**Abstract:** The current work focused on the sunlight-driven thermo-photocatalytic reduction of carbon dioxide (CO<sub>2</sub>), the primary greenhouse gas, by ethane (C<sub>2</sub>H<sub>6</sub>), the second most abundant element in shale gas, aiming at the generation of ethanol (EtOH), a renewable fuel. To promote this process, a hybrid catalyst was prepared and properly characterized, comprising of strontium titanate (SrTiO<sub>3</sub>) co-doped with ruthenium oxide (RuO<sub>2</sub>) and nickel oxide (NiO). The photocatalytic activity towards EtOH production was assessed in batch-mode and at gas-phase, under the influence of different conditions: (i) dopant loading; (ii) temperature; (iii) optical radiation wavelength; (iv) consecutive uses; and (v) electron scavenger addition. From the results here obtained, it was found that: (i) the functionalization of the SrTiO<sub>3</sub> with RuO<sub>2</sub> and NiO allows the visible light harvest and narrows the band gap energy (ca. 14–20%); (ii) the selectivity towards EtOH depends on the presence of Ni and irradiation; (iii) the catalyst photoresponse is mainly due to the visible photons; (iv) the photocatalyst loses > 50% efficiency right after the 2nd use; (v) the reaction mechanism is based on the photogenerated electron-hole pair charge separation; and (vi) a maximum yield of 64 μmol EtOH g<sub>cat</sub><sup>-1</sup> was obtained after 45-min (85 μmol EtOH g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup>) of simulated solar irradiation (1000 W m<sup>-2</sup>) at 200 °C, using 0.4 g L<sup>-1</sup> of SrTiO<sub>3</sub>:RuO<sub>2</sub>:NiO (0.8 wt.% Ru) with [CO<sub>2</sub>]:[C<sub>2</sub>H<sub>6</sub>] and [Ru]:[Ni] molar ratios of 1:3 and 1:1, respectively. Notwithstanding, despite its exploratory nature, this study offers an alternative route to solar fuels' synthesis from the underutilized C<sub>2</sub>H<sub>6</sub> and CO<sub>2</sub>.

## 1. Introduction

The global economy has been moving towards an ever-growing consumption of fossil fuels, together with the emission of anthropogenic greenhouse gases, which has led to an energy crisis and global warming. Therefore, the development of promising strategies aiming at the carbon dioxide (CO<sub>2</sub>) chemical conversion into renewable hydrocarbon fuels is urgent. In fact, Intergovernmental Panel on Climate Change (IPCC) has already reported the necessity for new options in the direction of 'negative emissions', even including the carbon dioxide removal (CDR) from the atmosphere targeting the global warming mitigation. Some advances have been made in the field of heterogeneous catalysis for the reduction of CO<sub>2</sub>, the main greenhouse gas. Still, many of the studies have predominantly focused on synthesizing chemical intermediates, such as syngas (CO + H<sub>2</sub>), alkenes, and aromatic compounds [1–4]. Furthermore, the transport and storage of syngas and alkenes

raise potential safety risks, due to the high toxicity range and flammability of these gases, respectively [5,6]. Nonetheless, a lack of feasible approaches to produce valuable and safer oxygenate molecules directly from CO<sub>2</sub> and other high environmental concern gases, such as shale gas, appears to exist.

A recent study performed by Xie et al. [7] has proposed a tandem reactor strategy that enables the synthesis of oxygenates (aldehydes and alcohols) by inserting the CO moiety from the CO<sub>2</sub> into alkenes generated from the underutilized ethane (C<sub>2</sub>H<sub>6</sub>), the shale gas second-largest component. This strategy comprised two stages: (i) one, where syngas and ethylene were generated through catalyzed CO<sub>2</sub>-assisted dehydrogenation and C<sub>2</sub>H<sub>6</sub> reforming at 600–800 °C; and (ii) a further one, where the readily-generated syngas and ethylene were used in a catalyzed hydroformylation reaction at 200 °C to produce propanal and/or 1-propanol. Additionally, other reactions of CO<sub>2</sub> with C<sub>2</sub>H<sub>6</sub> can also occur, including [8]: (i) oxidative dehydrogenation of ethane with CO<sub>2</sub>; (ii) non-oxidative dehydrogenation, (iii) cracking to form methane, and (iv) reverse water gas shift to produce water. So, depending on the catalyst properties and the reaction conditions, it is possible to foresee the synthesis of oxygenated compounds from the interaction between the CO<sub>2</sub> and ethane molecules in a single unit. However, as CO<sub>2</sub> is an extremely stable molecule, the catalytic processes' performance demands high temperature. Hopefully, this drawback can be compensated by employing thermo-photocatalysis [8–11].

Despite the several efforts made over the past few years towards photocatalytic reduction, the CO<sub>2</sub> conversion still suffers from very low efficiencies. However, the photocatalytic activity can be enhanced through the structural engineering of photocatalysts with different architectures and surface properties (e.g., bandgap engineering, nanostructuralization, macro/meso/microporous structuralization, etc.) [1,12–14]. Among the perovskite semiconductors, strontium titanate (SrTiO<sub>3</sub>) is a promising photocatalyst for CO<sub>2</sub> reduction because of its semiconducting properties, high thermal and photochemical stability, negligible toxicity, and low cost [15]. Besides, the surface defects of the SrTiO<sub>3</sub>, such as oxygen vacancy, can act as an electron trap, as well as a CO<sub>2</sub> absorption site [16]. There are precedents in the literature reporting that SrTiO<sub>3</sub> semiconductor modified by means of co-doping gives rise to highly efficient photocatalyst capable of enhancing hydrogen evolution [17–20]. The doping process with metals can change the semiconductor's optical and electronic properties through up-shift in the valence band (VB), or down-shift in the conduction band (CB), or even induce doping levels within the forbidden band. On that account, the photocatalyst may be enhanced regarding the photoresponse to visible light, the product selectivity, and the efficiency for CO<sub>2</sub> photoreduction [14]. A double doping approach using nickel (Ni) and ruthenium (Ru) transition metals can improve the photocatalytic activity and selectivity in the UV-visible region by changing the semiconductor's electronic structure [17,21]. Meanwhile, the nickel can act as an electron trap, suppressing the electron-hole pair recombination and, consequently, boosting the CO<sub>2</sub> photoconversion effectiveness [22]. Moreover, the harmless Ni<sup>2+</sup> is an important species as it concerns the co-doping with high-valence ions, since it maintains the charge balance and increases the photocatalytic performance [17,20].

To the best of our knowledge, there is only one study addressing the outstanding adeptness of the SrTiO<sub>3</sub> co-doped with RuO<sub>2</sub> and NiO, but as a photocatalyst on nitrogen fixation with water pursuing ammonia synthesis [23]. Also, as far as we know, there are no reports on literature regarding the thermo-photocatalytic conversion of CO<sub>2</sub> and C<sub>2</sub>H<sub>6</sub> into value-added oxygenate molecules. Accordingly, this study aims to contribute to this growing area of research by exploring the performance of the hybrid SrTiO<sub>3</sub>:RuO<sub>2</sub>:NiO catalyst towards ethanol production (EtOH) from CO<sub>2</sub> and C<sub>2</sub>H<sub>6</sub>, using solar-driven heterogeneous thermo-photocatalysis. The photocatalytic activity was evaluated at gas-phase under batch operation mode as a function of (i) photocatalyst composition, in terms of Ru and Ni loading; (ii) photothermal response; (iii) photoresponsiveness, under different optical radiation wavelength; (iv) photocatalyst reuse; and (v) the sacrificial agent addition, in a perspective of understanding the reaction mechanism.

