continuously at 25°C in darkness.

139

140 *Correlations between temperature and light conditions of donor plants and microspore viability,*  
141 *divisions and callus production*

142 We performed different microspore cultures using several randomly chosen plants from the E1 and  
143 E2 genotypes as donors of microspores. In total, 10 cultures of E1 and 6 cultures of E2 were  
144 performed, with a minimum of 9 replicates (culture dishes) per culture. In parallel, we recorded the  
145 temperature and light of the greenhouse module where these plants were confined, using  
146 thermometers and luxometers installed in the greenhouse and connected to a computer to transmit  
147 automatically the values every 20 minutes during the entire duration of the experiment (from  
148 January to September). We defined light as the illuminance directly received by plants and therefore  
149 measured inside the greenhouse, and expressed in kiloluxes (klx) in both cases. For each of the  
150 cultures analyzed, we calculated the average temperature and light corresponding to the day when  
151 flower buds were excised (from 00:00 up to the moment of excision, approximately at 10:00 hours),  
152 the whole day before, and two and seven days before. For each culture, we calculated the viability  
153 of microspores at the moment of isolation (day 0) and just after the 3-day heat shock (day 3). For  
154 this, we stained them with fluorescein diacetate and observed and counted as described above to  
155 calculate the percentage of viable microspores. The percentage of dividing microspores  
156 (microspores with two or more nuclei divided by the total number of microspores) was calculated  
157 by observing samples of microspore cultures at day 7, stained with DAPI as described in Rivas-  
158 Sendra et al. (2019), under the inverted epifluorescence microscope. Paired comparisons to study  
159 possible correlations between them were performed calculating their coefficient of determination  
160 ( $R^2$ ), defined as the square of the Pearson coefficient of correlation.

161

162 *Medium modifications*

163 Different variants were applied to the culture medium. First, changes in concentrations of hormones  
164 (100% vs 20%), NLN salts and vitamins (1x vs 2x) and sucrose (2% vs 4%, 5% and 10%) were  
165 assayed. Microspore density was initially adjusted to  $5 \times 10^5$  microspores/mL for all the experiments,  
166 unless otherwise specified. In the experiment of different plating densities, we evaluated the

167 response of cultures with the following plating densities:  $5 \times 10^4$ ,  $1 \times 10^5$ ,  $2 \times 10^5$ ,  $3 \times 10^5$ ,  $4 \times 10^5$ ,  $5 \times 10^5$ ,  
168  $1 \times 10^6$  and  $2 \times 10^6$  microspores/mL.  $5 \times 10^5$  microspores/mL is the density considered as standard in  
169 previous works (Corral-Martínez and Seguí-Simarro 2014; Miyoshi 1996; Rivas-Sendra et al.  
170 2015), so we used it as control. For all cases, we adjusted the different densities using a Neubauer  
171 improved chamber according to Camacho-Fernández et al. (2018). To assess the influence of  
172 different culture conditions, callus-like structures were observed and counted under a  
173 stereomicroscope after 30 days of culture. On the one hand, we counted the total of calli present in a  
174 plate, in order to estimate the efficiency of induction. On the other hand, we counted the number of  
175 calli with a size exceeding 1 mm, in order to estimate their growth. We expressed these two  
176 parameters per unit of volume (mL) of culture medium, except for the experiment of different  
177 plating densities, where the androgenic response was expressed as the number of calli per  $5 \times 10^5$   
178 microspores in order to normalize the effect of the different densities used. For each medium  
179 modification studied, three different repeats were performed, with at least three replicates (plates)  
180 per condition. We performed a test of analysis of variance with a  $p \leq 0.05$  to identify putative  
181 significant differences. Subsequently, we performed a Fisher's least significant difference (LSD)  
182 test for multiple comparisons with the aim of combining the treatment effects in homogeneity  
183 groups. Differences were considered as significant when the p-value exceeded 0.05.

