ABSTRACT

We report here on new vertebrate fossils from the latest Cretaceous of Albaina (Laño quarry, Condado de Treviño), northern Iberian Peninsula. They consist of an incomplete hadrosauroid femur, and two partial plates of turtles, one belonging to a Pleurodira (Bothremyidae), the other one to an indeterminate taxon, probably corresponding to a Pan-Cryptodira. They are the first dinosaur and turtle remains found in the Late Maastrichtian sublittoral beds of Albaina. Other components of this shallow marine vertebrate fauna are selachians (sharks, rays), actinopterygians (pycnodonts, teleosts) and marine reptiles (mosasaurids, plesiosaurs). The Albaina femur is one of the few hadrosauroid remains from the Late Maastrichtian of Europe found in marine environments, and the first one described from this kind of deposits in the Iberian Peninsula. The histological structure of the bone indicates that it belongs to an immature individual of small size.

Keywords: Hadrosauroidea, Bothremyidae, Pan-Cryptodira, Condado de Treviño, Late Maastrichtian, Spain.

RÉSUMÉ

De nouveaux fossiles de vertébrés découverts à Albaina (carrière de Laño, Condado de Treviño), nord de la Péninsule ibérique, sont décrits. Il s'agit d'un fémur incomplet d'hadrosauroïde et de deux plaques partielles de tortue, l'une appartenant à un Pleurodira (Bothremyidae) et l'autre à un taxon indéterminé, correspondant probablement à Pan-Cryptodira ; ce sont les premiers restes de dinosaure et de tortue trouvés dans les dépôts sublittoraux d'âge Maastrichtien supérieur d'Albaina. Les autres éléments de cette faune marine de vertébrés sont des sélaciens (requins et raies), des actinoptérygiens (pycnodontes et

1 téléostéens) et des reptiles marins (mosasauridés et plésiosaures). Le fémur d'Albaina est l'un
2
3 des rares fossiles d'hadrosauroïde découverts dans un environnement marin dans le
4
5 Maastrichtien supérieur d'Europe, et le premier décrit dans ce type de dépôts dans la
6
7 Péninsule ibérique. La structure histologique de l'os indique qu'il appartient à un individu
8
9 immature de petite taille.

23 **1. Introduction**

24
25 The Laño quarry is a disused silica sand quarry embracing the villages of Albaina and
26
27 Laño in the Condado de Treviño, which is an exclave of Burgos province (Spain) in the
28
29 northern Iberian Peninsula (Fig. 1). The quarry is located about 30 km south to the city of
30
31 Vitoria-Gasteiz (Álava). Some deposits uncovered by sand quarrying at this point have
32
33 revealed one of the most noteworthy Campanian-Maastrichtian vertebrate sites of Europe by
34
35 its taxonomic diversity, and provided relevant information about the composition and
36
37 affinities of both terrestrial-freshwater and shallow marine vertebrate faunas from the latest
38
39 Cretaceous of the Ibero-Armorican Domain in southwestern Europe (Astibia [et al.](#), 1990,
40
41 1999; Pereda-Suberbiola et al., 2000, in review).
42
43
44
45
46

47 Vertebrate fossils accumulate at two different stratigraphic units: the lower one contains
48
49 the so-called Laño 1 and Laño 2 sites, ascribed to the Late Campanian-Early Maastrichtian
50
51 interval, while the upper one, mainly located in the vicinity of the Albaina village, are
52
53 ascribed to the Late Maastrichtian. Therefore, there exists an important time gap between the
54
55 two stratigraphic units, which is represented in the Laño quarry by a low-angle unconformity
56
57 (Baceta et al., 1999; Berreteaga, 2008 and references). The fluvial beds of sites Laño 1 and 2
58
59
60
61
62
63
64
65

1 have yielded a diversified vertebrate association that consists of nearly 40 species, including
2 actinopterygians, lissamphibians, squamates, turtles, crocodyliforms, dinosaurs, pterosaurs
3 and mammals (see Pereda-Suberbiola et al., in review for an updated list). The sublittoral beds
4 of the Albaina site have yielded a diverse vertebrate assemblage so far composed of 37 taxa,
5 including sharks and rays (Cappetta and Corral, 1999), pycnodontiforms and teleosteans
6 (Poyato-Ariza et al., 1999), mosasaurids and plesiosaurians (Bardet et al., 1999, 2013).

7
8 In this paper, we describe three new interesting fossils from the Late Maastrichtian
9 sublittoral beds of the Albaina site (Laño quarry): the first identifiable dinosaur bone and two
10 isolated turtle plates. Their identity and palaeontological significance are also discussed in
11 detail.

16 17 18 19 20 21 22 23 24 25 26 27 28 29 30 31 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63 64 65

66 The detailed geology of the Laño quarry (including the Albaina beds) has been well
67 discussed in other publications (Astibia et al. 1990, 1999; Baceta et al., 1999; Gómez-Alday,
68 1999; Pereda-Suberbiola et al., 2000, in review; Berreteaga, 2008). Geologically, the area lies
69 on the southern limb of the Miranda-Treviño syncline (central part of the Sub-Cantabrian
70 Synclinorium). Quarrying has exposed at least a 70 m section of terrigenous and carbonate
71 rocks of Late Cretaceous-Paleogene age that records continental to shallow marine
72 environment within the southern Basque-Cantabrian Basin.

