Abstract

Fish anatomical vertical dimensions are extracted from a time-of-flight analysis of fish echo shape using narrow-bandwidth echosounding of swimming individuals. These vertical dimensions fit a Gumbel distribution model and are successfully correlated with fish weight. The proposed method can be used to estimate the mean weight of fish in aquaculture cages as an alternative to target strength measurements. Full-waveform acquisition and signal correlation techniques permitted to increase the signal-to-noise ratio and to improve the performance against traditional envelope-based echosounding.

Keywords: aquaculture, fish biomass, echosounder, waveform, pulse compression, fish morphometrics

1. INTRODUCTION

This work proposes an experimental acoustical method to estimate individual fish weight distribution of freely swimming fish, with special interest in its application to the monitoring of aquaculture floating cages. Fish target strength (TS) determination is the basis for acoustical fish size estimation in acoustical fisheries stock assessment. [1, 2, 3, 4]. The TS of a scatterer is defined as the logarithmic expression of the ratio of the backscattered wave intensity at 1 m

*email: vespinos@fis.upv.es

to the incident wave and it is evaluated in fisheries acoustics from the single echo envelope characteristics recorded with calibrated scientific echosounders.

10 The error sources in near range TS measurements have been widely discussed in several works [5, 6, 7, 8] including near field effects, partial insonification of fish, relative size of fish to beam volume, and related point-source violations, time-varying-gain accuracy, orientation of fish, etc. All these issues have been specially considered in the application to fish growth monitoring in aquaculture

15 sea pens [9] where distance plays a significant role. One of the main conclusions of the referred work is the lack of correlation between TS and fish length with dorsal aspect measurements. This correlation is only possible from ventral aspect measurements, with the ultrasonic transducer placed below the cage or in the pen bottom. Under this unusual geometry, acoustical techniques are recog-

20 nized as good candidates for biomass monitoring of caged fish. Our approach is addressed to obtain direct biometrics-related measurements, instead of a relationship between backscattered energy and length of the specimens, and to avoid the reported restriction to ventral aspect measurements.

Echo forms can provide information about the size, constitution and orien-

25 tation of a sonar target, which has been investigated since the early stages of echo-sounding techniques [10]. Burwen and Fleischmann developed an echo-length analysis approach in different references [11, 12, 13, 14] with a basic assumption: the bigger the fish the longer the resulting echo for a given emitted pulse duration and fish orientation. In those seminal works the echo length

30 analysis was performed with acoustical data obtained with state-of-art scientific echosounders and enveloped-based echo analysis, to perform TS measurements of different fresh water fish species. Their results showed the possibility of performing fish size classification following the echo length criterion and even the capability of differentiating among species with similar TS ranges.

35 Improvements to the technological limitations of scientific echosounders were given by Stanton and different co-workers, with the introduction of broadband emitting and acquiring systems and of pulse-compression techniques to improve signal to noise ratio (SNR) and temporal (spatial) resolution of pulses [15, 16].

The improvement of spatial resolution allowed individual scattering features to
40 be resolved within the fish. It also helped to observe that the time separations
between the first and last returns of the compressed echoes were strongly cor-
related with the angle of orientation of fish for a wide range of angles. Using
that information, they concluded that the orientation of individual fish can be
inferred from the processed broadband echo from a single ping [17]. Moreover,
45 pulse-compression of broadband echoes offered relevant information in the com-
parison of measured backscattering data, computed target strength simulations
and provided insight about the dominant scattering mechanisms from fish inner
structures [18].

The potential of cross-correlation techniques was also present in a different
50 line of work: fish counting or sizing in tanks. However in this case through
the estimation of the so-called total target strength of a scatterer in a perfectly
diffuse field [19], which involved the evaluation of the impulse response in a tank
with moving fishes using different time and positions recordings.