184

## 185 **Results**

186

### 187 **Effect of temperature and light conditions of donor plants**

188 For this experiment, we used plants of the E1 and E2 hybrids. Due to seasonal fluctuations of  
189 temperature, plants were exposed to temperatures of  $\sim 20^\circ\text{C}$  in winter,  $\sim 23^\circ\text{C}$  in spring and  $\sim 26^\circ\text{C}$  in  
190 summer (Figure 1A). Anyway, the range of temperature fluctuation ( $6^\circ\text{C}$ ) was low. The absence of  
191 records during two weeks in June was due to a temporary failure in the recording system. Light  
192 measured within greenhouses was variable, ranging from 3 to 10 klx, depending on the season. As  
193 typical in Mediterranean countries, the weekly average illuminance was minimal in winter, and then  
194 increased progressively until June (summer solstice), and then decreased again during autumn  
195 months. In August-September, a drastic decrease in average illuminance was due to unstable,  
196 cloudy and rainy weather, typical from the Valencian region at the end of summer - beginning of  
197 autumn. The viability measures made for E1 and E2 microspores (Figures 1B and 1C, respectively)  
198 ranged from 25% to 55% at the moment of isolation for *in vitro* culture and from 10% to 30% after  
199 the 3-day heat shock treatment. This treatment was the most likely cause of the viability drop.

200 For both genotypes, microspore viabilities at day 0 and day 3 were clearly proportional, with  
201 maxima during January-May and minima from June to July, the months where average temperature  
202 increased  $\sim 3^{\circ}\text{C}$  and illuminance was the highest. In August and September, however, viabilities  
203 increased up to levels comparable to spring months. This coincided with a drop of illuminance due  
204 to cloudy weather, as explained above, whereas temperatures remained unchanged. Together, these  
205 facts strongly suggested a relationship between the drop in viability of freshly isolated microspores  
206 and high illuminance conditions.

207 To gain a deeper insight on this, for each microspore culture we calculated the average light and  
208 temperature to which E1 and E2 donor plants were exposed during the day when flower buds were  
209 excised (up to the moment of excision, approximately at 10:00 a.m.), and one, two and seven days  
210 before. These data were crossed with viability of cultures at days 0 (at the moment of microspore  
211 isolation) and 3 (just after heat shock), number of microspore divisions counted at day seven, and  
212 number of calli per dish at day 30. As seen in Tables 1 and 2, the  $R^2$  coefficients revealed that in  
213 general, there was no correlation between the parameters studied, or the correlation found was  
214 weak. However, there were some cases where  $R^2$  revealed strong correlations ( $R^2 \geq 0.90$ ) between  
215 the two variables studied (bold  $R^2$  coefficients in Tables 1, 2). This was the case of light during one  
216 and two days before bud excision. We found that for both E1 and E2 genotypes, the luminous flux  
217 received by donor plants during the day before and even during the two days before bud excision  
218 explained more than 90% of the variability found for the viability levels observed just after  
219 microspore isolation. However,  $R^2$  coefficients for the correlations between illuminance at the day  
220 of bud excision (from 00:00 h up to the very moment of excision), and 7 days before excision, were  
221 very low, near zero, indicating the existence of a null or very low correlation. In other words,  
222 microspore viability appeared negatively influenced by the amount of light to which donor plants  
223 were exposed during the two days previous to bud excision, but not by the immediate light exposure  
224 nor by long-term (7 days) exposure.

225 In addition to viability at day 0 (microspore isolation), viability at day 3 (just after heat shock  
226 exposure) was also negatively affected in the E2 genotype, as revealed by the high  $R^2$  coefficients  
227 observed (bolds in Table 2). In the E2 genotype, viabilities at days 0 and 3 were also influenced by  
228 temperature, and the number of calli at day 30 was influenced by both temperature and illuminance  
229 conditions during the last 7 days before excision. On the contrary, the corresponding  $R^2$  values in  
230 E1 revealed a very low correlation in these cases. Together, these results suggested a strong  
231 correlation between illuminance and *in vivo* microspore viability in both genotypes. However,  
232 correlations between illuminance and day-3 viability, between temperature and viability (at both  
233 days), and between temperature/illuminance and number of calli were more genotype-dependent.