## 2. Results

### 2.1. Characterization of the Photocatalysts

The photocatalyst, used in the thermo-photocatalytic reduction of CO<sub>2</sub> with ethane, was obtained by functionalizing of commercial SrTiO<sub>3</sub> through a double doping approach with RuO<sub>2</sub> and NiO, as illustrated in Figure 1 and further described in the materials and methods section. To understand the structural and morphological changes on the SrTiO<sub>3</sub>:RuO<sub>2</sub>:NiO photocatalyst, several characterization techniques were used, namely: (i) UV-Vis diffuse reflectance spectroscopy (DRS), which was also applied for SrTiO<sub>3</sub> and SrTiO<sub>3</sub>:Ru<sub>2</sub> intermediate samples (Figure 2); (ii) X-ray diffraction (XRD) and Raman spectroscopy (Figure 3); (iii) energy-dispersive X-ray spectroscopy (EDS) mapping and transition electron microscopy (TEM) (Figure 4); and (iv) X-ray photoelectron spectroscopy (XPS) (Figure 5).

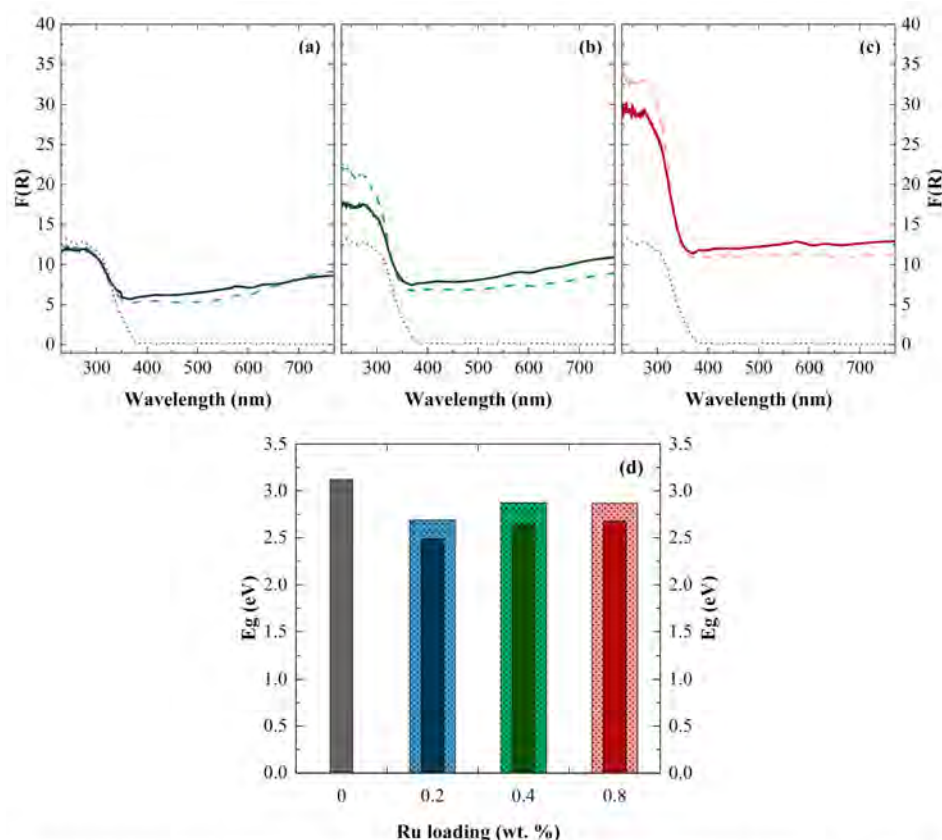

**Figure 1.** Schematic representation of the SrTiO<sub>3</sub>:RuO<sub>2</sub>:NiO photocatalyst preparation method.

Figure 2 depicts the UV-Vis DRS spectra (Figure 2a–c) and the optical band gap energy ( $E_g$ ) (Figure 2d) of the SrTiO<sub>3</sub>, SrTiO<sub>3</sub>:Ru and SrTiO<sub>3</sub>:RuO<sub>2</sub>:NiO samples, where it is possible to verify that: (i) the pristine SrTiO<sub>3</sub> presented a characteristic absorption band in the UV light region and the highest  $E_g$  value of ca. 3.2 eV (estimated through the application of Kubelka-Munk method [24]) in accordance with the literature [25], with an absorption edge around 380–390 nm, corroborating the need towards a spectral red-shift; (ii) the decoration of the SrTiO<sub>3</sub> with Ru nanoparticles indeed increased the response against the visible irradiation since the  $E_g$  values decreased by about 8–14%, compared to SrTiO<sub>3</sub>, resulting in a wide absorption band between 400–800 nm due to the RuO<sub>2</sub> plasmon band, as also recorded Mateo et al. [21]; (iii) the impregnation with nickel further increased the visible light harvest, mainly after 520 nm through the ion transition level [26], and narrowed the  $E_g$  between 14–20%, compared to SrTiO<sub>3</sub>; (iv) the global spectrum intensity progressively increased as the dopant concentration raised; (v) the  $E_g$  values did not follow a gradual decay pattern as the metal oxides' concentration increase, since the presence of excessive ions can induce intrinsic point defects, or oxygen vacancies, on the surface of metal-doped semiconductors, which may act as recombination centers [27,28]; and (vi) the double doping approach led to a partial suppression of the higher energy ions, resulting in a photocatalyst with weaker UV light absorption between 200–400 nm, when compared to Ru-doped SrTiO<sub>3</sub>, as similarly reported for the co-doping of SrTiO<sub>3</sub> with Ni and Ta/La [17,20,29].

Based on the XRD pattern (Figure 3), it can be observed that the SrTiO<sub>3</sub>:RuO<sub>2</sub>:NiO photocatalyst actually features the characteristic diffraction peaks of the SrTiO<sub>3</sub>, RuO<sub>2</sub> and NiO compounds, as expected. Moreover, it can also be inferred that the Ru and Ni metallic species were effectively oxidized on the semiconductor surface since the corresponding diffraction peaks matched with the RuO<sub>2</sub> and NiO reference XRD patterns (JCPDS 01-070-2662 and JCPDS 78-0643, respectively). From the Rietveld refinement, the sample reflection peaks were indexed to the tetragonal crystal system, with unit-cell lattice constants of a

$= b = 3.874 \text{ \AA}$  and  $c = 12.720 \text{ \AA}$  and axial angles of  $\alpha = \beta = \gamma = 90^\circ$  (estimated through Match! software). Conversely, the reference reflection peaks (JCPDS 35-0734) of the main photocatalyst component, the  $\text{SrTiO}_3$ , are indexed to a cubic crystal system ( $\alpha = \beta = \gamma = 90^\circ$ ) with standard lattice parameter values of  $a = b = c = 3.905 \text{ \AA}$  [30].

**Figure 2.** (a–c) UV-Vis diffuse reflectance spectra, represented as a Kubelka-Munk function of the reflectance— $F(R)$ , and (d) optical band gap energy ( $E_g$ ) for undoped  $\text{SrTiO}_3$  (dotted lines, darker solid bar), Ru-doped  $\text{SrTiO}_3$  (dashed lines, patterned bars) and Ru and Ni co-doped  $\text{SrTiO}_3$  (solid lines, colored solid bars) photocatalysts, using Ru concentrations of (a) 0.2 wt. %, (b) 0.4 wt. %, and (c) 0.8 wt. % and a [Ru]:[Ni] molar ratio of 1:1.

The change on the perovskite crystalline structure suggests that the tetragonal lattices of the composed  $\text{SrTiO}_3:\text{RuO}_2:\text{NiO}$  photocatalyst are mainly a consequence of the  $\text{SrTiO}_3$  semiconductor cubic lattice stretching along the  $c$  lattice vector, most likely across the co-doping process with the metallic species. This cubic-to-tetragonal transition can be associated with oxygen's octahedral rotation around the  $c$  axis [31]. Furthermore, given the similarity between the atomic radius of Ru and Ti (0.056 and 0.060 nm, respectively) [32], it could be assumed that the Ru atom was incorporated into the host  $\text{SrTiO}_3$  lattice, thus also interfering with the lattice's crystallinity. Finally, the photocatalyst's crystallite size was estimated according to Scherrer's equation [33,34], considering all diffraction XRD peaks. It was found out that the crystallite size ranged between 4.4 and 36.9 nm, presenting an average of 21.3 nm. This lack of uniformity observed on the crystallite's size distribution can be attributed to the production of more lattice defects and lattice strains in the post-co-doping thin films [35,36].