The underlying idea in this work is to obtain a direct or indirect measurement
55 of fish height from the time of flight (TOF) differences of echoes produced
in the physical limits or internal structures of an individual fish, swimming
perpendicularly to the acoustic beam axis. In principle there are no theoretical
considerations that could limit the application of this technique measuring either
from the sea surface (dorsal aspect of fish) or from below of the cage (ventral
60 aspect).

Biometric models for different species have been commonly derived in fish-
eries research relating fish total length to fish biomass. These biometric relation-
ships are useful tools in fish stock assessment, in fish physiological condition or
morphometric and genetic studies [20]. They are a fundamental part of the fish
65 biomass estimations based in stereoscopic image measuring systems, widely used
in aquaculture installations [21]. More specifically, some models have been used
to increase the precision of estimates from simultaneous measurements of fish
length and height [23], showing additionally that fish height varies isometrically
with fish body thickness and weight [24]. We assumed as starting hypothesis

70 that we could estimate fish biomass from fish models relating fish height to weight. In the following sections we will first describe the experimental setup used to obtain the full waveform acoustical backscattered signals, as well as the processing methodology and interpretation to extract biometric information of aquacultured gilt-head sea breams (*Sparus aurata*, Linnaeus 1758). Secondly, 75 we will summarize the results obtained from the measurements of dorsal and ventral aspect of fish, the discussion and conclusions in terms of the applicability of the proposed method to the monitoring of fish farming.

2. MATERIAL AND METHODS

2.1. *Fish collection and biometric measurements*

80 We sampled manually a collection of 1019 specimens of sea bream with weights comprised between 18 and 690 g, and tested different types of regressions to establish a weight (W) to height (H) relationship, to demonstrate the possibility of estimating gilt-head sea bream weight from height measurements in the most extended fish size range of production conditions.

85 Nevertheless, we limited our acoustical measurements to fish with heights that could be resolvable by TOF methods with the available configuration that will be introduced in the next subsection. We also wanted to study small differences in mean weight, just to insure that the resulting methods could be efficient growth monitoring tools for a better fish farm management. Therefore, from 90 the sampled specimens set, five highly homogeneous size-groups with small increments in mean weight between them were extracted. The average weights of each class were 159, 179, 194, 236 and 269 g with coefficient of variation lower than 0.2, and fish heights between 6.5 and 8.5 cm.

The experimental protocol was reviewed accordly with the Spanish Royal 95 Decree 53/2013 on the protection of animals used for scientific purposes [29] and carried out out in accordance with The Code of Ethics of the World Medical Association (Declaration of Helsinki) for animal experiments.

2.2. Acoustical data acquisition and processing

A small number of fish of each size class (4 individuals with exception of
100 one group of 8 fishes) was introduced in a small experimental cage of 3 m in
diameter and 2.7 m in height. The experiment took place in the facilities of the
IGIC in the harbour of Gandia (Spain). The resulting fish density was 0.3-0.62
individuals per cubic metre, measuring acoustically each class during 1 hour per
orientation (dorsal/ventral).

105 The pulse-echo waveform measurements analysed in this work were carried
out with laboratory equipment to explore the waveform characteristics of echoes
and the use of cross-correlation for pulse compression. The excitation and ac-
quisition system was a PXI system from National Instruments, composed of
a NI-5412 waveform generator and a 20 MS/s 8 bits NI-5102 digitizer, con-
110 trolled by a laptop. An Electronic Navigation Industries 2100L series 245 power
amplifier was utilized to achieve the needed high voltage to excite the piezoelec-
tric transducer. We used a Simrad 200-28CM composite ceramic single-beam
transducer with an aperture of 30° , a resonant frequency of 200 kHz with a
bandwidth of approximately 30 kHz, and a near-field distance less than 5 cm.
115 The transducer was mounted in the center of the cage, floating on the water
surface facing downwards for dorsal measurements, and at the bottom facing
upwards for ventral recordings. Source level was set to 203 dB, with the men-
tioned pulse length of $60 \mu s$ and ping rate of 5 Hz. The recordings were made
with a sampling frequency of 2 MS/s applied directly on the analogue signal
120 at transducer terminals. The acquired signals in the experimental process have
been treated and analysed with Matlab.