234

### 235 **Effect of foliar application of boron**

236 We evaluated the potential effect of the addition of boron to donor plants in microspore viability by  
237 FDA staining (Figures 2A, B). As seen in Figure 2C, no boron application was found to give rise to  
238 viability percentages significantly higher than controls without boron addition. Indeed, the highest  
239 concentration clearly produced a detrimental effect in microspore/pollen viability. This neutral or  
240 negative effect appeared specific for microspore/pollen viability, or at least not extended to the  
241 general development of the plant, since all donor plants presented a good, healthy aspect in general,  
242 and also in their different parts (leaves, stems, branches, flowers, etc.) at all the boron  
243 concentrations used (Figure 2D). In conclusion, boron did not to have a positive effect on viability  
244 of eggplant microspores/pollen, at least at the suitable stage for microspore embryogenesis.

245

### 246 **Response to changes in growth regulators, salts, vitamins and sucrose concentrations**

247 Next, we performed microspore cultures to evaluate the effect of different *in vitro* factors. Once  
248 vacuolated microspores and young pollen grains were isolated and *in vitro* inoculated (Figure 3A).  
249 the first divisions could be observed in some microspores after some days (arrowheads in Figure  
250 3B), whereas others remain arrested. Later on, microspore-derived calli (Figure 3C) were formed by  
251 undifferentiated proliferation of the microspore-derived embryos initially formed (Corral-Martínez  
252 and Seguí-Simarro 2012). Upon transference to solid medium, shoots regenerated from their surface  
253 (Figure 3D). Shoots were then excised and transferred to rooting medium (Figure 3E), where full  
254 plantlets regenerated *in vitro* (Figure 3F) three-four months after the onset of microspore culture,  
255 being ready for ploidy analysis by flow cytometry. Individuals found to have a 2C DNA content  
256 (the same than donor plants and twice the content of haploid individuals) were considered as DHs  
257 with no need for confirmation with molecular markers. In microspore cultures, only isolated  
258 microspores/pollen are present in culture dishes. Thus, all embryos, calli and plants obtained from  
259 these cultures must necessarily come from haploid microspores/pollen, as confirmed by our  
260 previous studies with microsatellite molecular markers in plants regenerated from microspore  
261 cultures (Corral-Martínez and Seguí-Simarro 2012). Confirmed DH individuals were then ready for  
262 *ex vitro* transference and acclimation.

263 The first assays of embryogenesis induction in microspores of the E1 and E2 genotypes, performed  
264 in parallel to the experiments described in the previous section, revealed that microspores of these  
265 genotypes had a low ability to undergo cell division and proliferation, yielding ~15-30 calli/mL  
266 under standard culture conditions. For this reason, we decided to include in the next experiments the  
267 DH36 eggplant DH line which, under the same conditions, produces hundreds of calli. As a first

268 approach to evaluate the effect of salts, vitamins, sucrose and growth regulators, we first increased  
269 the concentration of the NLN medium (including their salts, their vitamins and the sucrose added)  
270 and reduced the concentration of growth regulators. The increase in NLN medium and sucrose  
271 concentration was found to have no positive effect in E1 microspore cultures neither on the total  
272 production of calli (Figure 4A) nor on the number of calli larger than 1 mm (Figure 4B) with  
273 respect to controls. A reduction in the concentration of growth regulators to 20% increased 3.4-fold  
274 the total number of calli and 3.7-fold the number of calli larger than 1 mm. Combining 2x NLN, 4%  
275 sucrose and 20% growth regulators was found positive for the number of calli obtained (a 4.6-fold  
276 increase in the total number of calli, but not for the number of calli larger than 1 mm (Figure 4B)).  
277 With respect to the E2 genotype, the effect of changing the concentration of growth regulators was  
278 more reduced than for E1. However, combining 2x NLN, 4% sucrose and 20% growth regulators  
279 was found strongly positive in comparison with the control condition (Figure 4C), as for E1. The  
280 number of calli larger than 1 mm showed no significant changes (Figure 4D). Therefore, increases  
281 in the concentration of NLN medium and sucrose together with reduced levels of growth regulators,  
282 were found positive to increase the efficiency of embryogenesis induction in the F1 hybrids.