73 The Late Cretaceous succession is subdivided into three unnamed formations, considered
74 equivalent to the Sedano, Sobrepeña plus Valdenoceda, and Torme formations (Berreteaga,
75 2008; see also Floquet, 1991, 1998), which reflect substantive changes in lithology and fossil

1 content (Fig. 1). The basal part of the succession (equivalent to the Sedano Fm.) comprises
2
3 fluvial silty and sandy facies, where terrestrial and freshwater vertebrate fossils occur (Laño 1
4
5 and 2 sites), and is overlain by massively sand bar which was the commonly targeted bed in
6
7 the quarry. The sedimentary structures are consistent with channel areas within an extensive
8
9 braided river system (Gómez-Alday, 1999; Pereda-Suberbiola et al., 2000).
10
11

12
13 Above this interval, a succession of sandy lutites, occasionally microconglomeratic,
14
15 pedogenic carbonates and silty grey mudstones with plant remains and unidentifiable black
16
17 bone fragments represent an alluvial-palustrine system (Gómez-Alday, 1999).
18
19

20
21 The upper part of the exposed section (equivalent to the Torme Formation cropping out in
22
23 the Villarcayo area, Burgos Province, North-Castilian Platform) is composed of grey poorly
24
25 cemented sandstones and yellowish friable calcarenites, deposited during the maximum
26
27 transgression of the sea into this area. The maximum thickness of this formation throughout
28
29 the Laño area is about 10 to 12 m. Contrary to the invertebrate macrofossils (i.e. gastropods,
30
31 bivalves, ammonites, crustaceans), which are rather scarce in these carbonate rocks, fishes,
32
33 marine reptiles and layers of accumulated orbitoidids are characteristic. The upper unit
34
35 represents a shallow marine sublittoral environment. According to the selachian association, a
36
37 Late –but not latest– Maastrichtian age is given for the Albaina beds (Cappetta and Corral,

3. Material and methods

66
67 The vertebrate material described here was collected by breaking out calcarenite rocks
68
69 fallen from the upper beds of the Laño quarry face. These beds have been primarily targeted
70
71 for their content in marine vertebrate remains (Bardet et al, 1999, 2013; Cappetta and Corral,
72
73 1999; Poyato-Ariza et al., 1999). The dinosaur bone was found by two of us (G.M., J.L.) in
74
75 recently fallen blocks, whereas the turtle plates were already in the MCNA collection as a
76
77

1 result of regular prospecting in the fossil site by another of us (J.C.C.). Fossil preparation and
2
3 conservation was done in the MCNA laboratory, using standard preparation techniques.
4

5
6 Thin sections were made from the mid-shaft of the femur LU-JL-LAÑ001, which is
7
8 assumed to contain the most complete growth record of the bone (Sander, 2000; Stein and
9
10 Sander, 2009). The samples were cut and polished processed according to current techniques
11
12 (Lamm, 2013).

23
24
25 Cf. Pan-Cryptodira indet.
26

27
28
29
30 *Material.* MCNA 15055, a partial peripheral plate lacking the medial and latero-posterior
31
32 regions (Fig. 2A-C).
33

34
35
36
37 *Description.* The plate lacks its medial region. For this reason, the width/length cannot be
38
39 estimated. It is a peripheral that does not contact the plastron, but is close to the plastral
40
41 bridge. This plate is crossed by a sulcus located between two marginal scutes. Considering
42
43 that the most distal region of this kind of sulci is always anteriorly directed, this plate is
44
45 identified as a left peripheral. The angle between the dorsal and the ventral surfaces is greater
46
47 in the anterior region than in the posterior one (Fig. 2B-C). Therefore, the anterior margin
48
49 corresponds to that located nearest to the plastral bridge, this plate being a posterior
50
51 peripheral. Although the width of this plate is not known (i.e. the length between the medial
52
53 and distal margins), the ventral surface covered by the marginal scutes is relatively narrow,
54
55 substantially less than half of the width of the plate (Fig. 2B). A well-developed change of
56
57
58
59
60
61
62
63
64
65

1 level, which does not match the ventro-medial margin of the marginal scutes, is present. It is
2
3 parallel to that margin, being more medially located. The outer surface is partially altered.
4
5 However, several discontinuous dichotomous sulci are preserved. Therefore, this plate was
6
7 ornamented. Because the medial region is not preserved, it is not possible to know if the
8
9 pleural scutes overlapped the peripheral plates. It is interpreted that, if such overlap occurs, it
10
11 would be short, because the marginal scutes cover all the preserved dorsal region of the
12
13 peripheral plate.
14
15
16
17
18
19