The fundamentals of TOF methods used in ultrasonic metrology or non-
destructive testing establish that the spatial resolution is given by $c\tau/2$, being
 c the sound speed in the host medium and τ the pulse duration. The used
125 pulse length gives a theoretical resolvable distance between two scatterers in
water of approximately 4.5 cm. The real one being even greater due to the
transducer ringing time, and depending on detection threshold level. The use
of a tone burst signal for pulse compression does not offer an improvement to

the spatial resolution [25]. We performed a cross-correlation of the acquired
130 time series with the excited signal in order to maximize the signal-to-noise-ratio
(SNR) as indicated in [25, 26]. Once the signals were correlated, each ping envelope
was calculated and sequentially represented in a classic echogram. From
the echogram, single traces corresponding to individual targets were extracted,
excluding all of those that could be the result of the superposition of fish tra-
135 jectories at similar distances from the transducer. Also, the shape of the traces
was considered, in order to restrict the study as much as possible to fish swim-
ming horizontally (perpendicularly to beam axis). Therefore, only those with
symmetrical form or with a limited slope in the echogram were selected. To
estimate the real trajectory of fish was not possible since we used a single beam
140 transducer and we did not know if the fish was crossing the beam center or not,
and also swimming speed could not be obtained. Considering the longer traces
as those originated when crossing close to the beam center and the average dis-
tance to the transducer, we estimated the trajectory slopes from trace slopes in
the echogram and limited our data to those below 30 degrees. This was done
145 in order to restrict the study as much as possible, only to fish swimming as
horizontally as possible (perpendicularly to beam axis).

Each selected trace was individually analysed in terms of its ping-to-ping
evolution. The characteristic profile of the echoes in each ping was studied,
paying special attention to the repetitive patterns along the trace that could be
150 directly related to the gilt-head sea bream biometric parameters. A preliminary
analysis showed the existence of more than one local maximum in an elevated
number of echoes, mainly in the central part of the traces corresponding to fish
positions closer to the beam center and therefore less oblique. Traditionally,
for TS measurement purposes, this situation has been avoided, increasing the
155 emitted pulse length to link up single maxima echoes with individual fish.

Figure 1 (below-left) shows, as an example, the picture of three local maxima
obtained for one of the targets of the biggest fish size class under study, revealing
in principle the inner structure of the sea bream anatomy. We attributed the
larger echo amplitude to the reflection from the fish swimbladder, and the previ-

160 ous and later peaks to the water-to-fish ("entrance") and fish-to-water ("exit")
interfaces.

From the temporal difference between local maxima, information concerning
fish height and anatomical distances should be obtained. Maximum attention
should be paid to the algorithm used in the envelope detection for the analysed
165 signals. The envelope of the correlated waveform was calculated and the maxima
on it were the reference points for interval (distance) calculations.

The preliminary observation of the waveforms for the studied fish classes
showed that most of the echoes exhibited the masking of the first water-to-
fish interface by the swimbladder (highest) maximum. Nevertheless, the third
170 maximum was detectable in a major part of the central pings constituting the
fish traces, as shown in Figure 3, a common feature of both ventral and dorsal
measurements.

This common characteristic between measurements of both aspects (dorsal
and ventral), with a bigger amplitude of the last maximum in comparison with
175 the first one, when present, did not respond to an intuitive comprehension of the
pulse propagation and echo formation and numerical simulations were performed
in order to confirm our working hypothesis.

To simplify the analysis process (and to make an easier automation), the ping
with largest amplitude among all of the pings making up the trace was estab-
180 lished as a reference point. The full waveform for that ping was considered, and
the temporal interval between the two latter local maxima provided the input
for the distance calculation, assuming in a first approach a flesh sound speed
equal to 1.025 times the sound speed of sea water during each measurement
session[27].

185 The procedure was repeated for the previous and following pings of the trace,
while the latter local maximum exceeded a certain measurable threshold.

