Abstract

Several bi-functional materials based in palladium nanoparticles supported onto nanocrystalline titanium silicalite zeolite (Pd@TS-1) were prepared and used as active and reusable catalysts to direct PO production from hydrogen, oxygen and propylene through one-pot two-step combined process. This type of catalysts was able to carry out the consecutive process where palladium nanoparticles catalyzed the formation of H$_2$O$_2$ that was used as intermediate reagent for propylene epoxidation catalyzed by TS-1 nanocrystals, used as supporting active matrix. Influence of supercritical CO$_2$ conditions in batch reactions was evaluated together with the associated effect due to the presence of platinum promoters (Pd(Pt)@TS-1). Another reaction parameters were also considered, such as palladium loading, use of acidity inhibitors and modification of H$_2$/O$_2$/C$_3$ ratio. Reusability studies showed the high stability of the catalysts in consecutive catalytic cycles, being possible their regeneration.

Keywords: Propylene oxide; Bi-functional catalysts; Supercritical CO$_2$ conditions; Palladium nanoparticles; Titanium silicalite.
Introduction

Propylene oxide (PO) is an important monomer for production of polyurethane foams, resins and propylene glycol [1]. The PO production is about 7.5 million tons per year, which comes mainly from the chlorohydrins and organic hydroperoxide (Halcon Method) process. The chlorohydrins method was originally used for the production of ethylene oxide, but in the 1960s was replaced by a direct oxidation method and started to be used for the PO synthesis. In this method, propylene and chlorine react leading to a mixture containing different types of chlorohydrins, which react with an alkali to produce PO with high selectivity. However, this methodology has an important drawback: for each tone of PO produced, 1.4 tons of chlorine and 1 ton of Ca(OH)\(_2\) are necessary as sources, and 2 tons of CaCl\(_2\) are produced, together with a large amount of waste water containing the alkali salt. On the other hand, in the Halcon process, ethylbenzene hydroperoxide or tert-butyl hydroperoxide are employed as oxidants. Basically, the hydroperoxide reacts with propylene in the presence of a catalyst to yield PO. In these processes, methylbenzyl alcohol or tert-butanol are obtained as by-products, which are dehydrated to form styrene monomer and isobutylene. In this case, for each ton of PO produced, 2.5 tons of styrene monomer or 2.1 tons of isobutylene are obtained, being two by-products that are severely affected by market trends [2, 3, 4].

Taking into account that these two methods produce large amounts of by-products and co-products [5], the most convenient solution would be the direct oxidation with O\(_2\)\(_6\), although the high reactivity of the allylic C-H bonds in the propylene precursor makes extremely difficult this reaction [7, 8]. In this sense, it is reported that ethylene epoxidations can be carried out employing silver catalysts in the presence of only O\(_2\) [9]. However, when these catalysts have been employed in the case of propylene, results have certainly been poor [10]. So, it would be decisive to avoid the drawbacks associated to chlorohydrins and Halcon processes, being important the development of safe and low contaminating propylene epoxidation processes.

Related with safety and contamination, the use of catalysts becomes essential in the industry to prevent these problems. Homogeneous catalysts have been widely used in the industry, but their disadvantages, including their difficult and expensive recovery, poor thermal stability, limited applicability and the cost of catalyst losses makes desirable the use of another kind of catalyst. Although heterogeneous catalysts are sometimes less selective than homogeneous have also a wide applicability, and besides, important advantages, including easy and cheap catalyst separation and low costs associated to catalyst losses, factors which are enhanced by the catalyst reusability [11]. For these reasons, the preparation of heterogeneous catalysts which would catalyze the propylene epoxidation with high performances and selectivities would be highly desirable [12].