20 *Discussion.* The limited information provided by this element prevents its accurate
21
22 systematic allocation. Characters such as the absence of the autapomorphic ornamental
23
24 pattern of Dortokidae, a clade of basal Pan-Pleurodira recognized in the continental deposits
25
26 of Laño, as well as its larger size, allow excluding its assignment to that group. The absence
27
28 of tubercles confirms that this specimen cannot be assigned to Solemydidae, another clade of
29
30 turtles recognized in Laño. The presence of an ornamental pattern composed by discontinuous
31
32 and dichotomous sulci is shared with Bothremydidae (Pleurodira), the third clade recognized
33
34 in Laño. However, characters such as the relatively narrow ventral development of the
35
36 marginal scutes allow excluding its assignment to this group. This ornamental pattern has also
37
38 been identified in several undetermined pan-cryptodiran taxa recognized both in the Early and
39
40 Late Cretaceous of Western Europe (see Pérez-García et al., 2009; Pérez-García and
41
42 Murelaga, 2014), generally referred as “chelydroids” in aspect, and probably belonging to
43
44 different clades. Although all or at least some of these poorly known taxa have fontanelles
45
46 between the costal and the peripheral plates, the absence of information on the medial region
47
48 of MCNA 15055 does not allow comparing this character.
49
50

17

18
19
20
21
22
23 *Material.* MCNA 10863, the almost complete medial half of a sixth left costal plate (Fig.
24
25 2D-F).
26

27
28
29
30 *Description.* The only broken margin corresponds to the distal one. Therefore, the
31
32 preserved region of this costal plate allows knowing the morphology of the margins which
33
34 contacted with the neural series and with other costals. The antero-medial contact with a
35
36 neural is observed (Fig. 2E, F). The posterior region of this neural was relatively wide in
37
38 relation to its length. An approximately parallel margin to the axial axis suture, which is
39
40 interpreted as the medial contact with another costal plate, is developed in the medial edge of
41
42 the preserved costal. The postero-medial edge of this plate corresponds to the suture with
43
44 another costal, the medial area of contact of the last costals of the carapace being developed in
45
46 zigzag.
47
48
49
50

51
52 The medial region of MCNA 10863 is covered by a portion of a vertebral scute. The sulci
53
54 separating this scute and two pleural ones are observed (Fig. 2E, F). Therefore, this plate is an
55
56 even-numbered costal. Given this, plus its curvature, and the described contact with other
57
58 plates, this element can be attributed to a sixth left costal. Taken this into account, this plate
59
60
61
62
63
64
65

1 antero-medially contacts the sixth neural, medially the sixth right costal, and postero-medially
2
3 the seventh right costal. Consequently, the neural series is interpreted as discontinuous (i.e.
4
5 not continuous between the nuchal and the suprapygal plates), being composed of six plates.
6
7 The best preserved areas show that the plate was ornamented by discontinuous and
8
9 dichotomous sulci (Fig. 2E).
10
11
12
13
14
15

16 *Discussion.* Despite its limited information, it is possible to observe that MCNA 10863
17
18 shares several characters with *Bothremydidae*: a discontinuous neural series, the posterior
19
20 region of the last neural being noticeably wider than long; the morphology and arrangement
21
22 of the contact between the vertebral and the pleural scutes; and finally, the ornamental pattern.
23
24

25 The only bothremydid from the European Late Cretaceous record hitherto characterized by
26
27 the presence of six neurals is *Iberoccitanemys* Pérez-García, Ortega, and Murelaga, 2012.
28
29 However, variability in this character is known in some bothremydid taxa, as *Chedighaii*
30
31 *hutchisoni* Gaffney, Tong and Meylan, 2006, from the Late Cretaceous of United States, in
32
33 which the number of neurals varies from six to seven. In *Late Cretaceous taxa from*
34
35 southwestern Europe represented by several specimens, such as *Iberoccitanemys*, *Rosasia*
36
37 Carrington da Costa, 1940 and *Foxemys* Tong, Gaffney, and Buffetaut, 1998, the *so far*
38
39 *known* number of these plates is constant (being seven in the latter two taxa). *However,*
40
41 unpublished material of *Polysternon provinciale* (Matheron, 1869) *reveals* variability in the
42
43 neural series (*six or seven plates*). Therefore, some specimens of *Polysternon provinciale* with
44
45 the same number of neurals as in *Iberoccitanemys* are known. The Laño bothremydid
46
47 *Polysternon atlanticum* (the only bothremydid species currently identified here *sensu* Pérez-
48
49 García et al., 2010) has been recognized by relatively scarce and *disarticulated* material.
50
51 Lapparent de Broin and Murelaga (1999) indicated that its neural series *includes* at least seven
52
53 neurals, the costals 8 *medially* meeting. However, the morphology of the medial region of the
54
55
56
57
58
59
60
61
62
63
64
65

1 sixth costal MCNA 7051 from Laño (see plate 5.12 in Lapparent de Broin and Murelaga,
 2
 3 1999) is similar to that of the specimen MCNA 10863 from Albaina. Therefore, we recognize
 4
 5 that a neural series composed of six plates can be present in some *Polysternon atlanticum*
 6
 7 specimens. MCNA 10863 cannot be referred to *Polysternon provinciale* because thin
 8
 9 striations composed of parallel streaks are absent on the carapace. Therefore, the plate from
 10
 11 Albaina probably belongs to *Polysternon atlanticum*, the only bothremydid recognized in
 12
 13 Laño. However, given the limited availability of characters, and the described compatibility of
 14
 15 this element with other European representatives of Foxemydina, i.e. *Iberoccitanemys* (taking
 16
 17 into account its morphology, but also the arrangement of the neural and the costals with which
 18
 19 it is in contact), we opted for its identification as cf. *Polysternon atlanticum*.

