Textural properties of a food are that group of physical characteristics that arise from the structural elements of the food, are sensed primarily by the feeling of touch, are related to the deformation, disintegration, and flow of the food under a force, and are measured objectively by functions of mass, time, and distance [2]. It is known that the sensations experienced as the food material deforms and fractures during the initial stages of biting/chewing govern our acceptance or rejection of the product [1]. In this way, textural parameters can be considered as an attribute to assess acceptability and quality of products.

There are few studies of textural properties of dried and rehydrated foodstuffs, in special Mexican plums. Thus, the purpose of this work was to study the evolution of texture properties during rehydration process of plum slices dehydrated by tray drying and freeze drying.

## **2. Materials and Methods**

### **2.1 Raw material**

Mexican plums (“beetroot” ecotype) were obtained from Orizaba and Coscomatepec, Veracruz, Mexico and selected according to the ripening degree (30 % green, 70 % red).

The plums were washed and cut into slices of 3 cm of diameter and 0.2 cm of thickness for tray drying (TD) and 1.4 cm of diameter and 0.2 cm of thickness for freeze drying (FD). For freeze drying, the plum slices were frozen at -20 °C during 2 hours.

## 2.2 Drying process

Hot air drying was performed in a pilot scale vertical tray dryer (MOD-SEM-2 Polinox, MX) at air temperature of 53 °C during 4.5 h. The freeze drying was conducted in a laboratory scale dryer (Mod-742004 Labconco, USA) at 0.1 mbar vacuum pressure during 4.3 h<sup>[10]</sup>.

## 2.3 Texture Profile Analysis

The texture profile analysis (TPA) was performed on fresh, dehydrated and rehydrated slices of plum using a Texture Analyzer (CT3-100, USA). TPA involved properties as hardness, cohesiveness, springiness and adhesion and was carried out by two compression cycles and operating conditions of the equipment were selected according to the drying method applied in order to reach a right compression of the product. Cylindrical probes were used to perform TPA tests (25.4 mm diameter, 35 mm length for TD; 12.7 mm diameter, 35 mm length for FD). Table 1 shows operating conditions used for each size of slice, with its respective drying method.

*Table 1. Operating TPA conditions*

Operating conditions	Tray drying		Freeze drying	
	Fresh/ Rehydrated	Dehydrated	Fresh/ Rehydrated	Dehydrated
Trigger (N)	0.01471	0.01471	0.01471	0.01471
Deformation (mm)	1	1	2	1
Speed (mm/s)	1.2	1	1.5	1

Rehydration of plum slices was performed in water and milk at 10, 20 and 30 °C. For TPA test an amount of 7 slices were added to the immersion media. Every 5, 10, 15, 20, 25, 30 and 35 min a different slice was taken out, drained in absorbent paper and set in the texture analyzer to measure the texture parameters during rehydration. Every experiment was made by triplicate.

## 3. Results and discussion

### 3.1 Texture analysis of rehydrated freeze dried plums

Differences on texture properties during rehydration (Fig. 1 and 2) can be attributed to the swelling and the leaching of solubles also these results can be explained based on the fact that at short times of rehydration, samples are not still equilibrated with the presence of

great gradients of moisture content from surface to centre [9] and in consequence, affecting to the measure of texture profile.

Graphics (Fig. 1 and 2) show texture properties of freeze dried plum during rehydration and its variation with respect time. Analysis of variance (ANOVA) and the test of mean comparison (Dunnett) were conducted with a level of significance of 0.05. Texture properties of fresh plum were selected as the control. Final value of hardness (water, 10 °C) had no significant differences compared with fresh plum. In contrast there were significant differences at higher rehydration temperatures.

With respect to rehydration in milk, final values of hardness remained unchanged at the end of rehydration process with every temperature. Cohesiveness at 10 and 30 °C of plum rehydrated in water showed similar values than non-dried plum. On the other hand, rehydration in milk allowed to reached final cohesiveness values with no significant difference for all the temperatures used.