Besides the chlorohydrins and Halcon processes, the production of PO from propylene has also been carried out through two consecutive steps (Scheme 1): (i) H\(_2\)O\(_2\) formation from hydrogen and oxygen and (ii) generation of PO from propylene and previously formed H\(_2\)O\(_2\). Even, different industrial proto-types have recently been reported based in the combination of two connected reaction systems where the intermediate H\(_2\)O\(_2\) is circulated between the reactor vessels, such as the HPPO two-step process for propene oxide production based on the
direct synthesis of hydrogen peroxide [13, 14, 15]. Into this combined reaction route, several types or polymeric resins [16] and/or different transition metals [17, 18], such as Pd, Pt and Au, supported onto inorganic oxides have been able to directly produce H_2O_2 [19]. Additionally, titanium-silicalite zeolite (TS-1), firstly synthesized by Taramasso et al. [20], has been an excellent solid catalyst for the propylene epoxidation. Furthermore, in the last years, optimized synthesis methods of nanocrystalline TS-1 zeolites, from different synthesis routes, have allowed the development of highly active and recyclable titanium-catalysts for PO production, using ex situ generated H_2O_2 [21].

\end{align*}
\]

**Scheme 1.** Individual reaction steps to produce propylene oxide (PO).

The next step to improve the PO production would be to combine the two individual reaction steps in only one process, developing an efficient one-pot two-step system based in the in situ generation of H_2O_2 and the use of bi-functional solid catalysts. Nowadays, the catalytic processes which combine two or more consecutive reactions are being very attractive from sustainability point of view due to the reduction in the number of sub-processes associated to isolation and separation tasks of intermediate products [22]. Into this approach, the use of active and reusable bi-functional catalysts which contain metallic nanoparticles (NPs) embedded into inorganic oxide type-matrixes are currently being profusely considered for different catalytic processes [23, 24, 25].

With the discovery by Haruta et al. of bi-functional materials formed by Au nanoparticles (NPs) supported onto titania matrixes and their catalytic performances, a new possibility for the direct epoxidation of propylene through in-situ generated H_2O_2 was opened [19]. Specifically, this type of gold-catalysts were highly selective (>99%) in the direct vapor-phase oxidation of propylene to PO in the presence of oxygen and hydrogen, being established that Au nanoparticles with sizes between 2 and 5 nm were the most active for the PO production when titania is employed as the support. Also, it is nowadays accepted that when titania is used as supporting matrix, Au NPs smaller than 2 nm lead to the formation of propane and Au NPs larger than 5 nm lead to CO_2, while the most active sizes in Au@TS-1 catalysts is stills under discussion [26, 27]. In general, although markedly dependent of nanoparticles dimensions, the developed Au@TiO_2 catalysts up to now have been active and highly selective for the conversion of propylene through epoxidation processes, but suffered from deactivation, being its stability too low in the profusely studied gaseous phase catalytic conditions [8]. With the objective to increase the reactivity and stability of bi-functional gold-materials, Yap et al. concluded that Au@TS-1 catalysts containing Au nanoclusters with sizes between 1 and 2 nm were the most active for the epoxidation of propylene when TS-1 is used as a supporting matrix, being its stability also enhanced [28]. Optimization of gold-catalysts was recently achieved by Haruta et al., using aqueous alkaline solutions to increase surface defects in TS-1 supports. In this case, the majority of deposited gold nanoclusters exhibited sizes below 2 nm, being homogeneously distributed onto the inorganic matrix with reduced
metallic agglomeration. The resulting bi-functional Au@TS-1 catalysts improved the performances for PO production using a fixed-bed reactor [29].

During the last years and following with this approach, different metal loaded TS-1 catalysts have been used for the propylene epoxidation with *in-situ* generated H$_2$O$_2$ from hydrogen and oxygen as reagents to PO production. Due the wide explosion limits of hydrogen and oxygen mixtures, which could be explosive with hydrogen concentrations between 3.8 and 95.5 mol % [30], the use of an inert gas becomes essential in order to dilute the mixture at the same time that equal molar amounts of hydrogen and oxygen are used.