 38
 39
 40
 41

42
 43 *Material.* LU-JL-LAÑ001, a fragmentary right femur (Fig. 3).
 44
 45
 46

47
 48 *Description.* LU-JL-LAÑ001 consists of the medial and distal parts of a right femur, which
 49
 50 is broken just below the fourth trochanter (not preserved in the specimen). The bone shows
 51
 52 evidences of erosion, especially on the distal condyles (Fig. 3A-B). As preserved, the femur is
 53
 54 155 mm long for a maximum distal width of 60 mm (see measurements below); it probably
 55
 56 corresponds to a femur that did not exceed 380 mm in length when complete. The shaft is
 57
 58 straight in lateral and medial views (Fig. 3C-D). The cross-section at the preserved proximal
 59
 60
 61
 62
 63
 64
 65

1 end of the shaft is ovoid, wider than long; the medial side is longer anteroposteriorly than the
2 lateral one. The anterior surface of the shaft is convex whereas the posterior surface is slightly
3 lateral one. The anterior surface of the shaft is convex whereas the posterior surface is slightly
4 concave. Although eroded, the distal condyles seem to have been well-developed. They are
5 expanded anteriorly and posteriorly to form an H-shaped outline in distal view (Fig. 3E). The
6 anterior intercondylar groove for the passage of the extensor tendons is deep and U-shaped; it
7 is partially enclosed by expansions of both medial and distal condyles. In anterior view, the
8 medial condyle is wider than the lateral one and is located distally below it (Fig. 3A). In distal
9 view, the intercondylar flexor groove is deep, U-shaped, and narrower than the anterior
10 groove. The medial posterior condyle is wider and more projected than the lateral one, with a
11 slightly medial orientation (Fig. 3B). The lateral condyle is projected perpendicular to the
12 long axis of the femur. The posterolateral surface of the lateral condyle shows a shallow
13 vertical groove for the *M. ilio-fibularis*.

32 Measurements of femur LU-JL-LAÑ001:

- 35 - Length (as preserved) = 155 mm
- 37 - Minimum transverse width of shaft = 48 mm
- 40 - Maximum anteroposterior length of shaft = 32 mm
- 42 - Perimeter of shaft = 130 mm
- 45 - Maximum transverse width of distal end = 60 mm

49 *Discussion.* The combination of femoral characters observed in LU-JL-LAÑ001, i.e.
51 straight distal shaft, anteroposterior expansion of the distal condyles, and deep, nearly closed
52 intercondylar extensor groove on the distal end, allow us to assign the specimen to the clade
53 Hadrosauroidea (see Horner et al., 2004; Prieto-Márquez, 2008; Xing et al., 2012:
54 supplement). We follow here the stem-based definition of Hadrosauroidea by Sereno (1998):

59
60
61
62
63
64
65

1 all hadrosauriforms closer to *Parasaurolophus* Parks, 1922 than to *Iguanodon* Mantell, 1825.

2
3 It should be noted that the development of a deep intercondylar extensor groove, with the
4
5 edges of the groove meeting or nearly meeting anteriorly to enclose an extensor tunnel, has
6
7 been regarded by Wu and Godefroit (2012) as a synapomorphy of Hadrosauridae, a clade
8
9 defined by these authors as the most recent common ancestor of *Bactrosaurus* Gilmore, 1933
10
11 and *Parasaurolophus*, plus all the descendants of this common ancestor (see Sereno, 2005 and
12
13 Prieto-Márquez, 2010 for different definitions). According to Wu and Godefroit (2012), a
14
15 deep intercondylar extensor groove is absent in non-hadrosaurid ornithopods, including in
16
17 basal iguanodontians such as rhabdodontids, which subsisted in Europe until the latest
18
19 Cretaceous (Weishampel et al., 2003; Ösi et al., 2012).
20
21
22
23
24

25 In Europe, hadrosauroid femora have been found in several Maastrichtian localities, from
26
27 the Iberian Peninsula to Crimea passing through northern and central Europe (see Cruzado-
28
29 Caballero, 2012 for a list). Some of these femora have been referred in the literature to
30
31 Hadrosauridae indet. or Euhadrosauria indet. (see Dalla Vecchia, 2006; Cruzado-Caballero,
32
33 2012), but others belong to taxa like *Telmatosaurus* Nopcsa, 1903 (Weishampel et al., 1993),
34
35 *Tethyshadros* Dalla Vecchia, 2009 (late Campanian to early Maastrichtian according to Dalla
36
37 Vecchia, 2009b), “*Orthomerus*” (now regarded as a *nomen dubium*; see Brinkmann, 1988;
38
39 Horner et al., 2004) and the lambeosaurines *Arenysaurus* Pereda-Suberbiola et al., 2009 and
40
41 *Blasisaurus* Cruzado-Caballero, Pereda-Suberbiola & Ruiz-Omeñaca, 2010.
42
43
44
45
46