283 The production of callus in DH36 control cultures was found much higher than in the hybrid  
284 genotypes (11.4 and 10.2 times superior to E1 and E2, respectively). DH36 reacted differently to  
285 medium modifications in qualitative terms too (Figures 4E and 4F). Increased concentrations of  
286 NLN medium and sucrose increased 2.1 times the total number of calli, but affected negatively the  
287 number of calli larger than 1 mm. A reduced concentration of growth regulators showed no positive  
288 effect on the total number of calli, but the number of calli larger than 1 mm was 1.4 times higher.  
289 The combination of 2x NLN, 4% sucrose and 20% growth regulators was negative for the number  
290 of call larger than 1 mm. These results indicated that the hybrid genotypes showed a similar  
291 response to medium modifications, in general terms, whereas the response of the DH line was  
292 remarkably different.

293 Our next goal was to determine to what extent the observed effects were due to the changes in  
294 sucrose, in NLN medium or in both. The highest concentration of sucrose (5%) improved the total  
295 number of calli in E1 and E2 (5.4 and 66.6 times more, respectively), but not in DH36 (Figure 5A).  
296 There were no changes in the number of calli larger than 1 mm for E1 and E2, but this parameter  
297 was reduced in DH36 (Figure 5B). We tested even higher concentrations of sucrose (10%), but we  
298 found that they inhibited induction in all cases (data not shown). Therefore, an increase of sucrose  
299 to 5% clearly benefited the embryogenic response of hybrids, but not of DH36. This indicated that  
300 the positive effects previously observed in DH36 would come from the increase in concentration of  
301 NLN medium. To confirm it, we evaluated in DH36 the effect of combining 2x NLN concentrations

302 with 100% and 20% levels of growth regulators. The first combination provided the highest yield in  
303 total callus (Figure 6A), whereas the second provided the highest yield in number of calli larger  
304 than 1 mm (Figure 6B). Again, the response of DH36 to modifications in the composition of the  
305 culture medium was remarkably different from that of E1 and E2 hybrids.

306

### 307 **Response to different plating densities**

308

309 Finally, we tested whether cell density influences microspore induction and growth, as well as  
310 callus production. For this, we worked only with DH36, discarding E1 and E2 due to their low  
311 response to induction. Microspore densities below the standard of  $5 \times 10^5$  microspores/mL were  
312 positive in terms of number of total calli and the number of calli larger than 1 mm (Figure 7A). At  
313  $2 \times 10^5$  microspores/mL, the number of total calli counted was the highest (1.4 times more than the  
314 control), and increased the number of calli larger than 1 mm as well. However, the highest augment  
315 (1.6 times more than control) was observed for  $3 \times 10^5$  microspores/mL (Figure 7B). A density of  
316  $1 \times 10^5$  microspores/mL notably diminished the total number of calli (7.7 times less than control). A  
317 density of  $5 \times 10^4$  microspores/mL was insufficient to produce any calli in any culture plate (Figure  
318 7A). On the contrary, the response of densities higher than the standard, like  $1 \times 10^6$  microspores/mL  
319 was not significantly different from control. At  $2 \times 10^6$  microspores/mL, there was not response since  
320 bacterial contamination was systematically observed in all culture plates (data not shown).  
321 Altogether, eggplant microspores showed a different response when cultured at different densities.  
322 Typically, the response was higher at densities below the  $5 \times 10^5$  standard, but within a range, since  
323 below  $5 \times 10^4$ , the response is inhibited.

324

### 325 **Discussion**

326

#### 327 **As opposed to boron addition, light conditions of donor plants influence microspore viability**

328

329 The relationship between microspore embryogenesis and growth conditions of donor plants has  
330 been commonly acknowledged. However, not much work has been focused on the determination of  
331 their best conditions. For example, despite that the levels of certain elements is known to affect the  
332 general status of the plant, the only element whose relationship with embryogenic competence of  
333 microspores has been studied is nitrogen (Tsay 1981; 1982). The exogenous application of boron to  
334 leaves is known to have a specific effect in pollen, increasing its quality and viability, both *in vivo*  
335 and *in vitro*, in other solanaceae such as pepper (Peñaloza and Toloza 2018). Since more viable

336 microspores/pollen imply more embryos potentially produced and therefore increased efficiencies,  
337 it seemed reasonable to test whether this could have a similar effect in a related species such as  
338 eggplant. Unfortunately, this was not the case, at least in our eggplant genotypes. No positive effect  
339 in microspore/pollen viability was observed, being even negative at the highest concentration. Thus,  
340 we must discard this treatment to improve the efficiency of the process.