Specifically, Hoelderich *et al.* reported the use of solid bi-functional Pd@TS-1 catalysts in batch conditions, achieving higher C$_3$H$_6$ conversions (~20%) with medium selectivities (~70%), claiming additionally the use of iridium and gold species as palladium promoters, although the better results were obtained when platinum nanoparticles were incorporated as promoters. Further investigations showed that the previous impregnation of the catalyst with the corresponding salts and the use of alcohols or ketones as solvent for the catalyst impregnation with metallic species improved the PO selectivity. Furthermore, the autoreduction of Pd@TS-1 catalysts under pure nitrogen avoided the olefins hydrogenation with the reaction conditions, reducing the by-products formation [31]. Similar Pd/Pt@TS-1 bi-functional catalysts were also employed by Baiker *et al.* in a tubular flow reactor, achieving also medium PO yields, but suffering the catalysts a marked deactivation and changes in product distribution with time-on-stream. This fact was probably due to the formation of formic acid from methanol, used as co-solvent that catalyzes the generation of different by-products [32].

Nevertheless, the low yields obtained for the epoxidation of propylene with *in-situ* generated H$_2$O$_2$ to direct PO formation, together with the associated difficulty to work with explosive mixtures of hydrogen and oxygen as reaction reagents, make realistically unfeasible the industrial scaled of this catalytic process, being indispensable to find possible alternatives to this one-pot two-step combined reaction in presence of solid bi-functional catalysts. Nowadays, the use of supercritical CO$_2$ (scCO$_2$) as a solvent in different reactions is receiving considerable attention due its numerous advantages, including inactivity, low cost, no transfer limitations and high solubility [33]. In the case of direct PO production, the presence of CO$_2$ could provide a reaction medium capable to solubilize large quantities of gases, being possible to work in a non-flammable and safe environment in which to merge hydrogen and oxygen miscible with propylene and PO [34]. Moreover, the properties of scCO$_2$ in the region near the critical point (Tr = 1.0 – 1.1 and Pr = 1 – 2) are specially interesting. In this region, the single phase system has a density which enhances the dissolution power, the diffusivity of solutes is higher than in liquids and the viscosity is lower, enhancing mass transfer. These three properties make the reactants easier to reach the catalyst’s active site [35]

In this way, Wu *et al.* described the use of scCO$_2$ for the epoxidation of propylene with external H$_2$O$_2$ in presence of large grains of TS-1 as catalyst. The results showed that scCO$_2$ enhanced the efficiency of H$_2$O$_2$, and hence, the PO yields were increased [36]. On the other hand, the use of scCO$_2$ has also been reported by Beckman *et al.* for the direct PO production from hydrogen and oxygen with promising results. In their research, it was shown that the
addition of small volumes of methanol and water as co-solvents together with scCO$_2$ improved the PO selectivity (82%) and the yield (23%) of the reaction, using bi-functional Pd/Pt@TS-1 catalysts. In this case, the addition of an inhibitor facilitated the neutralization of surface acidity intrinsic to TS-1 support, suppressing associated side-reactions which favored the propylene hydrogenation, PO hydrolysis or the undesirable reaction between PO and methanol, used as co-solvent [37, 38]. Taking account the attractive results obtained, further studies would be necessary, using supercritical CO$_2$ as solvent to analyze its influence on the PO formation and the effect on reactivity of the heterogeneous catalyst that takes part in the reaction.

In the current study, several bi-functional materials based in Pd nanoparticles supported onto TS-1 nanocrystals have been prepared through different synthesis and deposition methods, being their reactivity evaluated for PO production from hydrogen and oxygen. The Pd@TS-1 catalysts were able to carry out the one-pot two-step consecutive process where metallic nanoparticles catalyze the formation of H$_2$O$_2$ that is used as intermediate for propylene epoxidation catalyzed by TS-1 nanocrystals. The effect of supercritical CO$_2$ as solvent, during the reaction process, together with the use of additional co-solvents was considered, seeking to enhance and optimize the performances and selectivities to PO direct synthesis. The physico-chemical modification of the bi-functional catalysts through the incorporation of Pt promoters and surface acidity inhibitors were also considered. The Pd(Pt)@TS-1 catalysts showed high stability, being possible their reuse and regeneration after consecutive catalytic cycles, partly recovering the initial activity.
Experimental

Catalyst preparation

Synthesis of nanocrystalline TS-1

The preparation of TS-1 nanocrystals, used as inorganic support, was carried out by combination of micellar and hydrothermal synthesis methodologies [39].