47 The general morphology of the hadrosauroid femora is quite conservative, but some
48
49 individual variation has been observed (Brett-Surman and Wagner, 2007). Few ontogenetic
50
51 changes have been documented in the limb bones (i.e., femora) and at least immature
52
53 specimens of basal hadrosauroids can provide reliable information for taxonomic and
54
55 phylogenetic inferences (Prieto-Márquez, 2011). LU-JL-LAÑ001 looks roughly like two
56
57 hadrosauroid femora from Els Nerets, Lleida (Casanovas et al., 1985) and Peguera, Barcelona
58
59
60
61
62
63
64
65

1 (Pereda-Suberbiola et al., 2003b), but they show signs of erosion and/or deformation. The
2
3 Albaina specimen apparently differs from the femora of *Telmatosaurus* (Weishampel et al.,
4
5 1993) and *Arenysaurus* (Cruzado-Caballero et al., 2013) in the absence of a closed extensor
6
7 tunnel (but an artefact due to erosion cannot be totally discarded for the Albaina femur).
8
9 Moreover, the Albaina specimen lacks the elliptical foramen located just above the anterior
10
11 distal condyles in several femora from Blasi 1 in Arén (Huesca) that could belong to
12
13 *Blasisaurus* (Cruzado-Caballero, 2012). LU-JL-LAÑ001 differs from the femora of
14
15 “*Orthomerus dolloi*” Seeley, 1883 from Limburg (Mulder, 1984; Mulder et al., 2005) in
16
17 having a U-shaped flexor groove (instead of V-shaped), and from the femur of an
18
19 indeterminate hadrosauroid from Bavaria in that the flexor groove is not so wide (Wellnhofer,
20
21 1994). Comparisons with *Tethyshadros* are difficult because in the latter the femur is only
22
23 available in lateral view (Dalla Vecchia, 2009b). The femur of both *Pararhabdodon*
24
25 *Casanovas, Santafé & Isidro, 1993* (Casanovas et al., 1999; Prieto-Márquez et al., 2006a) and
26
27 *Canardia* Prieto-Márquez et al., 2013 from Midi-Pyrénées is presently not known. At last, the
28
29 femora of “*Orthomerus weberi*” Riabinin, 1945 from the Crimea Peninsula and of an
30
31 indeterminate hadrosauroid from Bulgaria (Godefroit and Motchurova-Dekova, 2010) are
32
33 very fragmentary to make helpful comparisons. Waiting for the discovery of new material, the
34
35 Albaina femur is here referred to Hadrosauroidea indet.
36
37
38
39
40
41
42
43
44

45 As noted above, the estimated total length of the Albaina femur would be around 35 cm. It
46
47 is possible to estimate the body length of the Albaina hadrosauroid on the basis of more
48
49 complete hadrosauroid specimens. The femur of the complete and articulated specimen of
50
51 *Tethyshadros insularis* Dalla Vecchia, 2009 from the latest Cretaceous of Italy is 420 mm
52
53 long, representing 11.6 per cent of the total skeleton length (3620 mm from the tip of the
54
55 snout to the distal end of the tail; see Dalla Vecchia, 2009b: table). In specimens of the
56
57 hadrosaurine *Maiasaura peeblesorum* Horner and Makela, 1979, the femur length ranges
58
59
60
61
62
63
64
65

1 from 13.3 % to 15.5 % of the body length (including different growth stages, from nestlings to
2
3 adults; Horner et al., 2000: table 1). This ratio is similar in other hadrosauroid taxa, including
4
5 basal and derived forms (see Brett-Surman, 1989). Thus, the Albaina individual was
6
7 approximately 2.5-3 m in body length at death. Using the equation of Alexander (1989), the
8
9 estimated body mass of this individual was approximately 95 kg [body mass in kg = a ·
10
11 (circumference of femur in mm)^b, where a = 0.00016 and b = 2.73]. Histological studies by
12
13 Horner et al. (2000) suggested that the late juvenile stage represented by individuals of about
14
15 3 m may reach an adult size of about twice, but we prefer to be cautious about this type of
16
17 estimates until we have a better knowledge of both the mechanisms and growth rates in
18
19 hadrosauroids (see Brinkman, 2011).
20
21
22
23
24
25
26
27

28 **5. Bone histology of the hadrosauroid femur**

29
30 **Several bone slivers from the midshaft of the femur LU-JL-LAÑ001 were extracted in**
31
32 **order to study its bone microstructure.** The examination of bone histological features allow to
33
34 infer the ontogenetic stage of the individuals when perished (Chinsamy and Hillenius, 2004;
35
36 Chinsamy-Turan, 2005; Reid, 2012 and references therein). The reduced dimensions of the
37
38 bone (ca. 35 cm in length when reconstructed) suggest a **probable** young age for the specimen,
39
40 if not the presence of a dwarf adult hadrosauroid. The **ocurrence** of small-bodied dinosaurs
41
42 was not rare in the latest Cretaceous European archipelago (Company et al., in review). Bone
43
44 microstructure of juvenile dinosaurs **is clearly different from that of submature or mature**
45
46 **individuals, and** has been described in a variety of groups (Horner et al., 2000, 2009; Klein
47
48 and Sander, 2008; Cerdá et al., 2013)
49
50
51
52
53

54
55 The cortical bone at mid-shaft is largely dominated by a well-vascularised, uninterrupted
56
57 primary fibrolamellar bone tissue. The vascular network is mainly organized into a laminar to
58
59 plexiform pattern, composed of longitudinal and circumferential primary vascular canals, with
60
61
62
63
64
65