341 Seasonal variations affect the androgenic response of plants. Indeed, photoperiod, light intensity  
342 and temperature are factors proposed to be involved (reviewed in Dunwell 2010). In the particular  
343 case of eggplant, the scarce data available are restricted to the summer-autumn transition, where it  
344 was reported that the highest response was found between September and October (Tuberosa et al.  
345 1987). Based on this, it was proposed that, at least for the Mediterranean climate, the most favorable  
346 periods would be spring and autumn (Rotino 1996). Among the different parameters included in  
347 “seasonal variation”, it is known that temperature to which donor plants are exposed may modulate  
348 the androgenic response (Dunwell 1976; Dunwell 2010). It is reasonable to think that when donor  
349 plants are continuously exposed to temperatures close to those used to induce embryogenesis, they  
350 trigger a previous stress response that desensitizes microspores against the subsequent  
351 embryogenesis-inducing heat shock treatment. Far from this stressing range, this relationship is less  
352 clear. We showed that at least for one genotype (E2), viability and number of calli correlated with  
353 temperature and illuminance. However, the lack of uniformity between E1 and E2 makes us think  
354 that at most, this could be a genotype-dependent relationship that cannot be extended beyond  
355 eggplant E2.

356 In our experiments we found that light may affect the response even more than temperature.  
357 Response is affected by reducing the initial viability of isolated microspores. Since less microspores  
358 are alive, less embryos can be induced. We also refined this notion, revealing that the light  
359 immediately received by plants during the few light hours from dawn to the moment of bud  
360 excision did not correlate with viability. Similarly, the light received during the week before  
361 excision did not correlate either. In contrast, the period spanning along two days before bud  
362 excision and microspore isolation appeared critical for microspore viability. Illuminance has been  
363 shown important in some species for proper flower development (Saxena and Johansen 1987) and  
364 even for pollen viability, being this trait genotype-dependent (Dutta et al. 2017). In tobacco,  
365 different light intensities were related to different effects in MDE induction and progression  
366 (Dunwell 1976). Since nothing is known in eggplant about it, we could speculate that flower  
367 development and in particular microspore development in eggplant would also be affected by  
368 changes in illuminance. This way, higher illuminances would somehow preclude a proper  
369 development of eggplant microspores, thus reducing their viability. This, however, must be studied

370 more in depth and experimentally confirmed. The precise mechanism by which changes in  
371 illuminance would affect microspore viability would also be interesting to elucidate.

372 In conclusion, our results indicate that variations in light are related to viability of *in vivo*  
373 microspores, which will obviously have a reflection in the amount of callus produced. These  
374 variations appear differently perceived by donor plants of different genotypes, making them  
375 sensitive to different extents. Therefore, it would be advisable to evaluate, when possible, such  
376 sensitivity before working with a new eggplant material.

377

### 378 **DH36 does not respond to changes in culture medium conditions as hybrid genotypes do**

379

380 The source of carbon for cell metabolism and its concentration in the culture medium is an  
381 important parameter to consider in any *in vitro* culture technique. Different studies have addressed  
382 this issue in different species (reviewed in Seguí-Simarro 2010). In highly responding genotypes,  
383 the medium used to induce embryogenesis typically includes high concentrations of sucrose. This is  
384 the case of *Brassica napus*, where culture medium includes 13% sucrose (Custers 2003), tobacco  
385 with 8.6% sucrose (Touraev et al. 1996a), maize with 5.1% sucrose (Gaillard et al. 1991) or hot  
386 pepper, with 10% sucrose (Kim et al. 2008). In the *in vitro* culture of eggplant anthers, 12% sucrose  
387 is typically used at the initial culture stage (Chambonnet 1988). Instead, the liquid medium used for  
388 microspore culture contains 2% sucrose (Corral-Martínez and Seguí-Simarro 2012; 2014; Miyoshi  
389 1996). This led us to the hypothesis that perhaps, higher levels of sucrose could positively influence  
390 callus production. Our results were not homogeneous though. When we used high sucrose levels  
391 together with 2x NLN and 20% growth regulators, more calli were obtained in E1 and E2, but not in  
392 DH36. In DH36, the best results came from the use of high sucrose together with 2x NLN.  
393 Experiments increasing sucrose only showed a strong positive effect in E1 and E2, but not in DH36.  
394 Therefore, it appears that that increasing the concentration of NLN medium is positive for DH36,  
395 but not for hybrid genotypes. On the contrary, an increase in the concentration of sucrose greatly  
396 influences the response of hybrid genotypes, but not of DH36.