Specifically, 2.0 g of Tween 20 (s.d. FINE CHEM.) was dissolved in 32 g of distilled water. This surfactant solution was added to 19.2 g of TPAOH (32% aqueous solution) under mild stirring, resulting in the formation of a clear transparent solution. To the above micellar solution, 36 g of tetraethyl orthosilicate (TEOS, Aldrich) was added in a dropwise fashion under vigorous stirring. The stirring was continued for another 1 h. To this clear solution, 1.808 g of tetra-n-butyl titanate (TNBT, Aldrich) in 9.12 g of isopropyl alcohol (IPA, s.d. FINE CHEM.) was added dropwise under vigorous stirring. Stirring was continued for another 1 h. The resulting mixture still remained clear. The mixture was then crystallized at 433K for 18 h under autogeneous pressure. The product was recovered by centrifugation, washed with distilled water and dried (383 K, 12 h). The starting mixture has a molar composition as follows: 0.03 TiO₂ : SiO₂ : 0.12 TPAOH : 0.009 Tween 20 : 0.88 IPA : 14.45 H₂O. The calcination was carried out in a furnace in a flow of air at 550ºC for 3h.

Metallic nanoparticles deposition

(Pd+Pt)@TS-1 were prepared following the methodology described by Hancu et al. [40]. More in detail, 1.0 g of previously prepared and calcined TS-1 was placed in a glass flask and 5 ml of deionized water were added, followed by heating the solution up to 80ºC under continuous stirring. To this mixture, corresponding amounts of 15% (wt) [Pd(NH₃)₄](NO₃)₂ (Strem Chemicals) aqueous solution and [Pt(NH₃)₄]Cl₂ (Aldrich) were added upon the desired catalyst. The mixture was stirred for 24h, the solid obtained was filtered and washed with deionized water and it was finally dried at 60ºC overnight. Then, it was calcined at 150ºC for 4 h and reduced by H₂ at room temperature for 4 h. In the case of Pd@TS-1 catalysts, the procedure was the same but Pt complex was not added.

The general acronym of the synthesized bi-functional catalysts was Pdxx@TS-1, being xx indicative the palladium amount, percentage in weight, supported onto TS-1 support, i.e., 02, 04, 05 and 10 would correspond to 0.2 % wt, 0.4 % wt, 0.5 % wt and 1.0 % wt of Pd, respectively. When platinum promoter was also supported onto inorganic matrix, Pdxx(Pt)@TS-1 was the acronym used during the discussion. In these samples, the content of platinum corresponded approximately to 10 % in weight of palladium content.

Catalysts characterization

XRD analysis was carried out with a Philips X’PERT diffractometer equipped with a proportional detector and a secondary graphite monochromator. Data were collected stepwise over the 2° ≤ 2θ ≤ 10° angular region, with steps of 0.02° 2θ, 20s/step accumulation time and Cu Kα (λ = 1.54178 Å) radiation. C, N and H contents were determined with a Carlo Erba 1106 elemental analyzer, while while Pd and Pt contents were obtained by means of atomic absorption spectroscopy (Spectra AA 10 Plus, Varian). A Cary 5 spectrometer equipped with a
diffuse reflectance accessory was used for UV measurements. Volumetric analyses were performed by nitrogen adsorption isotherms at 77K with a Micromeritics ASAP2010. Before the measurements, the samples were outgassed for 12 hours at 100°C. The BET specific surface area [41] was calculated from the nitrogen adsorption data in a relative pressure range from 0.04 to 0.2. The total pore volume [42] was obtained from the amount of N\textsubscript{2} adsorbed at a relative pressure of ~ 0.99. External surface area and micropore volume were estimated with the t-plot method in the t range from 3.5 to 5. The pore diameter and the pore size distribution were obtained following the Barret-Joyner-Halenda (BJH) method [43] on the adsorption branch of the isotherms. Scanning and transmission electron microscopies (SEM and TEM) characterization were carried out in a JEOL6300 and Philips CM10 (100kV) microscopes, respectively. Before TEM observation, the samples were prepared by suspending the solid in ethanol, ultrasonically for 15 min and placing one drop on a carbon-coated copper grid (300 mesh).