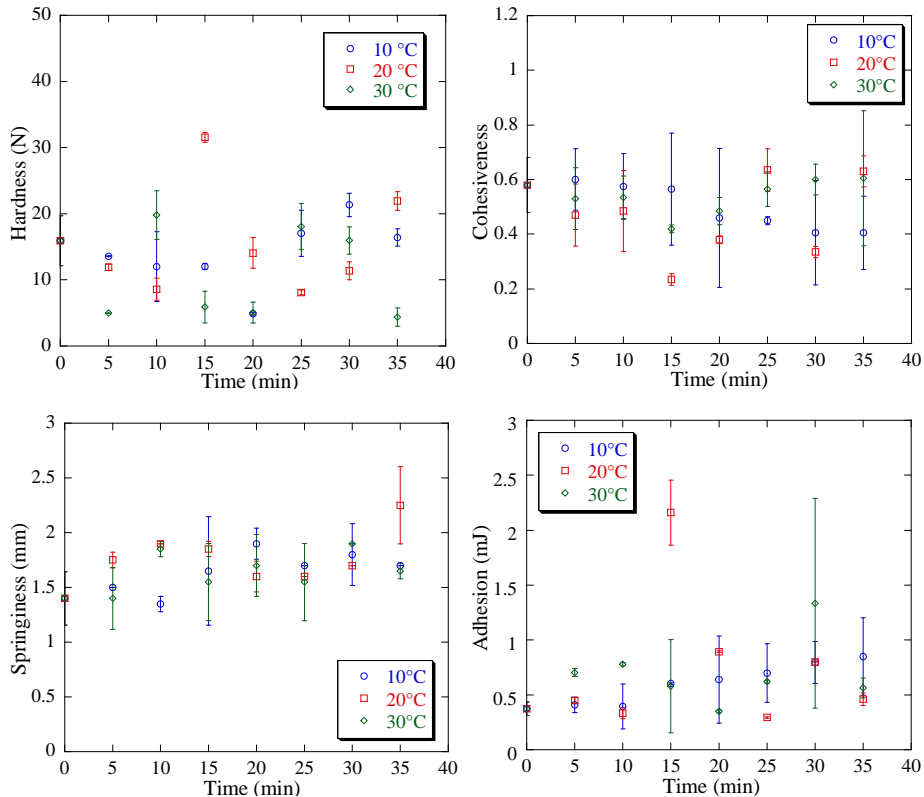

Fig. 1 Textural properties during rehydration of freeze dried plum immersed in water.

**Fig.2 Textural properties during rehydration of freeze dried plum immersed in milk.**

Springiness characteristics only showed significant differences at the ending of the rehydration in water at 20 °C, increasing from 1.5 to 2.25 mm. Slices of plum rehydrated in milk kept similar springiness than fresh ones. Adhesion characteristics had no significant differences in final values for both rehydration medias and rehydration temperatures.

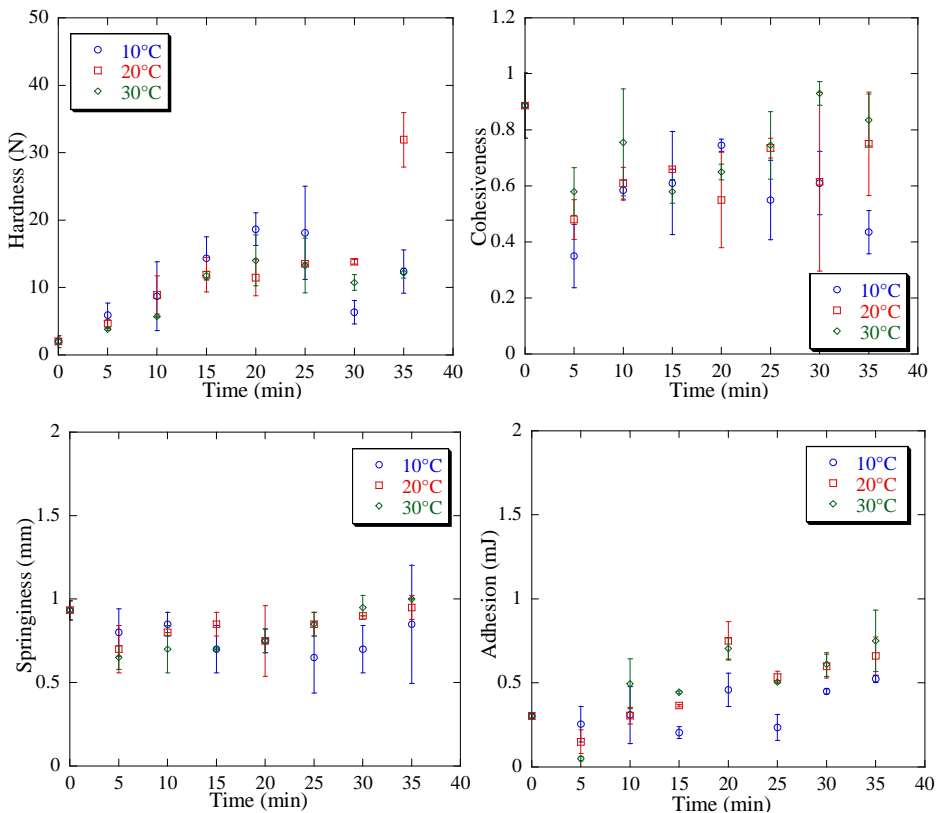

### 3.2 Texture analysis of rehydrated hot air dried plums

Textural properties of hot air dried slices of plum during rehydration and its variation with respect time are presented in Fig. 3 and 4. Statistical analysis indicated that hardness of plum rehydrated in water (10 and 30 °C) had no changes compared to fresh product. Milk immersion allowed to reach similar values at 10 and 20 °C. Cohesiveness final values presented no significant differences for water rehydration of plum. Milk immersion presented only significant differences at 20 °C. With respect to springiness, final values after immersion in water showed differences at 30 °C. In contrast, milk rehydration at the three temperatures used, presented higher values that were significantly different from fresh