The double doping process was also confirmed by the Raman microscopic spectrum (Figure 3: inset), which presents two characteristic  $E_g$  ( $507 \text{ cm}^{-1}$ ) and  $A_{1g}$  ( $618 \text{ cm}^{-1}$ ) bands, depicting the interaction of  $\text{RuO}_2:\text{NiO}$  with the  $\text{SrTiO}_3$ , as described by Álvarez et al. [37]. The insertion of the  $\text{Ni}^{2+}$  atom into the  $\text{RuO}_2$  lattice might have led to the variation in the Raman spectrum. Thence, a single wideband at  $507 \text{ cm}^{-1}$  was overlapped

to the longitudinal order (LO) photon mode and  $E_g$  active mode corresponding to NiO and  $\text{RuO}_2$ , respectively. Consequently, there was stress on the  $\text{RuO}_2$  lattice parameters, driving to the weakening of the  $A_{1g}$  band (Figure 3: inset).

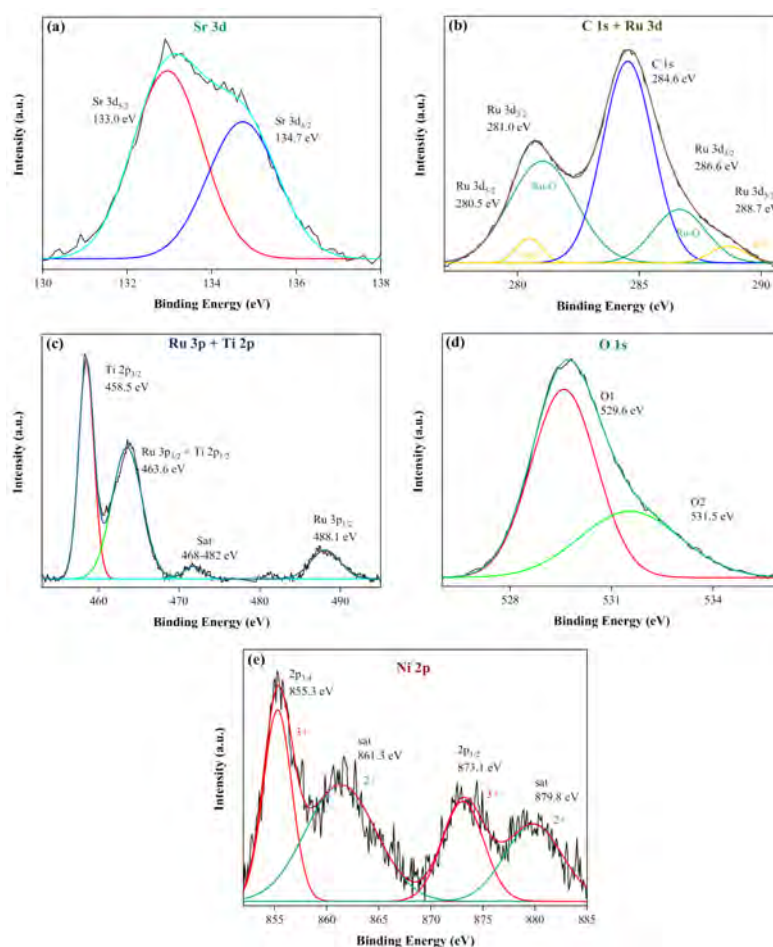

**Figure 3.** XRD pattern and Raman spectrum (inset) for  $\text{SrTiO}_3:\text{RuO}_2:\text{NiO}$  photocatalyst (0.8 wt. % of Ru; [Ru]:[Ni] molar ratio of 1:1). XRD diffraction peaks corresponding to either  $\text{SrTiO}_3$  (\*),  $\text{RuO}_2$  (°), and NiO (●).

The TEM micrographs (Figure 4) display agglomerates of uneven particles, which corroborates with the crystallite size distribution obtained from the XRD characterization, presenting a spherical-like morphology, sized between 60–90 nm, surrounded by smaller spherical-like particles, sized around 4–6 nm, corresponding to the  $\text{SrTiO}_3$  semiconductor (in agreement with the commercial specifications) and Ni and Ru metals, respectively. As expected, EDS mapping (Figure 4) confirms the presence of all elements used in the preparation of the photocatalyst, such as Sr, Ti, O, belonged to the  $\text{SrTiO}_3$  main compound, along with Ni and Ru metallic particles, whose existence are ascribed to the semiconductor co-doping process.

**Figure 4.** EDS elemental mapping (Sr, Ti, O, Ru, Ni) and TEM images for  $\text{SrTiO}_3:\text{RuO}_2:\text{NiO}$  photocatalyst (0.8 wt. % of Ru; [Ru]:[Ni] molar ratio of 1:1).

**Figure 5.** High-resolution XPS spectra of the (a) Sr 3d, (b) C 1s + Ru 3d, (c) Ru 3p + Ti 2p, (d) O 1s, and (e) Ni 2p occupied states recorded for the SrTiO<sub>3</sub>:RuO<sub>2</sub>:NiO photocatalyst (0.8 wt.% of Ru; [Ru]:[Ni] molar ratio of 1:1), along with the respective fitting and deconvolution curves.

XPS analysis (Figure 5) also attests to the elemental composition of the SrTiO<sub>3</sub>:RuO<sub>2</sub>:NiO photocatalyst, consisting of Ni, Ru, Ti, Sr, and O components, and the absence of any impurity. The spectrum of the Sr 3d occupied state (Figure 5a) shows the formation of a doublet signal with binding energies of 133.0 eV and 134.7 eV, associated with Sr 3d<sub>5/2</sub> and Sr 3d<sub>3/2</sub> orbitals, respectively, which is related to the bond between the Sr atom and the perovskite structure matrix. Although the C 1s + Ru 3d combined spectrum (Figure 5b) presents a signal interference associated with the C 1s reference (284.6 eV), from the deconvolution of this spectrum, it is possible to recognize a doublet signal ascribed to two chemically different Ru oxidation states, namely: (i) zero-valent Ru metal, with binding energies at 280.5 and 288.7 eV (Ru 3d<sub>5/2</sub>); and (ii) Ru oxides, with predominant intensity and binding energies at 281.0 and 286.6 eV (Ru 3d<sub>3/2</sub>). As regards the Ti element (Figure 5c), two peaks related to the Ti 2p<sub>3/2</sub> and Ti 2p<sub>1/2</sub> orbitals were recorded at binding energies of 458.5 eV and 463.6 eV, respectively, which are typical values for the Ti oxidation state in the SrTiO<sub>3</sub> [38]. However, the intensity peak at 463.6 eV also features an overlapping of the Ti 2p<sub>1/2</sub> and the Ru 3p<sub>3/2</sub> orbitals. On the other hand, the intensity peak at 488.1 eV was only assigned to the Ru 3p<sub>1/2</sub> region. Accordingly, Ru and Ti elements can affect the ligand screening at charge-transfer configurations [39]. Besides that, the energy region among 468–482 eV might be associated with satellite structures belonging to the main Ti 2p and Ru 3p occupied states. From the deconvolution of the O 1s spectrum (Figure 5d), two peaks were defined, namely O1 and O2, centered at binding energies of 529.6 eV and 531.5 eV, respectively. These peaks can be attributed to metal-oxygen bonds of the RuO<sub>2</sub> and NiO dopants, as well as to defects in the SrTiO<sub>3</sub> semiconductor [40–42]. The absence

of peaks above 531.5 eV may indicate that there is no chemical adsorption of oxygen in the sample [40]. Finally, the Ni 2p spectrum (Figure 5e) shows two spin–orbit doublets and two shakeup satellite peaks, the so-called “sat”. Specifically, the two main binding peaks at 855.3 and 873.1 eV and the other two satellite peaks at 861.3 and 879.8 eV were assigned to Ni<sup>3+</sup> and Ni<sup>2+</sup> species, respectively.