1 occasional radial anastomoses (Fig. 4A). The vascular canals are completely filled by osteonal
2 bone, indicating the complete formation of the primary osteons. Vascular arrangement
3
4 remains more or less constant throughout the cortex, except in the periosteal surface where it
5
6 becomes reticular (irregular distribution of vascular canals) (Fig. 4B). Nevertheless, there is
7
8 no appreciable reduction in vascular density towards the bone surface. In this part of the
9
10 compacta, many vascular canals open to the subperiosteal surface (Fig. 4B-C) suggesting
11
12 intensive bone deposition (i. e., bone growth). Isolated secondary osteons or small clusters are
13
14 mainly restricted to the middle and deep cortex. Growth lines are completely absent.
15
16
17
18
19
20

21 The high degree of osteonal development around the vascular canals, the presence of a
22
23 regularly organized fibro-lamellar tissue along the entire cortex, and the formation of
24
25 secondary osteons in the deep and middle cortex suggest that the examined specimen was not
26
27 from an early juvenile individual. The described histological organization is clearly different
28
29 from that of the early juveniles in which there is a slight degree of osteonal development
30
31 around the vascular canals (nearly all of them **not organized and longitudinally oriented**), the
32
33 fast-growing woven bone is the dominant histological type, and there is little evidence of
34
35 secondary remodeling in the compacta (Horner et al., 2000, 2009; Klein and Sander, 2008;
36
37 Cerdá et al., 2013). Nonetheless, the well-vascularized sub-periosteal region of the cortex,
38
39 provided with reticular canals opening to the outer surface, reveal that the specimen belongs
40
41 to a still growing individual of small size (a late juvenile-young adult: Horner et al., 2000).
42
43 There is no evidence of growth rings, slow-growing bone tissues (e.g. lamellar or parallel-
44
45 fibred bones), advance of the Haversian reworking or gradual reduction in vascular density
46
47 towards bone surface, which are distinctive features of more skeletally mature individuals.
48

50
51
52
53
54
55
56

57 **6. Implications.**

58 *6.1. Testudines*

59
60
61
62
63
64
65

1 The presence of three clades of turtles, all of them represented by taxa recognized as new
2
3 forms, was notified in the continental levels of Laño (see Lapparent de Broin and Murelaga,
4
5 1996). A turtle currently identified as a terrestrial form (Scheyer et al., 2012), *Solemys*
6
7 *vermiculata* Lapparent de Broin and Murelaga, 1996, was defined there. It belongs to a clade
8
9 of primitive turtles (Solemydidae). Solemydidae is known from the Late Jurassic to the latest
10
11 Cretaceous of North America and Europe. The other two taxa are members of Pan-Pleurodira,
12
13 both being aquatic forms. One of them, *Dortoka vasconica* Lapparent de Broin and Murelaga,
14
15 1996, is of small size (being the estimated maximum length of the adults less than 20 cm),
16
17 which belongs to a primitive lineage of Pan-Pleurodira exclusively recorded in Europe from
18
19 the Early Cretaceous to the Paleocene (Lapparent de Broin et al., 2004; Pérez-García et al.,
20
21 2014). The third clade recognized is Bothremydidae (Pleurodira), represented by *Polysternon*
22
23 *atlanticum*, also defined in Laño (see Lapparent de Broin and Murelaga, 1999; Pérez-García
24
25 et al., 2012). Although Bothremydidae is a clade of Gondwanan origin, several lineages of
26
27 this group diachronically migrated to Europe (Pérez-García and Lapparent de Broin, 2014).
28
29 So that bothremydids are the most abundant and diverse clade of turtles currently recognized
30
31 in the European uppermost Cretaceous record. Representatives of these three groups of turtles
32
33 have been found in numerous outcrops of the uppermost Cretaceous of southwestern Europe.
34
35

36
37 Some taxa of Bothremydidae have been recognized as marine littoral forms, or with the
38
39 ability to use the coastlines to migrate (Lapparent de Broin and Werner, 1998). The
40
41 bothremydids defined in the Late Cretaceous of Europe are considered as freshwater taxa.
42
43 However, their identification in some deposits interpreted as located near the coastline
44
45 suggests that they could live in environments with higher salinity than those in which the
46
47 representatives of Dortokidae lived (Pérez-García, 2012; Guede et al., 2013). Therefore, and
48
49 taking into account the environment in which the three clades of turtles recognized in the
50
51
52
53
54
55
56
57
58
59
60
61
62
63
64
65

1 continental deposits of Laño lived, the occurrence of Bothremydidae in Albaina appears more
2
3 probable than that of the representatives of the other two clades.
4

5
6 The presence of an indeterminate Pan-Cryptodira has also been reported in the Spanish
7
8 uppermost Cretaceous site of Lo Hueco (Cuenca) (Pérez-García et al., 2009). The presence of
9
10 unpublished “chelydroid”-like taxa has been also recognized in other Late Cretaceous sites of
11
12 Western Europe. These taxa, recognized as aquatic forms, could correspond to freshwater or
13
14 marine turtles (Pérez-García et al., 2009; Guede et al., 2013). No sea turtle has been identified
15
16 in the uppermost Cretaceous of the Basque-Cantabrian Region, to the exception of scapular
17
18 remains of an *Allopleuron*-like chelonioid from the Santonian of San Pantaleón de Losa
19
20 (Burgos) studied by Bardet et al. (1993). Only another indeterminate Pan-Cryptodira has been
21
22 mentioned in Mesozoic levels of the Basque-Cantabrian Region, more precisely from the
23
24 Hauterivian-Barremian of Vega de Pas (Cantabria) (Pérez-García and Murelaga, 2014).
25
26
27
28
29