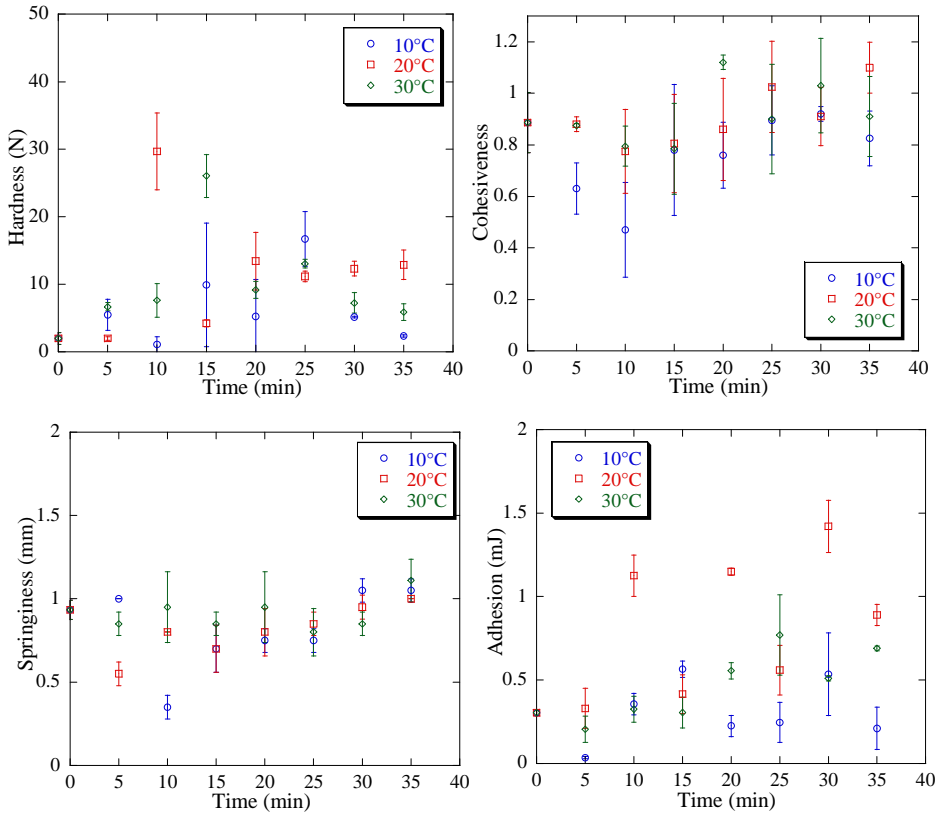

plum. Finally, adhesion for plum rehydrated in water was similar to fresh one at 10 °C; milk immersion reached the same characteristics at 10 and 20 °C.

As can be seen, there were variations of texture properties during and at the end of rehydration process, it can be attributed to the drying method used. According to Meda and Ratti [8], hot-air drying usually destroys the food thus, the final air dried products have a compact structure and a reduced volume, which can explain a non-uniform restoration of its original form, and as a consequence, variations during texture evaluation.

Assesment of texture profile of rehydrated plum slices allowed to see a clear influence of the drying methods. Freeze dried slices of plum presented less differences when compared to the fresh fruit. In contrast plums dehydrated by hot air, showed more variations on texture properties during rehydration. These differences were attributed to the tissue collapse and cell damage produced by higher air temperatures [11].

**Fig.3 Textural properties during rehydration of hot air dried plums immersed in water.**

*Fig.4 Textural properties during rehydration of hot air dried plums immersed in milk.*

#### 4. Conclusions

The texture studies were carried out on fresh, dehydrated and rehydrated plum slices, determining the parameters of hardness, cohesiveness, springiness and adhesion. Plum slices dehydrated by hot air presented more significant differences with respect to fresh plum that were attributed to the high temperatures during drying producing more structural damage as a consequence. On the other hand freeze drying allowed to reach texture characteristics close to fresh plum at the end of the most rehydration experiments. Finally it was possible to conclude that TPA provides valuable information not only after dehydration but also rehydration and application in freeze dried and hot air dried products, as plums, assures to the consumers a product with high quality and similar texture as fresh one, increasing its potential as snacks and cereal-based products.

### **Abstract**

*Artisanal fresh cheese is a type of cheese from Hispanic origin and one of the most consumed; however, its shelf life is short due to its pH is close to neutrality, high  $a_w$  and low salt content. The fluidized bed drying was employed as an efficient alternative to fresh cheese; however, in order to achieve the desired shelf life in a product, it is necessary to study different packaging and storage conditions that will depend on the specific characteristics of the product. A design of factorial experiments  $2^3$  was adopted, the storage study was carried out for 90 days, studying two qualitative variables: type of packaging and type of atmosphere in the packaging, and one quantitative variable: drying temperature.*

**Keywords:** *Dehydrated cheese; storage; water activity; type of packing.*

---

## 1. Introduction

Artisanal cheese is the most recognized cheese of Latin American origin and the most consumed internationally. Fresh cheeses have short shelf life because of their pH (near to neutrality), the high water activity and the low salt content. Usually, the shelf life of fresh cheese under refrigeration is seven days[3,5]. For this reason, fluidized bed drying was employed as an efficient alternative to preserve perishable food[4]. However, the need for proper packaging for traditional products has pushed to design packaging conditions according to the characteristics of each food[2]. Shelf life is an important feature of all foods and it may be define as the period that the food retains an acceptable level of eating quality from a safety and organoleptic point of view[10]. It is well known that vacuum packaging not only reduces the incidence of oxidative damage and inhibits aerobic bacteria, but also preserves sensory quality in foods, because under vacuum conditions, oxygen in the package headspace is reduced to <1%, maintaining stable moisture and water activity[6]. For this reason, vacuum packaging is an interesting alternative to storage in dehydrated samples as cheese.