**Catalytic tests**

The experiments for the direct synthesis of PO with in-situ generated H\textsubscript{2}O\textsubscript{2} were carried out in a 15 mL stainless steel autoclave coated with a Teflon beaker and with a relief valve, for safety. The stirring was driven by a Teflon-coated magnetic stirrer. Known amounts of catalyst (15 mg), acidity inhibitor (ammonium acetate) and co-solvent were added to the reactor, followed by the addition of propylene (2 mmol) and CO\textsubscript{2}. Known amounts of oxygen and finally hydrogen were then added to the reactor, which was then heated up until the desired temperature. The reaction experiments were carried out, unless otherwise stated, during 5h. After that time, the reactor was cooled down using a mixture of acetone and ice, and the pressure was slowly released by venting, recovering the gaseous mixture in an inert gas sampling bag. 3-pentanone was used for recovering any product that could be in the walls of the reactor, avoiding the employment of acetone because could be a possible by-product.

The amounts of propylene oxide, acetone, propionaldehyde, acrolein, isopropanol, 1-methoxy-2-propanol (MP1), 2-methoxy-1-propanol (MP2), propylene glycol (PG) and propylene carbonate were then analyzed using a Fisons Gas chromatograph GC8000 provided with a FID detector and a 60 m length 0.25 mm ID, 0.25 μm df. packed column. The amounts of propane and un-reacted propylene, oxygen and hydrogen were analyzed using a Bruker 450-GC which contains two different independent channels. The first one is provided with a thermal conductivity detector (TCD) and 3 different columns: Hayesep N (0.5 m length), Hayesep Q (1.5 m length) and a molsieve 13X (1.2 m length), employing argon as carrier. The second one is provided with two different flame ionization detectors (FID) and 3 different columns: a capillary column CP-Wax (1 m length and 0.32 mm ID), a CP-Porabond Q (25 m length and 0.32 mm ID) and another CP-Wax (5 m length and 0.32 mm ID.

Due the extensive list of possible by-products that have been reported in literature for this kind of reaction, all the products have been calibrated using mixtures with known composition. All the products in the liquid phase have been identified by GC-MS and by GC with commercial samples.
Results and discussion

Synthesis and characterization of catalysts

The bi-functional Pd@TS-1 catalysts were based in palladium nanoparticles supported onto nanocrystalline titanium silicalite TS-1 that exhibited a double function, as inorganic matrix and epoxidation catalyst of olefins. The modification with metallic promoters, such as platinum species was also considered to improve the catalytic activity of the solids (Pd(Pt)@TS-1).

The preparation of TS-1 nanocrystals was carried out by combination of micellar and hydrothermal routes in presence of surfactants which facilitate the formation of small crystallites during the synthesis process [39]. XRD diffractograms evidenced clearly that the as-synthesized and calcinated phases, removing organic structural directing agents, corresponded to crystalline TS-1 zeolite, showing the characteristic diffraction bands of MFI-type materials (Figure 1). The alkaline media present in the synthesis gel favored the formation of charged small nuclei which were probably surrounded by surfactant molecules, avoiding crystal growth. In fact, TS-1 nanocrystals with ~600 nm of size and containing very elevated titanium content (Si/Ti=35, ~2.0 % wt) were obtained (Table 1). In these samples, the totality of the titanium was tetrahedrally coordinated into the zeolitic framework, being this fact important to remark because it was reported that when high amounts of titanium are incorporated, significant octahedral extra-framework titanium was obtained, which is not active for epoxidation processes [44, 45]. UV-vis analysis and SEM inspection confirmed that the coordination state of the titanium on one hand, and the size distribution of the TS-1 crystals on the other, as shown in Figure 2. The textural properties obtained from nitrogen adsorption showed that the nanocrystalline TS-1 was microporous exhibiting a type I plate isotherm characteristic of conventional 3D microporous zeolites (Figure 3 and Table 1).