30 Therefore, the peripheral plate found in Albaina allows the identification of a fourth taxon
31
32 in the Laño quarry. Unlike taxa so far described there, this form probably belongs to Pan-
33
34 Cryptodira.
35
36
37
38
39

40 6.2. *Dinosauria*

41
42 LU-JL-LAÑ001 is the second hadrosauroid remain found in the Laño quarry, **the first one**
43
44 **being** an isolated tooth (MCNA 10510) from the fluvial deposits of the Laño 1 site, ascribed
45
46 to the Late Campanian-Early Maastrichtian (Pereda-Suberbiola et al., 2003a). Buffetaut
47
48 (2005) questioned the provenance of this tooth and suggested an accidental pollution from the
49
50 Late Maastrichtian marine beds that overlie the older sandy and silty layers which have
51
52 yielded the terrestrial and freshwater vertebrate remains. However, this hypothesis is rejected
53
54 here because the hadrosauroid tooth MCNA 10510 was obtained by screen-washing of the
55
56 fossiliferous fluvial sands and silts of Laño 1, and there is no clear evidence of reelaboration
57
58
59
60
61
62
63
64
65

1 processes in these beds (Pereda-Suberbiola et al., 2000, in review). Consequently, the Laño
2 quarry provides information of the occurrence of hadrosauroids in Iberia as early as the Late
3 Campanian: Laño is currently the only Iberian site where hadrosauroid material has been
4 found together with rhabdodontid and titanosaurian remains, the locality of Els Nerets in the
5 south-central Pyrenees of Lleida attesting of a similar dinosaur association is currently
6 regarded as Late Maastrichtian in age (Sellés and Vila, in review). The association of
7 hadrosauroids with *Rhabdodon* is unusual in the latest Cretaceous of southern France: it has
8 only been mentioned in the Late Maastrichtian Vitrolles-La-Plaine locality of Provence
9 (although an artefact due to reworking cannot be excluded; see Valentin et al., 2012).

10 It is interesting to note that the Albaina femur was found in marine deposits that have
11 yielded benthic foraminifera, invertebrates, selachians, osteichthyes and marine reptiles,
12 including turtles (Cappetta and Corral, 1999; Pereda-Suberbiola et al., in review). In addition
13 to the Laño quarry, hadrosauroid fossils have been reported from various Late Maastrichtian
14 marine sites of Europe: the Maastrichtian type area (Limburg and Liège; see Weishampel et
15 al., 1999; Jagt et al., 2003; Mulder et al., 2005; Buffetaut, 2009 and references), Midi-
16 Pyrénées (Paris and Taquet, 1973; Laurent et al., 1999, 2002; Laurent, 2003; Bilotte et al.,
17 2010), southern Bavaria (Wellnhofer, 1994), northwestern Bulgaria (Godefroit and
18 Motchurova-Dekova, 2010), and the Crimean Peninsula (Riabinin, 1945). The relative
19 abundance of hadrosauroid remains in Late Maastrichtian marine deposits of the European
20 archipelago probably reflects the dominance of these herbivorous dinosaurs on nearby
21 landmasses, as suggested by the large amount of fossils found in contemporaneous continental
22 sites of Europe and especially in the Ibero-Armorican Domain (see Dalla Vecchia, 2009a;
23 Prieto-Márquez et al., 2013). The occurrence of hadrosauroid fossils in shallow marine
24 environments can be interpreted as the result of the passive transport of floating carcasses

1 over fairly long distances from the mainland (Buffetaut, 1994; Godefroit and Motchurova-
2 Dekova, 2010).
3
4

5 Horner (1979) listed the dinosaur specimens from Upper Cretaceous marine deposits of
6 North America and noted the relative abundance of hadrosaurines (unadorned or solid crested
7 hadrosaurids), primarily in the Western Interior, suggesting that may have inhabited coastal
8 environments. Horner (1979) also noticed that approximately one-half of the specimens
9 belong to young or juvenile individuals the size or smaller than the type of *Claosaurus agilis*
10 (Marsh, 1872) (femur length 670 to 676 mm; Lull and Wright, 1942), and over three-quarters
11 of the specimens are from individuals smaller than the type of *Hadrosaurus foulkii* Leidy,
12 1858 (femur length 1055 mm; Prieto-Márquez et al., 2006b). According to Godefroit and
13 Motchurova-Dekova (2010), the overrepresentation of immature specimens in marine
14 deposits can be explained taphonomically as the result of an attritional death profile of the
15 fossil accumulation (instead of a local catastrophic event), with a selective mortality of
16 younger and smaller individuals (see Lauters et al., 2008).
17
18
19
20
21
22
23
24
25
26
27
28
29
30
31
32
33
34