## 2. Materials and Methods

### 2.1 Drying process

The artisanal cheese was obtained from a cheese making group located in the city of Tlalixcoyan, Veracruz, México. A fluidized bed dryer (Model Restch TG-200) was employed for the drying process. Drying conditions for this study were selected according to results reported by Domínguez-Niño *et al.*<sup>[4]</sup> (air temperature of 50 and 60 °C, drying time of 60 min and particle size of 2 cm).

### 2.2 Packaging of dehydrated cheese

The dehydrated cheese samples (12.1 g), were packaged in two types of packing (13.2 x 9.5 cm) made out of polyethylene and metalized with 30  $\mu$  thickness. The samples were sealed by means of a vacuum packing machine (Food saver model sealing system FSFSSL3880) under atmospheric conditions: air and vacuum (VP).

### 2.3 Physicochemical characterization

Moisture content: The moisture content was determined using an infrared moisture balance (MA35 SARTORIUS, Germany), at 65°C and 1 g of cheese.

Water activity ( $a_w$ ): the dehydrated cheese samples were analyzed at 25 °C using Aqualab water activity meter (model SERIES 3 TE, DECAGON, Washington).

Color difference: the sample color was measured by colorimeter of HunterLab (model MiniScan XE plus, Associates Laboratory, Retson, VA, USA). The equipment was calibrated with white and black standards tiles. The experimental color was determined by reflectance mode and expressed by  $L$ ,  $a$  and  $b$  parameters. The color difference ( $\Delta E$ ) was calculated using the following equation reported by Lozano-Acevedo et al.<sup>[8]</sup>.

$$\Delta E = \sqrt{(\Delta L)^2 + (\Delta a)^2 + (\Delta b)^2} \quad (1)$$

Where  $\Delta L = L$  of dried sample at storage time -  $L$  of initial dried sample,  $\Delta a = a$  of dried sample at storage time -  $a$  of initial dried sample and  $\Delta b = b$  of dried sample at storage time -  $b$  of initial dried sample.

Protein, sodium chloride and fat content: the protein content of the stored cheese was determined by a standard Kjeldahl method, using a nitrogen conversion factor of 6.38 for dairy products. Sodium chloride was assessed following the method described by James[7] and fat content was quantified by extraction method using Soxhlet equipment.

## 2.4 Experimental design

A mixed experimental design 2<sup>3</sup> was used. In this design two qualitative variables were analyzed type of packing (polyethylene and metalized) and atmosphere type (air and vacuum), and, as a quantitative variable, drying temperature of 50 and 60°C, thus making a total number of eight experimental storage condition (Table 1).

*Table 1. Experimental storage conditions of dehydrated cheese*

Experiment	Drying temperature (°C)	Packing type	Atmosphere
1	50	Polyethylene	Air
2	50	Polyethylene	Vacuum
3	50	Metalized	Air
4	50	Metalized	Vacuum
5	60	Polyethylene	Air
6	60	Polyethylene	Vacuum
7	60	Metalized	Air
8	60	Metalized	Vacuum

## 3. Results and discussion

### 3.1 Moisture content

Figure 1 shows the evolution of moisture of dehydrated cheese under different storage conditions (Table 1). The statistical analysis using the Dunnett test ( $\alpha=0.05$ ) shows less

significant differences in the samples that were dehydrated at 60°C. The increase in moisture

Figure 1. Evolution of moisture content in dehydrated cheese stored under different conditions: a) air and b) vacuum.

### 3.2 Water activity

Figure 2 shows the results obtained from the evolution of water activity of dehydrated cheese during storage at different conditions. The statistical analysis using the Dunnett test ( $\alpha = 0.05$ ) showed the existence of significant differences in the stored cheese with respect to the initial samples. The dehydrated samples at 60°C and stored under vacuum conditions were maintained below 0.6 units during the 90 days of storage, which can assure that the cheese is free of microbial growth and enzymatic deterioration.

Similar results were found by Akarca et al.[1] who reported that vacuum packaging prolongs the microbiological quality of mozzarella cheese for a considerably longer period of time.