Bi-functional Pd@TS-1 materials were obtained through the deposition of palladium species (from 0.2 % to 1.0 % in weight) by impregnation methodologies onto previously...
synthesized nanocrystalline TS-1 zeolite, used as supporting matrix, from the corresponding palladium salt precursors followed by reduction processes at high temperatures. The incorporation of additional metallic promoters was similarly carried out merging palladium and platinum salts in the same aqueous solution. Following this procedure, several Pd@TS-1 and Pd(Pt)@TS-1 materials were prepared with different loading of metallic species in function of metallic salts amount used during the synthesis process. The chemical content of the different samples prepared is shown in Table 1, being observed that the titanium content of TS-1 support (~2% wt) was not modified by the presence of metallic species.

Furthermore, the crystallinity of the zeolitic phase remained unmodified after the palladium and/or platinum deposition, such as it is confirmed by XRD patterns of the different Pd(Pt)@TS-1 samples which maintain the diffraction bands characteristics of MFI-type zeolites without formation of silica amorphous phases (Figure 4). It is important to point out that the deposition methodology followed to incorporate metallic species did not imply the generation of extra-framework titanium species because all spectra of the bifunctional samples showed only one band focused at ~200 nm, indicating the majority presence of titanium inserted into the TS-1 network (Figure 4). Only a slight reduction in the total surface area and microporous volume was detected in the samples when palladium and/or platinum species were finally supported onto inorganic zeolitic matrix (Table 1), probably due to the partial blockage of more accessible pores due to the presence of metallic nanoparticles, exhibiting in all cases type I isotherms characteristic of microporous zeolitic materials. This fact confirmed that the textural properties were not substantially modified due to the presence of supported metallic nanoparticles (Figure 3). From SEM micrographs, it was observed that the TS-1 morphology of the samples was preserved although palladium or platinum nanoparticles were deposited onto the zeolitic support, being in all cases the TS-1 nanocrystals observed around 600 nm of size. The TEM micrographs clearly evidenced the formation of palladium nanoparticles homogeneously dispersed along the inorganic matrix, exhibiting diameters focused at ~ 10-20 nm, without observing agglomeration phenomenon between metallic nanoparticles although the metallic content was increased (Figure 6).

Catalytic activity

Preliminary batch catalytic tests, using nanocrystalline TS-1 zeolite as catalyst from external H$_2$O$_2$ and propylene, were performed to produce PO. The results obtained clearly confirmed the high reactivity of the titanium silicalite TS-1 zeolite support to catalyze the epoxidation of propylene catalysts and the high efficiency of the process to obtain elevated PO yields (~80-85%) with high selectivity (~95-98%). This fact evidenced the validity of nanocrystalline TS-1 materials to be used as active supports to generate effective bi-functional catalysts after the incorporation of palladium and/or platinum nanoparticles. Moreover, the hydrothermal stability of the nanocrystalline TS-1 zeolite support was additionally studied through several catalytic runs carried out with the same sample. Specifically, in Figure 7, it was observed that the PO yield obtained after the first reuse of catalyst is similar compared with the results led by the activated fresh TS-1 catalyst. During the different reuses, it was observed that PO selectivity remained stable, although the catalytic activity at short times decreased. However, even if its activity slightly decreased, longer reaction times led to complete conversion of H$_2$O$_2$ in the presence of propylene to produce PO. In general, these results corroborated that the TS-1 zeolite, used as active supporting matrix in the following two-step reactions, was catalytically effective, stable and active after several catalytic runs, without observing a substantial activity loss.

Figure 7. Catalytic activity and reuses of a TS-1 zeolite support prepared by micellar route. The amount of the H$_2$O$_2$ was externally added according to the amount of the weight of catalyst used in each reuse. On average, $R_{H2O2/Ti}=120$. Propylene is added in excess, using H$_2$O$_2$ as limiting reactant. Reaction conditions: 14 bar of pressure, 60ºC, 5 h reaction time.