397 As to growth regulators, the pioneering work of Miyoshi (1996) showed the best results with 0.5  
398 mg/l NAA and 0.5 mg/l BAP. More recent works suggested that eggplant microspores are more  
399 sensitive to absolute concentrations of growth regulators than to the relative ratios between them.  
400 Indeed, Corral-Martínez and Seguí-Simarro (2014) reported more calli with the use of reduced  
401 NAA and BAP concentrations. Consistent with this, the present study found that reduced levels  
402 clearly have a strong and positive influence in hybrid genotypes, but not in DH36. This suggests  
403 that the response of DH36 to changes in the composition of the medium is opposite to the response

404 of hybrid genotypes. Apparently, this line reached a peak of performance, difficult to overcome by  
405 modifications of the medium.

406

#### 407 **Lower plating density reduces competence and allows for a higher efficiency**

408

409 Setting up the most suitable plating density is a key parameter for most if not all *in vitro* cell  
410 cultures. In microspore cultures, this parameter may have an effect in the number of calli or  
411 embryos produced, as well as in the quality and velocity of development (Camacho-Fernández et al.  
412 2018; Seguí-Simarro et al. 2011). Indeed, each species has different requirements in terms of  
413 plating densities. Examples of optimal densities are  $1.4 \times 10^6$  in apple (Höfer 2004) ,  $1 \times 10^6$  in barley  
414 (Esteves et al. 2014),  $1 \times 10^5$  in wheat or pepper (Kim et al. 2013; Sinha and Eudes 2015),  $5 \times 10^4$  in  
415 tobacco (Touraev and Heberle-Bors 2003), or  $4 \times 10^4$  microspores/mL in maize and rapeseed  
416 (Aulinger 2002; Robert et al. 2015). To ascertain whether microspore plating density influences the  
417 androgenic response, we evaluated a broad range of densities, finding that lower densities ( $2 \times 10^5$ -  
418  $3 \times 10^5$  microspores/mL) were the best for higher rates of callus production and callus growth. On  
419 the other hand, higher densities had a negative effect. This might be explained by two hypothesis:  
420 (1) an excessive accumulation of potentially toxic and/or inhibitory substances excreted by cells to  
421 the culture medium, or (2) the competition of cells for resources and space. Our experiments  
422 suggested the second option, because in most of them, an inverse correspondence between callus  
423 number and callus growth was found in the three genotypes used, but especially in DH36, where  
424 more calli are formed. Interestingly, the assay with the highest number of calli in DH36 was the use  
425 of 2x NLN medium and 2x sucrose (Figure 4E). Duplicating the availability of nutrients duplicated  
426 the callus yield. Besides, calli are induced structures, already formed, not supposedly affected by  
427 the excretion of putative inductive/inhibitory substances. In other words, when embryogenesis  
428 starts, microspore-derived structures are forced to share and therefore to compete for limited  
429 resources and space, reducing the growth rate.