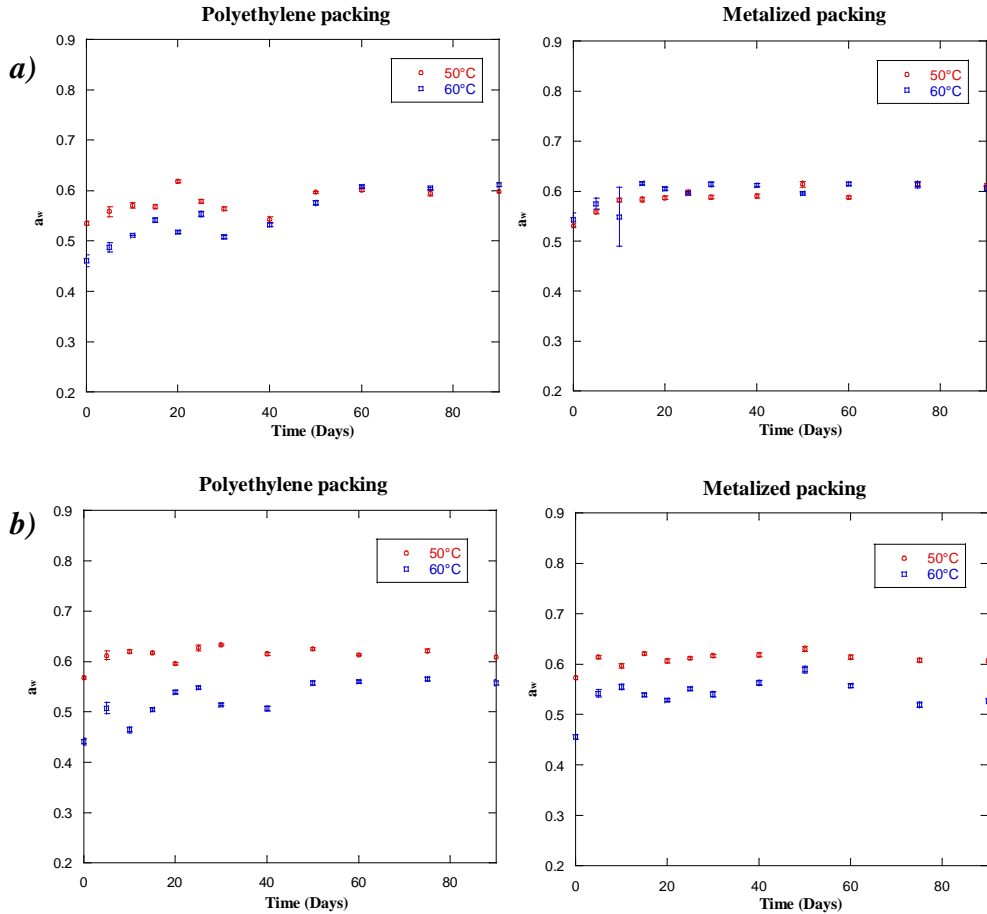

Figure 2. Evolution of water activity in dehydrated cheese stored under different conditions: a) air and b) vacuum

### 3.3 Color difference

Figure 3 shows the results obtained for the color difference during storage at different conditions. The statistical analysis using the Dunnett test ( $\alpha=0.05$ ) indicated significant changes among the different storage conditions.

During storage, a slight increase in *a* values and a clear increase in *b* values were observed. Therefore, a tendency towards yellowing occurred. According to the literature, dehydrated

foods lose color due to the oxidation of highly unsaturated molecules once exposed to light, air and chemical changes<sup>[9]</sup>.

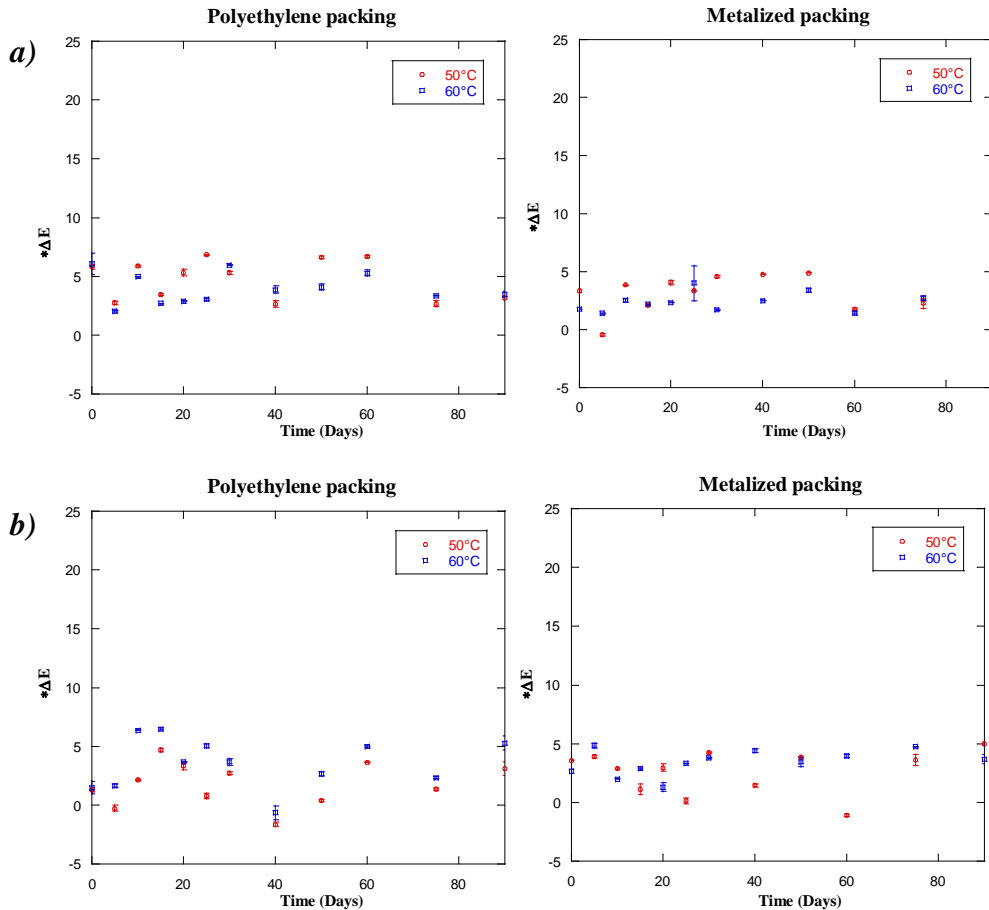

Figure 3. Evolution of color difference in dehydrated cheese stored under different conditions: a) polyethylene and b) metalized.