Considering these previous results, the next step was the study of the catalytic processes for the direct epoxidation of propylene with in-situ generated H$_2$O$_2$, during one-pot two-step reaction process (Scheme 1). With this purpose, batch catalytic tests were carried out for the direct PO production from directly hydrogen, oxygen and propylene, using before studied bi-functional Pd(Pt)@TS-1 nanocrystalline materials as catalysts. It is important to point out that it is characteristic of this type of consecutive process that when high yields to PO are obtained, also an increase in the amount of by-products formed during the reaction is observed, and high selectivities are only obtained at low propylene conversions, especially
when gold is employed as metal for the $\text{H}_2\text{O}_2$ synthesis from $\text{H}_2$ and $\text{O}_2$, in gaseous phase [28, 46]. When Pd catalysts have been tested under gaseous phase, no PO production has been observed [19] or very low yields have been obtained [47]. Specifically, in Scheme 2, the most typical by-products formed are shown, indicating the followed reaction pathway in each case. In this scheme are marked in red, the by-products detected in the catalytic tests carried out in this work, being this information necessary to correctly estimate the associated yield and selectivity to PO generation.

Scheme 2. Possible by-products formed during the direct PO formation through the in situ generated $\text{H}_2\text{O}_2$. In red, the by-products detected in this work. Some products could be generated from more than one reaction pathway.

Due to the high number of possible products that could be obtained in the reaction, it is decisive to find the most favorable reaction conditions, using bi-functional solid catalysts, for both the in situ generation of $\text{H}_2\text{O}_2$ and the consecutive epoxidation of propylene, in order to obtain high PO yield and selectivity, avoiding the by-products formation. Supercritical CO$_2$ (scCO$_2$) has been claimed to be a good solvent for the direct production of PO, enhancing also the $\text{H}_2\text{O}_2$ efficiency for the epoxidation reaction [36]. For this reason, scCO$_2$ conditions were used in presence of bi-functional Pd(Pt)@TS-1 catalysts. The reactions were carried out up to 80 bar and 60ºC, in supercritical conditions, according the best results described at literature [38].

The catalytic results shown that the bi-functional Pd(Pt)@TS-1 catalysts were able to produce $\text{H}_2\text{O}_2$ from $\text{H}_2$ and $\text{O}_2$ that reacted with the propylene to generate PO, using CO$_2$ as solvent and in absence of another co-solvents (Table 2). Specifically, when the reaction process was carried out with Pd(Pt)@TS-1 catalyst, the conversion of propylene was high (~52 %), although the PO selectivity was low (~6 %), being propane the main reaction product, although methoxy-propanols and propylene glycol were also detected. However, the formation of high amounts of undesirable by-products was not avoided which implied reduced PO productivities
With the objective to improve these results, different reaction parameters were considered such as the incorporation of additional co-solvents together with the presence of metallic promoters.

a Reactions were carried out during 5h with pressures around 75-80 bar and 60°C, feeding 2 mmol of propylene and 15 mg catalyst. b Gaseous molar ratios. c Propylene conversion. d Propylene oxide, methyl propanols, propylene glycol and propane selectivities. e Propylene oxide yield. f Acidity Inhibitor (CH₃COONH₄).

It is described into the state-of-art that the addition of small amounts of promoters in the catalyst increased the production of PO [32]. For this, some TS-1 catalysts, containing Pd and Pt as metallic species, were prepared and tested on different conditions, using MeOH as co-solvent in the reaction medium. The results obtained shown that better performances were obtained with the Pd02(Pt)@TS-1 catalyst in presence of MeOH, achieving PO selectivities and yields of ~19 % and ~10 %, respectively (entry 2). However, the formation of high amounts of undesirable by-products (methyl propanol and propylene glycol) was not avoided which implied reduced PO productivities. In general, these data clearly confirmed the benefits of the use of metallic promoters and co-solvents for the PO production with in-situ generated H₂O₂ in supercritical CO₂ conditions, being detected that the use of water as additional co-solvent substantially worsened the catalytic results (entry 3).