## 2.2. Assessment of the Photocatalytic Activity

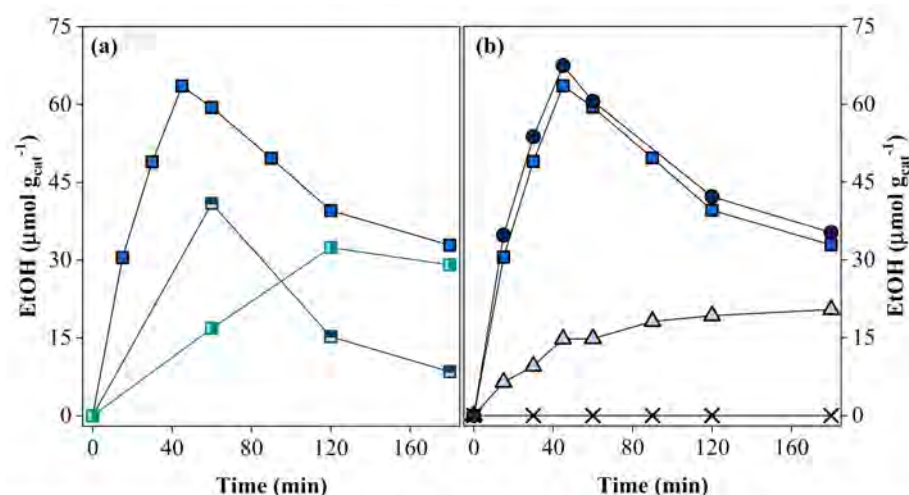

### 2.2.1. Effect of the Co-Doping Metal Loading

The main product detected during the gas-phase batch-mode photocatalytic trials was ethanol (Figure S1a). So, it was the only compound thoroughly explored across this paper, conversely to the remaining ones. Furthermore, other products such as hydrogen, carbon monoxide, ethylene, diethyl ether, and water were also identified. However, their concentration continuously remained below the analytic equipment detection limit (<2 ppm). It should also be mentioned that experiments with a Ru content null or higher than 0.8 wt.% were not performed, since a study reported by Mateo et al. [21] has disclosed that: (i) both RuO<sub>2</sub> and SrTiO<sub>3</sub> have indispensable roles regarding CO<sub>2</sub> methanation, as the first act as the active specie and the second act as the support and the promoter of the photoinduced charge separation; and (ii) a Ru dosage of 1.2 wt.% led to lower photocatalyst activity than a 0.4 wt.% Ru loading, due to the increase of the average Ru nanoparticle size.

The influence of different Ru (0.2, 0.4 and 0.8 wt.%) and Ni ([Ru]:[Ni] molar ratios of 1:0, 1:0.3, 1:1, and 1:2) dosages within the SrTiO<sub>3</sub> semiconductor towards the photo-thermal-assisted ethanol production is showed in Figure 6. It was found that: (i) the selectivity for ethanol formation was only achieved when Ni was present in the photocatalyst composition; (ii) the ethanol’s generation was raised as (a) the Ru content increased, keeping the [Ru]:[Ni] molar ratio in 1:1 and (b) the [Ru]:[Ni] molar ratio augmented until 1:1, using a Ru concentration of 0.8 wt.%; and (iii) a maximum ethanol production of almost 64 μmol EtOH g<sub>cat</sub><sup>−1</sup> was attained after 45-min reaction (the equivalent to 85 μmol EtOH g<sub>cat</sub><sup>−1</sup> h<sup>−1</sup>), considering the best catalyst. According to Myint et al. [8], reforming and oxidative dehydrogenation of ethane with CO<sub>2</sub> using FeNi as catalyst shows selectivity to ethylene formation via the C–H bond cleavage. So, there is an opportunity to improve ethanol’s formation either by ethylene hydration or by inserting CO<sub>2</sub>-derived CO into ethane-derived ethylene [43]. Moreover, the Ni<sup>2+</sup> species may act as electron traps, which will suppress electron-hole pairs recombination, thus ensuring an effective charge separation [22] and favoring ethanol generation. On the other hand, when Ni<sup>2+</sup> is doped in excess, the photocatalytic CO<sub>2</sub> reduction reaction could be hindered by the low availability or even the lack of photogenerated electrons, thus decreasing the amount of the reaction by-products. This effect was experimentally checked when the [Ru]:[Ni] molar ratio was increased from 1:1 to 1:2, keeping the Ru content at 0.8 wt.%, as no improvement was spotted regarding the ethanol production yield. Therefore, the photocatalyst composed of a Ru loading of 0.8 wt.%, a [Ru]:[Ni] molar ratio of 1:1, and a reaction time of 45–60 min were selected for the following assays.

Nevertheless, after 45-min reaction time at 200 °C, the ethanol concentration started to decrease, indicating the formation of other by-products (Figure 6). In fact, the presence of diethyl ether was identified through GC-MS analysis (Figure S1b), but in concentrations below the detection limit of the GC analytical method (< 0.05 ppm). This side-product could have been produced from the ethanol dehydration, according to Equation (1) [44]. A study performed by Oliveira et al. [45] has shown that this reaction was favored for temperatures between 180 and 200 °C, using Cu-Fe/ZSM-5 catalysts. In comparison, for temperatures above 200 °C, the formation of ethylene was endorsed instead, using ZSM-5 or Fe/Pure ZSM-5 catalysts.

**Figure 6.** Evolution of the ethanol production from  $\text{CO}_2$  and  $\text{C}_2\text{H}_6$  as a function of the photoreaction time, using different  $\text{SrTiO}_3:\text{RuO}_2:\text{NiO}$  photocatalyst compositions: (a) Ru loadings of 0.2 wt.% ( $\blacksquare$ ), 0.4 wt.% ( $\blacksquare$ ), and 0.8 wt.% ( $\blacksquare$ ), keeping a [Ru]:[Ni] molar ratio of 1:1; (b) [Ru]:[Ni] molar ratios of 1:0 ( $\times$ ), 1:0.3 ( $\blacktriangle$ ), 1:1 ( $\blacksquare$ ), and 1:2 ( $\bullet$ ), fixing the Ru content on 0.8 wt. %. Experimental conditions:  $P_{\text{C}_2\text{H}_6} = 1.01$  bar;  $P_{\text{CO}_2} = 0.35$  bar; 20 mg of photocatalyst;  $T = 200$  °C; and  $I = 1000$   $\text{W m}^{-2}$ .

### 2.2.2. Effect of the Reaction Temperature

Xie et al. [7] have presented a two-step approach that allows the synthesis of value-added oxygenates from the reaction of  $\text{CO}_2$  with ethane, via heterogeneous dehydrogenation/reforming and hydroformylation catalysis, using a combination of  $\text{Fe}_3\text{Ni}/\text{CeO}_2$  (first reactor) and Rh-based catalysts (second reactor) at temperatures of 600–800 °C and 200 °C, respectively. On the other hand, according to a review published by Nair et al. [11], a synergy can be achieved when combining thermal catalysis with photocatalysis, i.e., the hybrid thermal-photocatalysis process, which might permit work at relatively lower temperatures. For instance, despite  $\text{CO}_2$  methanation usually occurs in temperatures between 300 °C and 550 °C [46], Mateo et al. [21] have reported the  $\text{CO}_2$  methanation at 150 °C using  $\text{SrTiO}_3:\text{RuO}_2$ -driven photocatalysis. Therefore, the temperature must be a crucial parameter to take into consideration in this kind of process.