### 3.4 Protein, fat and sodium chloride content

During the drying process the concentration of proteins, fat and NaCl in the cheese samples increased considerably due to the elimination of water in the product. The cheese samples showed a decrease in the content of proteins, fat and NaCl after storage with respect to the sample analyzed at time zero, 40.4477, 35.8573 y 3.2901% (Table 2). The analysis of variance ( $\alpha=0.05$ ) showed that the drying temperature had influence on the protein and fat content at the end of storage, this can be attributed to the gain of moisture during storage.

The results may indicate that the conditions of use of the storage reduce the oxidation reactions in the dehydrated cheese. The use of vacuum packaging has shown to maintain stability in parameters such as color and fat and protein content, maintaining its physicochemical quality.

*Table 2. The experimental results of protein, sodium chloride, fat content of dehydrated cheese at the end of storage period.*

<b>Experiment</b>	<b>Protein content (%)</b>	<b>Fat content (%)</b>	<b>NaCl content (%)</b>
<b>01</b>	37.9848	41.1643	3.0947
<b>02</b>	38.0924	38.2357	3.1295
<b>03</b>	38.4578	41.2845	3.2236
<b>04</b>	38.0628	39.4582	3.0568
<b>05</b>	40.1912	38.7047	3.6326
<b>06</b>	39.5431	40.4399	3.4123
<b>07</b>	40.2083	41.1547	3.4072
<b>08</b>	40.1238	37.6055	3.469

#### 4. Conclusions

According to the results obtained in this study, samples packed in vacuum and dehydrated at 60 °C were found to be adequate for storage for 3 months, because they obtained the lowest moisture gain and maintained water activity below 0.6 units allowing to guarantee the stability of the product. The content of proteins, fat and NaCl was maintained during the storage period, ensuring the physico-chemical quality of the dehydrated cheese. Finally, dehydrated cheese can be used as a snack or as an ingredient in traditional food because it has similar characteristics to the fresh cheese.

### Abstract

Dehydration is widely involved in tobacco processing such as tobacco leaf curing, tobacco trip redrying and cut tobacco drying, which plays a key role due to its effect on the physical and chemical quality of tobacco. The current drying methods in tobacco processing mainly use heat conduction, heat convection or their combination to dehydrate tobacco materials. However, radiation heat transfer as one of basic heat transferways has not been investigated in the tobacco drying. In the present work, infrared radiation dryer was designed to explore the tobacco infrared radiation drying characteristics. The effect of radiation heat transfer conditions and vacuum on the drying kinetics and temperature of tobacco leaves was investigated. Diffusion coefficient of middle tobacco leaves C2F is between  $0.848 \times 10^{-10} \sim 1.597 \times 10^{-10} \text{ m}^2/\text{s}$ . At the same time, the pore structure and petroleum ether tobacco extracts in dried tobacco were also analyzed in order to explore the different effects of infrared radiation drying and traditional drying technology on tobacco quality.

**Keywords:** Flue-cured tobacco; Infrared radiation; Vacuum; Drying kinetics; Tobacco quality

---

## **1. Introduction**

In tobacco primary processing, drying plays a key role due to its effect on the physical and chemical quality of tobacco<sup>[1]</sup>. Therefore, to explore new drying method is always the focus of tobacco processing technology. In terms of heat transfer ways, the current drying methods in tobacco processing mainly use heat conduction, heat convection or their combination to dehydrate tobacco materials. However, radiation heat transfer as one of basic heat transfer ways has not been investigated in the literatures involving tobacco drying. The infrared-vacuum drying, infrared-hot air drying and infrared-heat pump drying, have been investigated and applied in the argo-processing such as seeds, vegetables and fruits<sup>[2-8]</sup>. Many results have showed that the infrared radiation drying could improve the drying efficiency, reduce the shrinkage of dried materials and maintain the nutrient and functional components when compared to the traditional hot-air drying method. Whereas, there is little work on the infrared radiation heat transfer in the current tobacco industry, especially in the tobacco primary processing. Considering this, in the present work, two kinds of infrared radiation dryer were designed to explore the tobacco infrared radiation drying characteristics, including the fixed bed dryer and cylinder dryer. The effect of radiation heat transfer conditions and vacuum on the drying kinetics and temperature of tobacco leaves was investigated.