The recordings obtained by means of fish ventral and dorsal insonifications
were analysed with the above explained method and the results relating the
obtained *acoustical distances* to fish weights are given in the following section.

190 *2.3. Numerical simulations*

In order to interpret the observed echo-shape characteristics we performed some numerical simulations of the backscattered signal. A numerical model using the finite element method was implemented using the COMSOL Multiphysics software package. The aim of the simulation was to find out if the existence and interplay of three expected echo maxima, each one corresponding
195 to the water-fish interface, to the swimbladder and the fish-water boundary, respectively. We sought to confirm if the temporal distance between them responded to changes in the geometrical distances and sizes of the constitutive elements. Numerical simulations were performed with an idealized geometry, both
200 for ventral and dorsal incidence. Figure 1 (above-right) shows the simulated geometry. The scattering object was designed in a simplified scheme, considering an ellipsoid with fish flesh acoustical properties ($c=1525$ m/s, $r=1043$ kg/m³) where two spheres with air ($c=343$ m/s; $r=1.21$ kg/m³) and fish bone ($c=2273$ m/s, $r=1100$ kg/m³) [27] were embedded. The scatterer was surrounded by
205 a rectangular water ($c=1500$ m/s, $r=1026$ kg/m³) domain. The walls of this domain were modelled as outside radiating walls. To minimize the memory requirements, the calculus was performed using an axisymmetric configuration with 16 nodes per wavelength. In the case shown in Figure 1, the dimensions of the ellipse were 8.5 and 3.5 cm along and transverse to the wave propagation
210 direction respectively; both fish bone and swimbladder radius measured 5 mm. The incident acoustic wave was simulated as a 10 period length squared pulse, with a central frequency of 200 kHz.

3. RESULTS

3.1. Biometric relationships

215 We have plotted in Figure 2 the results of the manual sampling of the gilt-head sea bream collection. The experimental height data (between 3 and 11 cm) and the corresponding fish weights are shown. From the data we obtained a fitted fractional power expression of weight (W) as a function of height (H),

$W = 0.7536H^{2.7791}$, with a correlation coefficient $R^2 = 0.9782$. This fitted curve
220 is also given in Figure 2, together with 95% confidence limits for the mean of the
manually sampled weights, and 95% confidence limits of new weight predictions
for given heights.

3.2. Numerical results

The numerical simulations of the backscattered signal with an idealized
225 structure with the dimensions of the biggest size class replicated fairly the echo
waveform obtained from measurements (see Figure 1 below-right). The simula-
tions showed the common feature of a higher central maximum, and the relative
difference between the first and third maximum, being the last bigger one. The
temporal distance between the maxima responded to slight changes in the sim-
230 ulated positions of fish bone and swimbladder, and also reflected the masking
of the first maximum when the pulse duration was increased to 12 periods, or
alternatively when the sizes of the inner structures were bigger.

3.3. Acoustical height measurements versus fish weight

The resulting average distance to the transducer of the selected traces for our
235 measurements was 73 and 84 cm for the ventral and dorsal cases respectively.
The -3 dB diameter of the beam at such distances were 40 and 50 cm, assuring
that fish were totally insonified. The number of pings in each trace was between
7 and 12. Approximately 50 % of selected traces had symmetrical shape; the
rest accomplished the maximum slope criterium exposed above.

240 In the case of ventral measurements, SNR improved from 23.5 to 36.4 dB
by applying cross-correlation with the excited signal; it was observed in a high
number of traces (up to 90 %) the appearance of echoes derived from the swim-
bladder and the dorsal interface of the target, as it is outlined in Figure 3. In
addition, the previous echo maximum, associated with the ventral interface,
245 turned up in a significant number of the cases (mainly for the biggest fishes),
most of the studied specimens presented a masking of this kind of maximum.
Even in the cases that the echo maximum associated with the ventral interface

was observed, its amplitude was always lower than the amplitude of the maximum corresponding to dorsal interface. Following the procedure explained in the Materials and Methods section, the distance between the maximum amplitude peak (attributed to the swimbladder interface) and the latter detected local maximum was determined, and a *mean ventral acoustical height* (*VAH*) was established for each group of sea breams as given in Table 1.