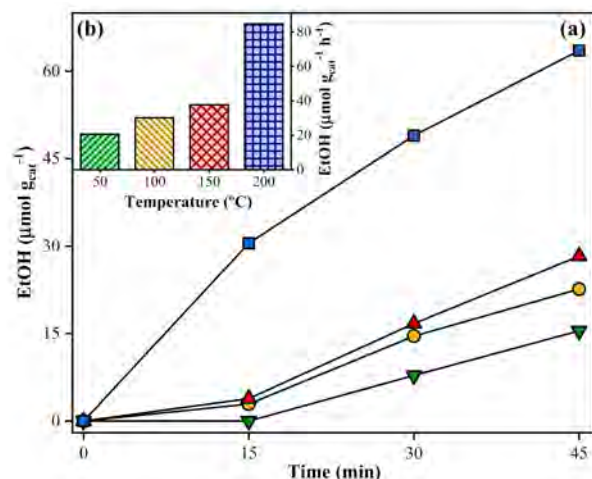

Figure 7 displays the photothermal influence on the catalytic activity towards ethanol production from the  $\text{CO}_2$  and  $\text{C}_2\text{H}_6$  reaction, from which it is possible to verify that by increasing the temperature from 50 °C to 150 °C the ethanol's production proportionally increased ca.  $0.17 \mu\text{mol g}_{\text{cat}}^{-1} \text{h}^{-1}$  per each Celsius degree, considering the timeframe irradiation of 45 min. Distinctively, when the temperature was raised from 150 °C to 200 °C, the ethanol formation yield significantly increased by about 125%, the equivalent to a specific reaction rate increment of  $0.94 \mu\text{mol g}_{\text{cat}}^{-1} \text{h}^{-1} \text{°C}^{-1}$ . The nonlinear transition in the heating experiments suggests that at 200 °C there are more molecules with energy values equal to or higher than the reaction activation energy [47]. Therefore, this temperature was chosen to pursue further experiments. It should also be mentioned that the influence of higher temperatures on the reaction rate was not explored due to reactor thermic limitations.

### 2.2.3. Effect of the Optical Radiation Wavelength

In order to evaluate the spectral response of the best photocatalyst, which can be directly linked to the UV-Vis DRS data, different radiation cut-off filters (no filter, 400 nm, 515 nm, 550 nm, 665 nm and dark) were used in the thermal-photocatalysis reaction regarding ethanol production. From the UV-Vis DRS data (Figure 2), it was found that the estimated  $E_g$  of the  $\text{SrTiO}_3:\text{RuO}_2:\text{NiO}$  photocatalyst was lower than of the pristine  $\text{SrTiO}_3$ , most likely due to interfacial combination and matched band edges among the different nanomaterials. This means that the electron-hole pairs of the composed photo-

catalyst, contrary to the pure perovskite, can be generated under visible irradiation by low-energy photons. For that reason, a better photocatalytic activity can be anticipated under visible light.

**Figure 7.** Evolution of the (a) ethanol production from CO<sub>2</sub> and C<sub>2</sub>H<sub>6</sub> as a function of photoreaction's time and the respective (b) reaction rate (for the maximum production), at 50 °C (▼); 100 °C (●); 150 °C (▲), and 200 °C (■). Experimental conditions: 20 mg of SrTiO<sub>3</sub>:RuO<sub>2</sub>:NiO; [Ru]:[Ni] = 1:1 (molar); Ru = 0.8 wt. %; P<sub>C<sub>2</sub>H<sub>6</sub></sub> = 1.01 bar; P<sub>CO<sub>2</sub></sub> = 0.35 bar; and I = 1000 W m<sup>-2</sup>.

From Figure 8, it can be seen that: (i) the control experiment in the dark exhibited negligible ethanol formation; (ii) the photoresponse decreased as the excitation wavelength increased; (iii) the Ru- and Ni-co-doped SrTiO<sub>3</sub> showed some residual photocatalytic activity, even excited at wavelengths higher than 655 nm; and (iv) the contribution of the visible radiation (>400 nm) for the global reaction efficiency is about 63% and, as such, higher than of the UV irradiation. These results, along with the ones from the previous section, showed that the use of heterogeneous thermal-catalysis alone is not able to promote any ethanol generation, and the use of heterogeneous photocatalysis by itself, at temperatures equal to or lower than 150 °C, lead to low reaction yields. So, it can be concluded that a synergy effect between UV-Vis radiation and temperature was attained and the integration of these two parameters is essential aiming at the generation of ethanol.

The difference observed on the ethanol production yield, concerning the trials without filter and using the 400 nm cut-off filter, can be ascribed to the activity of the SrTiO<sub>3</sub> since it is only excited by high-energy UV photons. The results here presented are in good agreement with the UV-vis DRS spectra and the estimated values of the optical band gap energies (Figure 2), which showed that the metals co-doping led to an improved photocatalyst with higher visible light absorption and lower band gap energy. Within the visible spectrum, the catalyst photoresponse was greater in the high-energy region, most probably because noble metal nanoparticles, such as Ru, present insightful optical properties due to the strong absorption in the visible light range, called the plasmon band [48]. Furthermore, the absorbance for the wavelengths above 550 nm can be attributed to the plasmon resonance related to the Ni nanoparticles [20,49]. Taking all the above into account, the photoresponse of the SrTiO<sub>3</sub>:RuO<sub>2</sub>:NiO catalyst can be attributed to the SrTiO<sub>3</sub> semiconductor excitation, as well as of the Ru and Ni plasmon band, being the latter more efficient towards ethanol production.

The ethanol's production yield obtained in the current work (85 μmol EtOH g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup>) is comparable to the others reported in the literature using the same full-length illumination system, i.e., a 300 W xenon lamp, but through artificial photosynthesis using CO<sub>2</sub> and H<sub>2</sub>O as reactants instead. Dai et al. [50] have presented a study regarding the photocatalytic reduction of CO<sub>2</sub> at 4 °C using a PTh/Bi<sub>2</sub>WO<sub>6</sub> photocatalyst, under batch mode operation, where the ethanol production yield was 5.1 μmol EtOH g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup>, which

is 17-fold lower compared to the present study. On the other hand, Cheng et al. [51], using a continuous planar optofluidic microreactor filled with  $C_2CdS-Cu^{2+}/TiO_2$  photocatalyst at a flow rate of  $4\text{ mL min}^{-1}$  and  $80\text{ }^\circ\text{C}$ , obtained an ethanol production rate of  $109\text{ }\mu\text{mol g}_{\text{cat}}^{-1}\text{ h}^{-1}$ , which is slightly above (28%) to the one attained in this work.

**Figure 8.** Evolution of the (a) ethanol production from  $\text{CO}_2$  and  $\text{C}_2\text{H}_6$  over time and the respective (b) reaction rate (for the maximum production), as a measure of the catalyst photoresponse under full illumination ( $1000\text{ W m}^{-2}$ ), using filters with different cut-offs: no filter (■), 400 nm (●), 515 nm (▲), 550 nm (◆), 665 nm (●), and dark (▼, covering the photoreactor with aluminum foil). Experimental conditions: 20 mg of  $\text{SrTiO}_3:\text{RuO}_2:\text{NiO}$ ;  $[\text{Ru}]:[\text{Ni}] = 1:1$  (molar);  $\text{Ru} = 0.8\text{ wt. \%}$ ;  $P_{\text{C}_2\text{H}_6} = 1.01\text{ bar}$ ;  $P_{\text{CO}_2} = 0.35\text{ bar}$ ; and  $T = 200\text{ }^\circ\text{C}$ .