## **2. Materials and Methods**

### **2.1 Materials**

The flue cured tobacco C2F from Luoyang of China were chosen as experimental materials. Tobacco leaves were pretreated into cut tobacco by a cutter. The raw material is pretreated as follows: by adding a calculated amount of distilled water to cut tobacco, and moisture content of cut tobacco was adjusted to the desired level of moisture content. In this work, moisture content of the testing cut tobacco was set as 30% (on the wet basis). After adjusting the moisture content, cut tobacco was bagged and put into isothermal and equal humidity equipment to balance moisture for 48h.

### **2.2 Experimental apparatus**

The structure of infrared-vacuum drying apparatus was shown in Fig.1. The drying chamber size is 45\*45\*45 cm. 4 pieces of ceramic radiant panel with the size of 12\*12 cm were arranged in the rectangular on the top of drying chamber. A temperature sensor is installed on ceramic radiant panel and connected to the temperature controller unit, which could control the radiation temperature with the precision of  $\pm 1$  °C. A vacuum pump with the swept volume of 4 L/s (S.T.P.) is connected to the drying chamber through exhaust line. The pressure of drying chamber is adjusted and controlled by the flow meter and vacuum

meter in exhaust line. A weighing sensor with the precision of 0.1g is set at the bottom of drying chamber. During the drying experiments, the radiation heat transfer conditions and vacuum degree can be flexibly adjusted according to requirements.

**Fig.1 Infrared-vacuum drying apparatus. 1 The bottom of cabinet; 2 Vacuum pump; 3 Buffer vessel; 4 gas flow meter; 5 Vacuum meter; 6 Temperature display panel; 7 Bracket; 8 weighing sensor; 9 Material plate; 10 the upper of cabinet; 11 radiant panel; 12 weight display panel; 13 radiation temperature sensor; 14 material temperature sensor; 15 temperature controller**

### 2.3 Experiment methods

Before drying, the radiation temperature and distance are set as the desired levels. Then the apparatus is preheated for 30 min until the stable radiation temperature is reached. The sample of 35g cut tobacco is put into a thin layer on the material plate and then placed on the bracket of weighing sensor. The vacuum pump is started and pressure of drying chamber is adjusted to the desired level. During drying of cut tobacco, the mass and temperature data of sample are collected at the frequency of 30s until the constant weight of sample is reached. Four levels of radiation temperature are investigated, and they are 353 K, 368 K, 383 K and 398 K. The pressure of drying chamber is investigated at the levels of 30 kPa, 45 kPa, 60 kPa and 75 kPa (absolute pressure).

## 3. Results and discussion

### 3.1 Infrared-vacuum drying curves of cut tobacco

The moisture and temperature evolution of cut tobacco were investigated at different levels of radiation temperatures, as shown in Fig.2. It can be seen that, when radiation temperature changed from 353 K to 398 K, the drying times of samples were reduced by 50% (when cut

tobacco was dehydrated to the moisture content of 12%). The temperature of cut tobacco during drying also has an increasing trend at higher radiation temperature, and the final temperature of sample has a slight increasing.

Fig. 2 Effect of radiant temperature on cut tobacco moisture content and temperature

The moisture and temperature evolution of cut tobacco were investigated at different levels of vacuum degrees, as were shown in Fig.3. As can be seen, the vacuum degree has opposite influence on the drying rate and temperature of cut tobacco. Low pressure, namely high vacuum degree, resulted in the increasing of drying rate and the decreasing of final sample temperature. The effect of vacuum degree was associated with its impact on the following two aspects. On the one hand, high vacuum degree could increase the difference of vapor partial pressure between the internal and external of wet materials. At the same time, high vacuum degree also leads to the low boiling point of water, which reduces the evaporation temperature of water during drying. The synthetic effect of the above two aspects caused that drying rate increased and final sample temperature decreased when vacuum degree is increased.

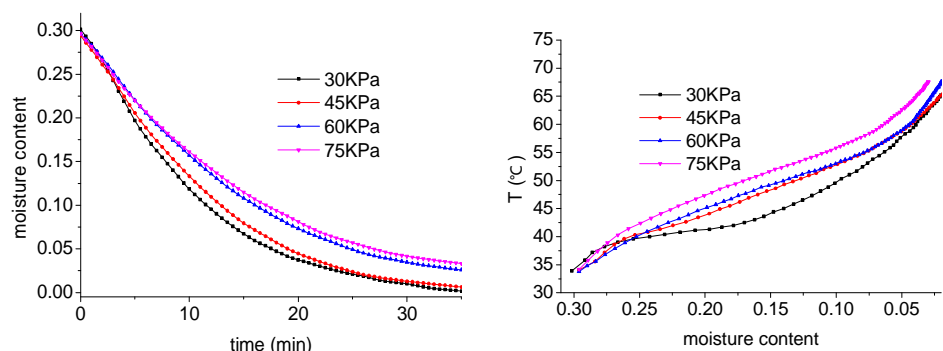

Fig. 3 Effect of vacuum level on cut tobacco moisture content and temperature

### 3.2 Moisture diffusion coefficient of cut tobacco

According to the Fick's second law<sup>[9]</sup>, the following diffusion equation was used to describe the variation of cut tobacco moisture.