Regarding the measurements obtained by means of dorsal insonification, the characteristic echoes provided, in a lower number of traces, information attributed to the swimbladder and the ventral interface responses with a similar waveform structure to those shown in Figure 3. The SNR in the case of dorsal measurements was significantly lower than the ventral ones (improving with correlation from 10.7 to 18.1 dB), and the number of discarded pings was thereby higher. The detection of the latter secondary maximum was much more seldom than for the ventral case which can be observed in the number of valid pings (about a 70 % of the total number analysed) shown in Table 2. This characteristic could be associated with scattering phenomena due to the different shapes of the upper and lower contours of the sea breams, the different influence of fish bones, etc. In spite of this, a mean *dorsal acoustical height* (*DAH*) was established for every size class of fish as given in Table 2.

The dependence of weight versus the measured quantities (*VAH* and *DAH*) is depicted in Figure 4 showing high correlation coefficients in both cases with an exponential adjustment. The obtained expressions are: for ventral measurements, $W = 0.0464 VAH^{4.8228}$, with a correlation coefficient $R^2 = 0.9849$, and for the dorsal case, $W = 2.7794 \times 10^{-5} DAH^{9.4357}$, with a correlation coefficient $R^2 = 0.9976$. Notice in Figure 4 how mean *VAH* increases more rapidly than mean *DAH* with fish weight.

3.4. Statistical modelling of measured acoustical heights

We have studied the measured value distributions for each weight class, showing that the *acoustical heights* follow a probability distribution that fits a Gumbel distribution model. Considering different weights, we obtained dif-

ferent distributions but the same pattern. The different weights are associated with the same model of distribution but with different parameters depending on weight. In Tables 1 and 2, the sample size (n), the mode and the scale parameters of the fitted Gumbel model, the p-value for the Kolmogorov-Smirnov test, the theoretical means and standard deviations computed from the model are shown, considering the different weights for *DAH* and *VAH*, respectively. Figure 5 shows the adjusted Gumbel-like models for the ventral case and the correlations of the model mean value VAH_G with the sampled mean height (H) and alternatively with the sampled mean length (L) for each class. The adjustments are given by the following relations: $L = a \times 10^{b*VAH_G}$ with $a = 4.0602$, $b = 0.1326$ and $R^2 = 0.9927$; $H = a \times 10^{b*VAH_G}$ with $a = 1.2024$, $b = 0.1435$ and $R^2 = 0.9938$, with absolute errors below 1%. Similar results are obtained for the dorsal case (not shown).

4. DISCUSSION

4.1. Biometric relationships

Fish weight for all growing stages of the collection of aquacultured gilt-head sea breams can be predicted from fish height using the obtained biometric model of Figure 2. It should be noticed how fairly the prediction interval for the average fish weight (dashed lines) reproduces the variability of the real data and the high value of the regression coefficient for the minimum quadratic adjustment. Obviously, the obtained expression would depend on the particular genetics of the produced fish and their condition, as it is common to all biometric relationships, and should be tuned for each particular exploitation.

4.2. Measured "acoustical heights"

Echoes received by the transducer are originated from the reflections due to a change of impedance in the transmission medium. The larger echo amplitude can be attributed to the reflection from the fish swimbladder. In this case, the gas inside the bladder results in a high impedance change and therefore a

great amount of energy is reflected to the transducer. Regarding the previous and later peaks, these should correspond respectively to the water-to-fish ("entrance") and fish-to-water ("exit") interfaces. The interface water-tissue implies a minor impedance change and accordingly provides less energy to the returned
310 echo than the swimbladder. These phenomena are reflected in the difference of amplitudes among the maxima constituting the single fish echo.