Despite the fact that the use of MeOH as co-solvent effectively enhanced the formation of PO, propane still was the main product. Moreover, it is known that the acidity of the TS-1 surface promoted the decomposition of the PO produced, leading to by-products [31]. Additional water was also formed during the one-pot reaction and, consequently, H₂CO₃ formation is favored in presence of CO₂ which increases the medium acidity, facilitating the decomposition of PO, especially if MeOH was used as co-solvent and favoring the production of ring-opening products, such as methyl-propanols, dropping the PO selectivity. Taking in account all these considerations, the reaction was carried out in the presence of acidity inhibitors such as ammonium acetate, which is a well-known pH-controller buffer. In this case, the acidity was effectively controlled during the reaction process, avoiding the formation of methyl-propanols and propane which were promoted in acidic medium. In fact, the results in Table 2 showed that the use of this acidity inhibitor enhanced the formation of PO (yields of ~10 %), achieving selectivities up to 40% due to the minimization of PO ring opening phenomenon, using Pd02(Pt)@TS-1 catalyst (entry 4).
On the other hand, the $\text{C}_3^\text{H}_6$/$\text{H}_2$/O$_2$ ratios used during the catalytic tests were also analyzed, being observed that when higher amounts of O$_2$ were used in the reactor batch in presence of MeOH, H$_2$O and acidity inhibitor, propane formation was markedly reduced, i.e., the main hydrogenation product (entries 4 and 5). Particularly, improved results were obtained when $\text{C}_3^\text{H}_6$/$\text{H}_2$/O$_2$ molar ratios of approximately 1/1/1 were used during the combined catalytic process, achieving PO selectivities close to 70 % with PO yields maintained around of 10% (entry 5). Moreover, the benefits of the metallic promoters was corroborated because the catalytic activity of Pd02@TS-1 sample, without platinum nanoparticles, tested in the most suitable reaction conditions, implied a slight reduction in the total propylene conversion that worsened the final PO yield (entry 6).

Taking into account that the presence of metal nanoparticles was necessary for the generation of H$_2$O$_2$ from H$_2$ and O$_2$, the amount of metals deposited onto the TS-1 support was also studied in order to obtain as much H$_2$O$_2$ as possible, at the same time that selectivity to PO in the epoxidation of propylene remained high. For this, several bi-functional catalysts with different Pd loading (0.5% and 1.0% in weight of Pd) were checked, being observed that the PO selectivity was maintained (~70%) but associated to progressive propylene conversion decrease (entry 7). This phenomenon was more marked when the palladium loading was higher, decreasing the PO yield up to 7%, approximately (entry 8). These results showed that it was more convenient the use of catalysts with palladium content lower than 0.5% wt which exhibiting metallic nanoparticles with diameters around 15-20 nm (Figure 6).

Finally, the stability of the bi-functional Pd(Pt)@TS-1 catalysts was evaluated through three consecutive catalytic cycles. After each reuse, the catalyst solid was recovered and exhaustively washed with methanol. The results obtained showed that, overall after the third reuse, an appreciable decrease in the PO selectivity and propylene conversion were observed, confirming a partial deactivation of bimetallic supported catalysts (Figure 8). This fact could be associated to incorporation of organic compounds, from reaction media, during the catalytic process which blocked several active sites. When these surface organic species were removed through thermal treatments then regenerated and reactivated bi-functional catalyst recovered, at least partially, its initial activity (Figure 8).

Conclusions

Promising results were obtained to direct propylene oxide (PO) production through one-pot two-step consecutive process from hydrogen, oxygen and propylene, using supercritical CO₂ conditions in batch reactors in presence of optimal bi-functional catalysts, based in palladium nanoparticles supported onto nanocrystalline titanium silicalite zeolite (Pd@TS-1). These catalysts were prepared and characterized, being active and reusable to carry out the two-step process in which metallic nanoparticles catalyzed the generation of in-situ hydrogen peroxide as intermediate product for propylene epoxidation catalyzed by TS-1 active matrix. The combined process was performed in presence of only one solid and recyclable catalyst without necessity to use separated catalytic processes, avoiding additional steps related with the removing or separation of sub-products and/or intermediate substrates. All these facts would imply a higher efficiency of global catalytic route inside of more sustainable and environmental combined process. Further improvements were achieved through the modification of different reaction parameters, being concluded that use of methanol as co-solvent, presence of acidity inhibitors, incorporation of platinum nanoparticles as promoters (Pd(Pt)@TS-1) and employ of high amounts of oxygen in the reaction media increased the PO yields (~10%) and selectivities (~70%), always working in supercritical CO₂ conditions. Partial deactivation of the catalysts was observed during successive catalytic cycles probably due to adsorbed organic compounds during the catalytic process, being possible their regeneration after thermal treatments.