35 Lambeosaurines and non-hadrosaurid hadrosauroids have been reported in Europe (Dalla
36 Vecchia, 2009a; Pereda-Suberbiola et al., 2009b; Prieto-Márquez et al., 2013). The possible
37 presence of hadrosaurines (Cruzado-Caballero et al., 2010b) has been questioned by Prieto-
38 Márquez et al. (2013). With regard to the hadrosauroid records from the Late Maastrichtian
39 marine deposits of Europe, the specimens are mostly fragmentary and not diagnostic beyond
40 *Hadrosauroida* gen. et sp. indet. All these specimens, with the exception of “*Orthomerus*
41 *weberi*” from Crimea (estimated femur length 750-800 mm; Riabinin, 1945), belong to small
42 individuals (i.e., femur length of “*Orthomerus dolloi*”: 495 mm, Seeley, 1883; femur length of
43 the Bavarian taxon: 340 mm, Wellnhofer, 1994). We can wonder if the small size of the
44 specimens reflects the presence of immature individuals or of small-bodied adults. The
45 Albaina femur is presently the only hadrosauroid specimen found in the marine facies of

5
6
7

8 **7. Conclusions**

9

10 The Laño quarry (northern Iberian Peninsula) is one of the most noteworthy Late
11 Cretaceous vertebrate sites of Europe, with abundant fossils found in two different
12 stratigraphic units: the lower one contains the Laño sites, of fluvial origin, which have yielded
13 a diverse vertebrate assemblage composed of dinosaurs and other continental vertebrates,
14 ascribed to the Late Campanian-Early Maastrichtian; the Late Maastrichtian overlying marine
15 beds of Albaina are rich in selachian, actinopterygian and mosasaurid teeth found in
16 association with benthic foraminifera and invertebrates. New vertebrate fossils collected from
17 fallen calcarenitic blocks of the quarry are the first turtle and dinosaur specimens discovered
18 to date in the sublittoral beds of Albaina. They consist of two partial turtle plates, one of them
19 belonging to a Bothremydidae (Pleurodira) and the other probably to an indeterminate Pan-
20 Cryptodira, and a partial femur of a hadrosauroid ornithopod. Although the presence of
21 Bothremydidae was previously known in the older continental levels of Laño, the other turtle
22 taxon cannot be attributed to any of those recorded there so far, thus this discovery enlarges
23 our knowledge of the vertebrate diversity from the Laño quarry. With regard to the ornithopod
24 femur, it is the first hadrosauroid specimen described from Late Maastrichtian marine deposits
25 of the Iberian Peninsula, and one of the scarce dinosaur remains found in European marine
26 environments of this age. The examination of the histological features of the femur suggests
27 that it belongs to an immature, still growing (a late juvenile-young adult) individual of small
28 size. Based on comparisons with other hadrosauroid taxa, its estimate body length at death
29 was approximately 3 m. This and other finds suggest an overrepresentation of immature
30 hadrosauroid specimens in the Late Cretaceous marine deposits.

Caption of figures

Fig. 1. Simplified geological map of the south-central part of the Basque-Cantabrian Region and stratigraphic column of the Laño quarry showing the position of the fossil vertebrate beds (map compiled from the Spanish National Geologic Map, MAGNA 1:50.000; the column follows standard lithologic patterns). Albaina location is also indicated in the inset map of Iberia.

Fig. 1. Carte géologique simplifiée de la partie sud-centrale de la Région Basco-Cantabrique et colonne stratigraphique de la carrière de Laño montrant la position des niveaux fossilifères à vertébrés (carte d'après la Carte géologique nationale d'Espagne, MAGNA 1:50.000; la colonne suit les modèles lithologiques standards). La localisation d'Albaina est aussi indiquée sur l'encart d'Iberia.

Fig. 2. Albaina turtles. A-C, MCNA 15055, cf. *Pan-Cryptodira* indet., partial periferal plate in dorsal, ventral and anterior views. D-F, MCNA 10863, cf. *Polysternon atlanticum* (Bothremydidae), sixth left costal plate, interpretative schema, dorsal and ventral views. The continuous lines represent the preserved margins of the plate, the dashed lines are broken edges, and the dotted lines correspond to the hypothetical reconstruction of the adjacent plates. Black lines represent the sutures between plates; grey and wider lines indicate the border of the scutes. Abbreviations: c, costal plate, n, neural plate; PL, pleural scute; V, vertebral scute.

Fig. 2. Tortues d'Albaina. A-C, MCNA 15055, cf. *Pan-Cryptodira* indet., plaque périphérique partielle en vues dorsale, ventrale et antérieure. D-F, MCNA 10863, cf. *Polysternon atlanticum* (Bothremydidae), 6^{ème} plaque costale gauche, schéma interprétatif et vues dorsale et ventrale. Les lignes continues représentent les bords préservés de la plaque, les lignes

1 discontinues les bords cassés, et les lignes en pointillé correspondent à une reconstitution
 2
 3 hypothétique des plaques adjacentes. Les traits noirs représentent les sutures entre les plaques,
 4
 5 et les traits gris plus épais les frontières entre les écailles. Abréviations : c, plaque costale, n,
 6
 7 plaque neurale ; Pl, écaille pleurale ; V, écaille vertébrale.