430 We also demonstrated that there is a minimal threshold of microspore density below which  
431 embryogenesis is not induced. Similar findings were described by Kim et al. (2008) in microspore  
432 cultures of hot pepper. It is known that embryogenic microspores excrete different factors that may  
433 have a positive influence in neighbor microspores, promoting their entry into embryogenesis and/or  
434 growth (Borderies et al. 2004; Paire et al. 2003; Žur et al. 2015). At very low microspore densities,  
435 these factors may become too diluted to have an effect. It was also interesting to note the systematic  
436 appearance of bacterial contamination at very high densities (10x the optimal density proposed  
437 hereby). Most likely, endogenous bacteria typically present in the intercellular spaces of different

438 plant tissues and organs, including anther walls, are responsible for this. These endophytes cannot  
439 be eliminated with the routine surface disinfection of buds or anthers, and may proliferate if the  
440 initial inoculum is high enough. Higher microspore densities would carry higher levels of bacterial  
441 inoculum, A similar phenomenon has been reported in pepper, which makes mandatory the routine  
442 use of antibiotics (Lantos et al. 2012; Parra-Vega and Seguí-Simarro 2013; Supena et al. 2006).

443

#### 444 **Concluding remarks**

445

446 We used for this work two hybrids and a DH line. In our experiments, callus production was always  
447 higher (from 10 to 85x higher) in DH36 than in hybrids. The DH36 line showed also four times  
448 more response than the hybrid used to develop this line (Rivas-Sendra et al. 2017b). Ideally, DH36  
449 may produce up to ~450 calli/mL, which implies a minimum of ~450 initially induced embryos/mL.  
450 This yield is at the levels found in the best responding lines of model species. We also showed that  
451 the response of DH36 was quite difficult to enhance by adding modifications to the medium, since  
452 many of these modifications negatively influenced callus growth, as opposed to their effect in  
453 hybrid genotypes. Thus, the nature of DH36, whose homozygous alleles were selected according to  
454 their high response to induction of embryogenesis, could be approaching the performance of this  
455 line to a maximum level, making it hardly sensitive to minor modifications of the medium. In turn,  
456 we were able to increase the efficiency of 'Bandera', the hybrid line from which DH36 was derived,  
457 by changing medium composition (Corral-Martínez and Seguí-Simarro 2012; 2014).

458 In most of the highly responding model systems, exogenous growth regulators are not needed to  
459 induce embryogenesis. Examples of this are rapeseed (Custers 2003), maize (Gaillard et al. 1991),  
460 tobacco (Touraev et al. 1996a) and wheat (Touraev et al. 1996b). Embryos are induced in these  
461 species using no growth regulators, or using them at very low concentrations. This points to an  
462 endogenous production of growth regulators enough for their requirements. In recalcitrant species,  
463 the scenario is the opposite, it is essential to add exogenous growth regulators to promote cell  
464 division and/or morphogenesis (Seguí-Simarro et al. 2011). The null or negative response of DH36  
465 to changes in the levels of growth regulators would suggest that this line has an endogenous balance  
466 of growth regulators better fitted to embryogenesis induction under the standard concentrations of  
467 growth regulators in the culture medium used. This, in turn, would be an indirect support to the  
468 notion that DH36 is sensitive but less dependent than hybrid genotypes on the addition of  
469 exogenous growth regulators. This is consistent with the fact that DH36 was selected for high  
470 response in a specific culture medium containing a fixed composition in term of growth regulators

471 (0.5 mg/l NAA and 0.5 mg/l BAP). The possibility of selecting lines with different androgenic  
472 response is an additional evidence of the genetic control of this trait.

473 However, the levels of growth regulators may not necessarily be the same at all culture stages.  
474 Indeed, unbalanced growth regulator levels may affect negatively to the progression of embryos,  
475 thereby causing the transformation of globular embryos into calli, the main bottleneck in eggplant  
476 microspore culture (Seguí-Simarro 2016). This would surely be the next step to approach DH36 to  
477 model lines of other species.

635

636

637 **Figure legends**

638

639 **Figure 1.** Effect of greenhouse temperature and light in the viability of *in vivo* microspores. **A**  
640 illustrates the fluctuations of temperature and light in the greenhouse where E1 and E2 donor plants  
641 were grown during the months from January to September. **B, C:** Microspore viabilities for the  
642 different microspore cultures just upon isolation from anthers (day 0) and after the heat shock  
643 inductive treatment (day 3), and microspore divisions after 7 days of culture, for E1 (**B**) and E2 (**C**)  
644 genotypes. Viabilities and divisions are expressed as percentages from the total of microspore  
645 counted  $\pm$  standard deviation.