The measurement of fish height by TOF techniques would be always limited by the spatial resolution of the acoustical setup. Fish vertical dimensions would depend on its size and its orientation, and the precision in the measurement of
315 the water-to-fish and fish-to-water interfaces would be affected by the possible superimposition of the corresponding echoes with those produced by other inner structures. As it can be seen in the x-ray image of a gilt-head sea bream in Figure 1 (upper-left panel), the swimbladder is slightly tilted as it is common in several species, thus extending its contribution to the echo amplitude along the vertical
320 direction.

The combination of the spatial resolution and the fish morphometrics allowed the measurement of distances related to biometric dimensions not considered initially, such as an averaged distance from swimbladder to the fish back (when measuring the ventral aspect) or to fish belly (from dorsal measurements).

325 The exact reproduction of the echo waveform characteristics in the experiment was not the objective of the performed numerical trials. Being cautious about the origin and result of the different backscattered waves superimpositions (e.g. head bone mixed with tissue boundaries), and aware of the differences with more realistic fish geometries, the simulations provided the necessary confidence
330 to assume that the method allowed us to obtain an alternate *acoustic height*. The exponential expressions obtained for both VAH and DAH offered very good correlation coefficients with fish weight, offering the VAH measurements a wider value interval for the measured weight collection. This fact supports the hypothesis that *VAH* is related to biometrics of the upper part of the fish, whilst
335 *DAH* integrates information of the fish belly, since sea breams exhibit positive allometric growth [20], increasing faster the dorsal part of the fish than the

ventral one. It can also be observed that the mean values adjust to the weight evolution in spite of being the standard deviations of the measured *acoustical heights* for each weight are quite high (up to 14 and 18 % for dorsal and ventral measurements, respectively).
340

The p-values obtained for the Kolmogorov-Smirnov test, when analysing the statistical modelling of the measured *acoustical heights* are always much greater than 0.05, with the only exception of *VAH* values associated with weight 194 g. The setting to a Gumbel distribution model is then statistically significant, and in most cases, the mean and the standard deviation of the adjusted models
345 are similar to the mean and the standard deviation obtained from the samples, respectively. We must see the importance of the direct relationship of both measured *acoustical heights* to fish height (and also to fish length) as evidenced in Figure 5. This is an evidence of the interrelation of the different fish dimensions. It must also be noted the low number of echoes needed to fit the probability
350 distribution models, in clear contrast with target strength based methods [9] which would require much longer recording times.

4.3. Applicability to production conditions and broadband techniques

The approach presented here infers fish size for a given fish orientation (dorsal or ventral aspect) of a confined swimming fish. The variability in the fish
355 orientation is directly projected into the dispersion of the measured *acoustical heights* and probably revealed by the different parametrization of the obtained Gumbel distributions for the different sizes. Nevertheless, their means arise as robust indicators of fish size. Fish orientations were determined in this experiment both by the beam aperture and the limited dimensions of the cage, that
360 conditioned fish behaviour (with direct connection with their size), but also by the criteria of trace selection in the echogram (like in Figure 3).

Two questions arise when considering the applicability of the method to production conditions: first, the behaviour in a bigger cage of fish would produce a
365 bigger dispersion of fish trajectories. Second, the associated high densities make difficult to obtain single fish tracks. Usually fish swim circularly in aquaculture

cages, but they do it in a variety of trajectories not necessarily horizontal, occasionally performing vertical excursions. Our method extracts information about fish dimensions from selected fish traces in the echogram, those corresponding
370 to fish swimming more closely to a perpendicular trajectory to the acoustic beam axis. In our experimental setup, the cage was small and the activity of fish reduced in comparison with production conditions, and therefore most of the tracks were horizontal, but we did select those traces from the echogram corresponding to the desired fish trajectories. The method can be generally
375 applied to an echogram of production conditions taking into account that only symmetrical traces in the echogram correspond to horizontal fish trajectories and that those with limited slope in the echogram can correspond to limited slope in their physical trajectories. The fact that the acoustical fish height measurements fit a Gumbel distribution is an indication of the minimum condition
380 of the measurable height if the fish is horizontal (perpendicular to beam axis), and the dispersion around that value is a consequence of the slight deviations from the desired fish orientation. Nevertheless the good fits obtained between manually sampled fish length and height versus the mean of the Gumbel fitted model for the acoustically measured height (Figure 5) assure good size estimations. The use of a split-beam system could add a stronger selection criterion
385 by determining fish trajectory orientation and its relative position to beam axis, thus reducing dispersion in measurements.