#### 2.2.4. Effect of the Photocatalyst Reuse

Photocatalyst stability towards ethanol's production by thermal-photocatalysis with  $\text{CO}_2$  and  $\text{C}_2\text{H}_6$  was investigated during four consecutive batch cycles, using the same  $\text{SrTiO}_3:\text{RuO}_2:\text{NiO}$  sample. Unfortunately, after successive photocatalyst uses, the ethanol's formation rate is significantly decreased (>50% in the 2nd use), reaching a total inhibition right after the 4th use (Figure 9a), indicating poor photocatalytic stability. The TEM images (Figure 9b) clearly exhibit an increase in the opaqueness of the deactivated photocatalyst (Figure 9b.1), when compared to the fresh one (Figure 9b.2), indicating the presence of some impurities onto the catalyst surface, which can block the active sites, thus decreasing the reaction efficiency [52]. Furthermore, molecules able to absorb with multiple bonds, such as CO and other unsaturated hydrocarbons, can act as a poison for the catalyst because they can interact with metals by means of chemisorption through multiple and reverse bonding [53]. Given these results, the photocatalyst reactivation was tried to reduce the poisoning effect, after the 4th use, by two methods: (i) calcination with  $\text{O}_2$  from the air, at  $350\text{ }^\circ\text{C}$  for 2 h, in an effort to oxidize the salts of the active catalytic materials into active metal oxides; or (ii)  $\text{H}_2$  flow at  $200\text{ }^\circ\text{C}$  for 2 h, in an endeavor to reduce the metals co-doped and remove the elements causing the poisoning. Nevertheless, both reactivation mechanisms did not have the desired effect, obtaining almost null ethanol production yields.

#### 2.3. Reaction Mechanism Proposal

In an attempt to understand the potential mechanism of the gas-phase photo-thermal-reaction of  $\text{CO}_2$  with  $\text{C}_2\text{H}_6$ , mediated by sunlight, four extra experiments were carried out, adding: (i) 0.2 mmol of  $\text{O}_2$ ; (ii) 0.3  $\mu\text{mol}$  of  $\text{H}_2\text{O}$ ; (iii) 4  $\mu\text{mol}$  tetracyanoethylene (TCNE); or (iv) 10  $\mu\text{mol}$  of TCNE (Figure 10).

**Figure 9.** (a) Evolution of the ethanol production from CO<sub>2</sub> and C<sub>2</sub>H<sub>6</sub> as a function of photoreaction time, after (i) 1 cycle (■), 2 cycles (◆), 3 cycles (△) and 4 cycles (○) of the photocatalyst use, and (ii) reactivation of the photocatalyst, resulting from the 4th cycle, with H<sub>2</sub> flow (◀, at 200 °C for 2 h) or air-driven calcination (∇, at 350 °C for 2 h). Experimental conditions: 20 mg of SrTiO<sub>3</sub>:RuO<sub>2</sub>:NiO; [Ru]:[Ni] = 1:1 (molar); Ru = 0.8 wt. %; P<sub>C<sub>2</sub>H<sub>6</sub></sub> = 1.01 bar; P<sub>CO<sub>2</sub></sub> = 0.35 bar; T = 200 °C and I = 1000 W m<sup>-2</sup>. (b) TEM images of the (.1) fresh and (.2) inactivated photocatalyst (after the 4th use).

**Figure 10.** Evolution of the (a) ethanol production from CO<sub>2</sub> and C<sub>2</sub>H<sub>6</sub> as a function of photoreaction's time and the respective (b) reaction rate (for the maximum production), in the absence (■) and the presence of electron scavengers: 4 (◐) and 10 (◑) μmol of TCNE; 0.2 mmol of O<sub>2</sub> (▲); or 0.3 μmol of H<sub>2</sub>O (◄). Experimental conditions: 20 mg of SrTiO<sub>3</sub>:RuO<sub>2</sub>:NiO; [Ru]:[Ni] = 1:1 (molar); Ru = 0.8 wt. %; P<sub>C<sub>2</sub>H<sub>6</sub></sub> = 1.01 bar; P<sub>CO<sub>2</sub></sub> = 0.35 bar; T = 200 °C and I = 1000 W m<sup>-2</sup>.

TCNE was chosen as an electron scavenger since the cyano groups (CN) have low-energy  $\pi^*$  orbitals and, consequently, present a high ability to accept electrons [54]. Therefore, it is expected that the chemical reduction reaction of CO<sub>2</sub> by the photogenerated electrons at the photocatalyst conduction band is impaired. It was also reported that CN<sup>-</sup> and NCO<sup>-</sup> small-molecules can inhibit CO<sub>2</sub> reduction and CO oxidation [55,56]. In this way, the oxygenate molecules production is also affected by CO insertion hindering. Accordingly, Figure 10a discloses that the addition of 4 μmol of TCNE severely blocked the ethanol production, being achieved a reaction rate of only 5.6 μmol EtOH g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup> (in contrast with the 85 μmol EtOH g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup> obtained in the absence of electron scavengers), while the utilization of 10 μmol of TCNE causing its total inhibition. This behavior suggests that the reaction mechanism is based on the charge separation into valence band holes and conduction band electrons.

The addition of water along with the CO<sub>2</sub> and C<sub>2</sub>H<sub>6</sub> diminished the reaction rate by about 47%, as can be seen in Figure 10b. In this case, the ethanol yield might have been compromised by the preferential production of carbonic acid through the reaction of CO<sub>2</sub> with H<sub>2</sub>O, according to Equation (2), before the formation of the potential ethanol precursors, C<sub>2</sub>H<sub>4</sub> and CO.

Even though O<sub>2</sub> can act as an electron scavenger in CO<sub>2</sub> hydrogenation reaction [57], in the present study, the ethanol yield was increased in its presence, reaching up to a production rate of about 1.7-fold higher (146 μmol EtOH g<sub>cat</sub><sup>-1</sup> h<sup>-1</sup>). This profile suggests that the photogenerated electrons were used by O<sub>2</sub> to produce ethanol. According to Bergner et al. [58], the main products obtained from the reaction of oxygen atoms with ethane are ethanol, acetaldehyde, ketene, and CO. Ethanol formation is explained by the inclusion of one O(<sup>1</sup>D) atom into an ethane C–H bond, representing a promising path to the chemical complexity [58,59]. Moreover, at low O<sub>2</sub> concentrations, the production of CO and H<sub>2</sub>O by the incomplete combustion of C<sub>2</sub>H<sub>6</sub> may occur. Hence, the improved ethanol yield can also be linked to CO generation since two CO molecules can form C<sub>2</sub>H<sub>4</sub> and C<sub>2</sub>H<sub>5</sub>OH, as proposed by Yang et al. [43].

So far, it can be established that the ethanol production is straightly connected with the reaction products of the CO<sub>2</sub> and/or C<sub>2</sub>H<sub>6</sub>, taking into account the following pathways [8,60]: (i) dry reforming of C<sub>2</sub>H<sub>6</sub>, producing H<sub>2</sub> and CO via Equation (3); (ii) oxidative dehydrogenation of C<sub>2</sub>H<sub>6</sub> with CO<sub>2</sub>, generating C<sub>2</sub>H<sub>4</sub>, CO and H<sub>2</sub>O, according to Equation (3) and (4); (iii) non-oxidative dehydrogenation, converting C<sub>2</sub>H<sub>6</sub> into C<sub>2</sub>H<sub>4</sub> and H<sub>2</sub>, given by Equation (5); (iv) reverse water gas shift, forming CO and H<sub>2</sub>O, as shown in Equation (6); and (v) cracking of ethane to yield methane, through Equation (7).