646

647 **Figure 2.** Application of boron to donor plants. A and B show images of FDA staining of  
648 microspores from control plants (A) and from plants treated with 200 mg/L of boron (B). C:  
649 Percentages of viable microspores for the control and the three boron concentrations applied. Bars  
650 represent standard deviation. Different letters represent statistically significant differences  
651 according to the LSD test with  $p \leq 0.05$ . D: Donor plants after three weeks of treatment with boron:  
652 Bars: 50  $\mu\text{m}$ .

653

654 **Figure 3.** Eggplant microspore cultures. A: Freshly isolated microspores, just after inoculation for  
655 *in vitro* culture. B: Seven-day-old cultures. Note the growth of induced, proliferating microspores  
656 (arrowheads). C: Thirty-day-old cultures, where microspore-derived calli are clearly visible. D:  
657 Calli cultured in solid medium. In some of them, shoots are induced to regenerate. Note that other  
658 calli do not regenerate shoots, and other die. E: Isolated, rooting shoot. F: Fully rooted, entire DH  
659 plant. Bars: A-C: 50  $\mu\text{m}$ . D, E: 1 cm.

660

661 **Figure 4.** Effect of increased concentrations of NLN medium and reduced levels of growth  
662 regulators in E1, E2 and DH36. **A, C** and **E:** Total calli produced at day 30. **B, D** and **F:** Calli larger  
663 than 1 mm produced at day 30. Note the different scale in **E** and **F**. In each chart, the first column  
664 corresponds to control conditions. Bars represent standard deviation. Different letters indicate  
665 statistically significant differences according to the LSD test with  $p \leq 0.05$ . **nt:** not tested.

666

667 **Figure 5.** Effect of increased concentration of sucrose in E1, E2 and DH36. **A:** Total calli produced  
668 at day 30. **B:** Calli larger than 1 mm produced at day 30. For each genotype, the first column  
669 corresponds to control conditions. Bars represent standard deviation. Different letters indicate  
670 statistically significant differences according to the LSD test with  $p \leq 0.05$ .

671

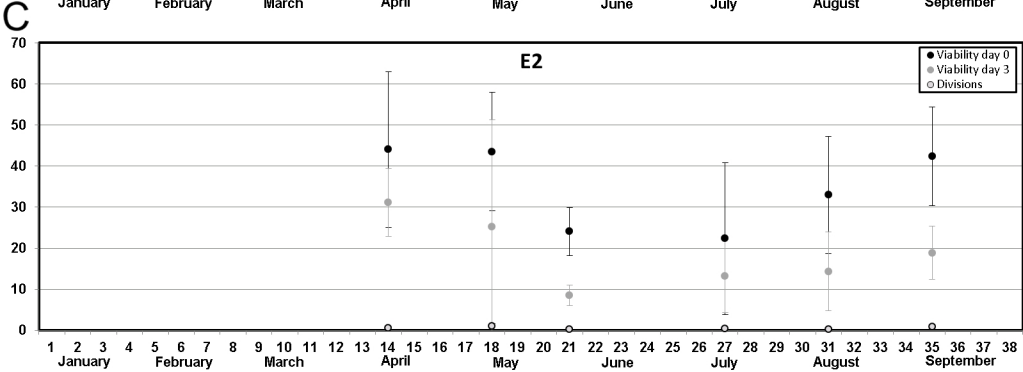

672 **Figure 6.** Effect of increased concentration of NLN medium in DH36. Total calli produced at day  
673 30. **B:** Calli larger than 1 mm produced at day 30. For each genotype, the first column corresponds  
674 to control conditions. Bars represent standard deviation. Different letters indicate statistically  
675 significant differences according to the LSD test with  $p \leq 0.05$ .

676

677 **Figure 7.** Effect of different plating densities in microspore cultures of the DH36 line. Total calli  
678 produced at day 30. **B:** Calli larger than 1 mm produced at day 30. To be able to compare among  
679 densities, efficiency is expressed as calli per  $5 \times 10^5$  plated microspores (calli/ $5 \times 10^5$  msp). Bars  
680 represent standard deviation. Different letters indicate statistically significant differences according  
681 to the LSD test with  $p \leq 0.05$ .