The observation of individual fish traces has been a common problem in fisheries acoustics when estimating the biomass of a school and it was preferred
390 to obtain *in situ* measurements of TS for such a purpose. The common method has been to obtain fish traces from fish on the periphery of schools or in less dense portions of school, these may not be representative of the total [28]. In any case this approach should be tested to evaluate its validity with farmed fish, selecting fish tracks from above or below the dense shoal. Transducer's beam
395 aperture is another key point to consider on this question. A wider aperture (like the one used in the present work) would allow to insonify close fishes completely, above or below the school, and a narrower one could separate fish

tracks at longer distances. A compromise on this subject should be explored in production conditions.

400 The spatial resolution of the employed technique is quite limited because of the use of narrow band pulses, being close to the distances to be resolved with the smallest fish sizes and species under study, but it could be easily improved using chirp signals. The resolution function of the emitted frequency sweep bandwidth BW is then given by $c/2BW$, being c the sound speed in
405 the host medium. This is a new feature of the next generation of scientific echosounders (like Simrad-Kongsberg EK80), that can extend its application to all sizes of aquacultured fish, and therefore to any of the production cycles of commercial intensive exploitation in floating cages. It must be mentioned that the measurement of fish structures dimensions could also be used as an species
410 differentiation variable for the development of complementary stock assessment algorithms in fisheries acoustics.

5. CONCLUSIONS

Full waveform analysis of fish echoes allowed us to obtain direct information of gilt-head sea bream morphometrics and to relate this information to fish
415 weight. The measuring scheme (from sea surface or from cage bottom) does not have a practical influence on the viability of the fish weight estimation based on a TOF method. Future steps should now be taken both to the application of the presented technique in aquaculture production conditions, with higher fish densities, size and orientation distributions dispersions, as well as the extension
420 of the technique to other aquacultured species.

Table 2. *Acoustical height* measurements from dorsal aspect (DAH) and its adjustment to a Gumbel-like distribution model.

Figure Captions

Figure 1. a)) Upper panel, left: x-ray image of a gilt-head sea bream weighing 330 g. The swimbladder appears as a dark area below the spine. b) Lower panel, left: Correlated full waveform of a single sh echo shape for a central ping in a typical trace for the biggest sea bream size class measured in the experiment. c) Upper panel, right: Simplified geometry of a 3D axisymmetric sh used for numerical simulations. Semimajor axis of the ellipse corresponds to wave incidence direction. d) Lower panel, right: Correlated full waveform obtained from a numerical simulation with the main simplified structures of gure c) with a 10 cycles incident pulse. Ventral incidence result is plotted both for experimental measurement and numerical simulation.

Figure 2. Sampled weight (W) versus height (H) plotting for 1019 aquacultured specimens of gilt-head sea bream (dots). The solid line represents the minimum quadratic adjustment of the data. The dashed line represents the 95% confidence interval for the average of the measured weights for the same fish height. The dotted line represents the 95% confidence interval for a new weight prediction for a given height.

Figure 3. An idealized representation of a fish trajectory and the corresponding trace formation in the echogram as shown. We plot the obtained correlated waveforms for each ping, depending on its position in the selected trace.

Figure 4. Mean fish class weight versus both mean ventral and dorsal *acoustical heights* (labelled VAH and DAH, respectively).

Figure 5. a) Upper: Probability density functions (PDF) following a Gumbel-like model of mean *ventral acoustical heights* for each size class. b) Lower: Linear representations for the correlation between the sampled mean length (height) of each size class and the mean obtained from the Gumbel model for the *ventral acoustical height (VAH)* distribution.