Additionally, syngas (CO and H<sub>2</sub>) can likewise be used to produce oxygenated organic compounds, such as methanol, ethanol, or mixed higher alcohols, based on the side reactions of the conventional Fischer–Tropsch (FT) process. In other words, following a polymerization mechanism, CO is activated on metal (Ru, Ni, Fe or Co) or metal carbide adsorbed (CH<sub>x</sub> or OCH<sub>x</sub>, with x = 0–3) intermediates that will react by a sequence of consecutive coupling to generate C<sub>2</sub>+ products (C<sub>n</sub>H<sub>m</sub> or C<sub>n</sub>H<sub>m</sub>O) [61]. Therefore, ethanol can be obtained from syngas in conformity with Equation (8). Furthermore, as previously mentioned, besides from CO bond insertion, ethanol production can also be achieved from ethylene hydration, according to Equation (9) [43], which might involve the breakage of the alkene's π and O–H bonds of the water and the formation of C–H and C–OH bonds.

Building on the information above mentioned and assuming that no methane was generated and H<sub>2</sub>O was detected in the reactor after proper cooling, a theoretical global equation regarding the formation of ethanol from CO<sub>2</sub> and C<sub>2</sub>H<sub>6</sub> is proposed in Equation (10).

This reaction supposes that 3 moles of ethane react with 4 moles of CO<sub>2</sub> to form 4 moles of CO and 3 moles of ethanol. However, in all the experiments, the [C<sub>2</sub>H<sub>6</sub>]:[CO<sub>2</sub>] molar

ratio was 3:1, which might explain the non-appearance of CO among the reaction products. Moreover, given the high initial concentration of  $C_2H_6$  comparatively to  $CO_2$ , the non-oxidative dehydrogenation could have been favored. Notwithstanding, this hypothesis cannot be accurately confirmed since the  $C_2H_4$  content was always below the  $\mu GC$  detection limit ( $<2$  ppm). On the other hand, the fact that ethanol production was increased when  $O_2$  was present (Figure 10) might be related to the hydroformylation stem from the generated ethylene [8].

Based on the results discussed, a coherent mechanism for hybrid  $SrTiO_3:RuO_2:NiO$  catalyst towards the production of ethanol (EtOH) from  $CO_2$  and  $C_2H_6$  is here proposed (Figure 11). As previously evidenced, near 60% of the ethanol has been produced under visible light illumination, where electron excitation in  $SrTiO_3$  UV-vis absorption is limited to the UV region. Hence, this photocatalyst's photoresponse in the visible region can be attributed to the  $RuO_2$  and  $NiO$  nanoparticles' optical absorption deposited on the  $SrTiO_3$ . In this case, co-doping causes a charge difference resulting in the distribution of electrons across the Ru–O and Ni–O covalent bands. Meanwhile, photoinduced electrons ( $e^-$ ) are easily promoted from the valence band (VB) to the conduction band (CB), creating holes ( $h^+$ ) in the VB. The excited electrons in the CB of the  $SrTiO_3$  are continuously transferred to adjacent atoms to maintain the neutrality of the metal oxide nanoparticles, that phenomenon was reported by the Schottky barrier theory. The synthesis gas is produced via  $CO_2$ -assisted hydrogenation, in which case the electron reduces  $CO_2$  into intermediates,  $CO_2^-$  and  $HCOO^-$ , with an uncertain transition state. Then photoinduced electrons in the metal oxide sites combined with  $H^+$  reduce these intermediates, resulting in  $H_2$  and CO. On the other hand, holes in the VB of  $SrTiO_3$  are captured by surface-bound  $OH^-$  on the semiconductor to form  $\cdot OH$  radicals. These hydroxyl radicals can abstract a hydrogen atom from ethane to generate ethyl radicals, probably bonded to the surface. Simultaneously, ethane reforming occurs via the activated C–H bond and subsequent formation of the alkoxides and ethyl, which are adsorbed and oxidized via  $h^+$  or  $\cdot OH$  to an intermediate radical, converting to ethylene. Finally, these reaction intermediates when coupling ethyl and hydroxyl radicals, or through oxidation or hydration of ethylene result in ethanol formation.

**Figure 11.** Possible reaction pathway and mechanism towards ethanol production, from  $CO_2$  and  $C_2H_6$ , on the surface of the hybrid  $SrTiO_3:RuO_2:NiO$  catalyst, by means of solar-driven heterogeneous thermo-photocatalysis.

### 3. Materials and Methods

#### 3.1. Chemicals

Ruthenium chloride ( $\text{RuCl}_3 \cdot \text{H}_2\text{O}$ ) with 36.96% (*w/w*) purity was obtained from Johnson Matthey, London, UK. Nickel chloride ( $\text{NiCl}_2$ ) with 99.99% (*w/w*) purity was provided by Aldrich, Saint Louis, MO, USA. Strontium titanate ( $\text{SrTiO}_3$ ) nanopowder (<100 nm particle size) with  $\geq 99\%$  (*w/w*) purity was supplied by Sigma-Aldrich, Saint Louis, MO, USA. Ethylene glycol ( $\text{HOCH}_2\text{CH}_2\text{OH}$ ) with 99% (*w/v*) purity was purchased from Sigma-Aldrich, MO, USA. Ethanol absolute and acetone, 99.8% and 99.5% (*v/v*), respectively, were supplied by Panreac AppliChem, Spain. Tetracyanoethylene with 98% (*w/w*) purity was acquired from Aldrich, Saint Louis, MO, USA. All chemicals were used as received without further purification. Ultrapure water was obtained from a Milli-Q IQ 7000 ultrapure-water system (18.2 M $\Omega$  cm at 25 °C, Merck, Darmstadt, Germany). For gas chromatography and reactants feeding system, the gas bottles of helium 5.0 (99.999%), nitrogen 2.8 (99.8%), oxygen 2.5 (99.5%), hydrogen 5.0 (99.999%), carbon dioxide 4.5 (99.995%), ethane 3.5 (99.95%) and synthetic air K 5.0 (99.999%) were supplied by Linde, Dublin, Ireland.

#### 3.2. Preparation of the $\text{SrTiO}_3\text{:RuO}_2\text{:NiO}$ Photocatalyst

Initially, different amounts of  $\text{RuCl}_3 \cdot \text{H}_2\text{O}$  (to obtain a final Ru content of 0.2, 0.4 and 0.8 wt.%) were added to a suspension of  $\text{SrTiO}_3$  nanopowder in ethylene glycol (5 mg mL<sup>-1</sup>), previously obtained by sonication at 700 W for 30 min, where  $\text{Ru}^{3+}$  was impregnated and reduced by reflux method at 180 °C, for 8 h, under continuous stirring (1000 rpm), as reported by Mateo et al. [21]. Then,  $\text{SrTiO}_3$ -Ru nanoparticles were recovered by vacuum filtration (Nylon membranes, Membrane Solution MS<sup>®</sup>, Seattle, WA, USA) and further washed with a mixture of ultrapure water (1 L) and acetone (200 mL), and dried in an oven at 100 °C for 2-h. The actual concentration of  $\text{Ru}^{3+}$  in the  $\text{SrTiO}_3$ -Ru nanopowder was estimated by ICP-OES, whose values are depicted in Table S1.

Afterward,  $\text{NiCl}_2$  was impregnated in  $\text{SrTiO}_3$ -Ru nanoparticles (with Ru:Ni molar ratios of 1:0, 1:0.3, 1:1, and 1:2, based on the ICP-OES results). In this sense, 200 mg of  $\text{SrTiO}_3$ -Ru nanopowder was dispersed in 10 mL of ultrapure water by sonication at 700 W for 15 min. Then, this dispersion was dried at 70 °C, under slow stirring, and when the solution volume halved, 5 mL of a  $\text{NiCl}_3$  solution ( $\text{NiCl}_3$  dissolved in ultrapure water) was added dropwise. The slow mixing was kept until complete evaporation of the water. Subsequently,  $\text{SrTiO}_3$ -Ru- $\text{NiCl}_2$  nanopowder was reduced under  $\text{H}_2$  atmosphere (100 mL min<sup>-1</sup>) at 200 °C for 2 h. Lastly,  $\text{SrTiO}_3$ -Ru-Ni nanoparticles were oxidized by calcination at 350 °C for 3 h, under ambient atmosphere, to obtain the nanostructured  $\text{SrTiO}_3$ - $\text{RuO}_2$ - $\text{NiO}_2$  photocatalyst. The preparation procedure is summarized in Figure 1. The Ni concentration in the catalyst was also assessed by ICP-OES (Table S1).

#### 3.3. Photocatalyst Characterization

The final photocatalyst composition in terms of Ru and Ni metals was determined by inductively coupled plasma-optical emission spectrometry (ICP-OES, Varian 715-ES, CA, USA) after aqua regia extraction. The best photocatalyst was also characterized by Raman spectroscopy, X-ray photoelectron spectroscopy (XPS), transition electron microscopy (TEM), energy-dispersive X-ray spectroscopy (EDS) mapping, X-ray diffraction (XRD), and UV-vis diffuse reflectance spectroscopy (DRS).

Raman spectroscopy analyses were carried out in a Horiba, Kyoto, Japan, Jobin YvonLabram HR UV-Visible-NIR (200–1600 nm) Raman Microscope Spectrometer, using a 632 nm laser as the excitation source. XPS was recorded on a SPECS spectrometer (SPECS, Berlin, Germany) with a Phoibos 150 9 MCD detector using a non-monochromatic X-ray source (Al and Mg) operating at 200 W, to compensate for any kind of charging effect, being the C1s binding energy peak at 284.6 eV used as a reference. TEM images and EDS mapping were recorded in a Philips CM300 FEG system (Philips, Amsterdam, The Netherlands) with 100 kV operating voltage. Dried samples were prepared onto a carbon-coated copper TEM grid. Lattice parameter measurements for  $\text{SrTiO}_3$  co-doped

were performed by XRD analysis. The photocatalyst's powder XRD pattern was recorded using a Philips (Amsterdam, The Netherlands) X'PERT diffractometer, equipped with a proportional detector and a secondary graphite monochromator. Data were collected stepwise over the  $2\theta$  ranges with an accumulation time of  $20 \text{ s step}^{-1}$ . UV-vis DRS analysis in the range of 200–800 nm was recorded on a Cary 5000 spectrophotometer from Varian (CA, USA).

### 3.4. Experimental Procedure

Thermo-photo-assisted experiments were carried out in batch operation mode at gas-phase, using a photocatalytic apparatus entailing four main parts (see Figure S2): (i) a 51 mL pressurized cylindrical reaction vessel made of quartz glass and equipped with a temperature controlling system ( $\leq 200 \text{ }^\circ\text{C}$ ) and a pressure gauge ( $\leq 2 \text{ bar}$ ); (ii) a  $1000 \text{ W}\cdot\text{m}^{-2}$  mercury-xenon lamp (visible light type) connected to a Lightningcure Spot LC8 light source (Hamamatsu, Japan), reproducing the solar light spectrum within  $400 < \lambda < 700 \text{ nm}$ ; (iii) reactants feeding system with a regulator of high pressure ( $2^\circ$  stadium); and (iv) an analytical system composed of one micro gas chromatograph (GC) provided with a thermal conductivity detector (TCD) and a GC provided with a flame ionization detector (FID). The  $\mu\text{GC-TCD}$  (Agilent 490 MicroGC, CA, USA) was equipped with two channels, both with independent TCD, using Ar as the carrier gas. One channel had a MolSieve 5A column (MS5A 10 m heated, injector, backflush) to analyze  $\text{H}_2$ . The other had a Pore Plot Q (PPQ 10 m heated, injector, backflush) column to analyze  $\text{CO}_2$ , CO, and  $\text{C}_1\text{-C}_4$  hydrocarbons. The GC-FID (Varian 3900, CA, USA) was equipped with an HP-5 column (30 m length, 0.25 mm, inner diameter, and 0.25  $\mu\text{m}$  film) and using argon as the carrier gas to analyze oxygenates, such as EtOH and diethyl ether.

The cylindrical quartz vessel (Figure S2) had an input and an output sealed by vacuum fittings and syringe valves (SV) provided with push buttons (PB), to allow the sampling of the gas from the reactor headspace using a gas syringe. The reactor also had an internal pressure meter (PM), working up to 2 bar. The heating system was composed of a fiberglass heating tape (FHT), placed around the reactor, and a temperature probe (TP), located between the reactor's end and the FHT, both connected to a digital thermostat temperature controller (DTTC), able to control the temperature up to  $200 \text{ }^\circ\text{C}$ .

Before each experiment, the reactor was washed five times with ultrapure water and dried at  $200 \text{ }^\circ\text{C}$ . After cooling until room temperature, 20 mg of the photocatalyst, with the desired composition, was introduced in the reactor's center. Then, the reactor inlet was connected to a gas bottle and a purging with  $\text{C}_2\text{H}_6$  was performed for 5 min, keeping both valves open. Afterward, the reactor's outlet was closed until the pressure increased by 2 bar and successively opened to eliminate any residual gas. This process was repeated 4 times. In the sequence, the intended gaseous proportions of  $\text{C}_2\text{H}_6$  and  $\text{CO}_2$  were fed to the reactor with the outlet valve closed, reaching a pressure of 1.35 bar. Subsequently, the DTTC was connected to the reactor and programmed for  $50 \text{ }^\circ\text{C}$ ,  $100 \text{ }^\circ\text{C}$ ,  $150 \text{ }^\circ\text{C}$  or  $200 \text{ }^\circ\text{C}$ . Once the desired temperature was reached, 2 min were awaited until the pressure stabilized. Lastly, the initial sample was collected immediately before the reaction was initiated by turning on the illumination.

## 4. Conclusions

The heterogeneous thermo-photocatalysis induced by  $\text{SrTiO}_3$  co-doped with  $\text{RuO}_2$  and NiO has shown itself a promising process to convert  $\text{CO}_2$ , the main greenhouse gas, and  $\text{C}_2\text{H}_6$ , the second main constituent of shale gas, into EtOH, a value-added chemical, under simulated sunlight at moderate temperature. In contrast with some traditional techniques that use these compounds at temperatures between  $300$  and  $900 \text{ }^\circ\text{C}$ . The optimized  $\text{SrTiO}_3\text{:RuO}_2\text{:NiO}$  thermo-photocatalyst (0.8 wt.% Ru; [Ru]:[Ni] molar ratio of 1:1) exhibited the highest photocatalytic activity at  $200 \text{ }^\circ\text{C}$ , under batch operation mode, achieving a maximum ethanol's production rate of  $85 \mu\text{mol EtOH g}_{\text{cat}}^{-1} \text{ h}^{-1}$ , starting from a gas-phase mixture with a  $[\text{CO}_2]:[\text{C}_2\text{H}_6]$  molar ratio of ca. 1:3.

The catalyst photoresponse towards EtOH generation can mainly be ascribed to the visible photons since UV radiation contributed only about 37% to the global reaction efficiency. This behavior is in good agreement with UV-Vis DRS characterization, where it was found that the double doping process increased the photocatalyst's visible light absorption by decreasing its optical band gap energy. The absence of radiation and NiO on the photocatalyst's surface resulted in no ethanol formation, and temperatures below 200 °C considerably decreased the reaction's yield by more than 55%. Regrettably, the photocatalyst showed poor stability, as the decay on ethanol's production was significant right after a 2nd use (>50%), reaching total inhibition after a 4th use. Mechanistic studies adding electron scavenger molecules suggested that the photogenerated electron-hole pairs' charge separation indeed contributed to the thermo-photoconversion reaction. Moreover, it was inferred that the ethane non-oxidative dehydrogenation pathway towards EtOH synthesis was favored, considering that the molar ratio between C<sub>2</sub>H<sub>6</sub> and CO<sub>2</sub> was 3 to 1, when it should have been 3 to 4, taking into account the general equation proposed in this exploratory paper. In any case, more insights are needed regarding the feasibility of this process towards the intensification of the reaction between these underutilized gases aiming at the production of solar fuels.