$$\frac{M - M_e}{M_0 - M_e} = \frac{8}{\pi} \sum_{n=0}^{\infty} \frac{1}{(2n + 1)^2} \exp\left[-\frac{(2n + 1)^2 \pi^2 D_e t}{4L^2}\right] \quad (1)$$

Where,  $M_0$ ,  $M$  and  $M_e$  are the moisture content of cut tobacco at  $t=0$ ,  $t=t$  and  $t=\infty$ , respectively. The  $D_e$  is the effective diffusion coefficient of cut tobacco. The  $t$  is drying time.  $L$  is half of cut tobacco width. In the above equation, the  $M_e$ , as equilibrium moisture content of cut tobacco at the drying condition, could be neglected. The  $L$  is 0.5mm. The first three terms were taken into account to calculate the effective diffusion coefficient<sup>[10]</sup>. The calculated values of  $D_e$  for two kinds of tobacco were shown in Table 1. It can be seen that the diffusion coefficient of tobacco during infrared-vacuum drying increased with the increasing of radiation temperature and vacuum degree. The radiation temperature has more significant influence on diffusion coefficient than vacuum degree. The diffusion coefficient of middle tobacco leaves C2F is between  $0.848 \times 10^{-10} \sim 1.597 \times 10^{-10} \text{ m}^2/\text{s}$ .

*Table 1. The  $D_e$  experimental values of cut tobacco*

Radiation temperature / K	Vacuum degree / kPa	$D_e (\times 10^{-10}) / \text{m}^2 \cdot \text{s}^{-1}$
353	30	0.8409
368	30	1.0317
383	30	1.2657
398	30	1.5529
383	45	1.1049
383	60	0.9645
383	75	0.8419

### 3.3 Pore structure in dried cut tobacco by different drying methods

The microstructure of dried cut tobacco was analyzed by SEM. Different drying methods were compared, including infrared-vacuum drying, infrared drying and traditional hot air drying at 55°C. The results were shown in the Fig.4. It can be seen that both the infrared-vacuum drying and infrared drying resulted in the porous microstructure in the cross section of cut tobacco. This indicated that the infrared radiation heat transfer decreased the pore drying shrinkage of pore structure compared to the traditional hot air drying, as could be related to the penetrating heating characteristics of infrared radiation.

Fig. 4 Pore structure of cut tobacco C2F by different drying methods: (a) dried by infrared radiation and vacuum, (b) dried by infrared radiation, (c) dried by hot air

### 3.4 Petroleum ether tobacco extracts in dried tobacco

The petroleum ether tobacco extraction mainly consists of volatile oil, resins, fatty acids, waxes, lipids, sterols, and pigments. Its content is often considered as an important index in estimating the quality of tobacco aroma. The petroleum ether tobacco extraction in dried cut tobacco by different drying methods was analyzed, as shown in the Table 2. It can be seen that the infrared radiation heat transfer improved the content of petroleum ether tobacco extraction compared to the traditional hot air drying. The tobacco aroma change during drying mainly could be related to two factors. The one is the Maillard reaction in tobacco during drying, which led to the increase of aroma components. The other one is the evaporative loss of volatile flavor components. The infrared radiation heat transfer may be more beneficial to the Maillard reaction than the hot air drying. However, the vacuum would cause the increasing loss of volatile flavor components. The effect of two aspects resulted in that the petroleum ether tobacco extraction content for infrared-vacuum drying is higher than that of hot air drying, while lower than that of infrared drying.

Table 2. The petroleum ether extract content

Drying methods	petroleum ether extract content / %
Before drying	3.95
Hot air drying	4.01
Infrared-vacuum drying	4.23
Infrared drying	4.67

## 4. Conclusions

The infrared-vacuum drying characteristics of flue-cured tobacco leaf were investigated. Drying quality of tobacco was analyzed by comparing to the traditional hot air drying. The results showed that the average drying rate and final temperature of cut tobacco increased

with the increasing of radiation temperature. The vacuum degree has opposite influence on the drying rate and temperature of cut tobacco. Low pressure, namely high vacuum degree, resulted in the increasing of drying rate and the decreasing of final sample temperature. Diffusion coefficient of middle tobacco leaves C2F is between  $0.848 \times 10^{-10} \sim 1.597 \times 10^{-10}$  m<sup>2</sup>/s. The infrared radiation heat transfer decreased the pore drying shrinkage of pore structure compared to the traditional hot air drying. The infrared drying resulted in the higher petroleum ether tobacco extraction content than infrared-vacuum drying and hot air drying.

### Abstract

Moisture sorption isotherms of the habanero pepper powder were determined using the Dynamic Vapor Sorption (DVS) method at 20, 25, 35, 45 and 55 °C in a range of water activity from 0.10 to 0.90 at which the processes of drying, packing and storage of habanero pepper are developed. The sorption capacity decreased with increasing temperature at a given water activity and the sorption isotherms showed a sigmoid form (Type II). The hysteresis phenomenon was observed in the sorption isotherms at all temperatures studied and it was more pronounced at temperatures high. The experimental sorption curves were fitting to the GAB, BET and Oswin models. It was concluded that the models that best describe the adsorption and desorption data for habanero pepper dehydrated powder were the GAB and Oswin models. The isosteric heat of water sorption was calculated with the moisture content data in equilibrium. The desorption isotherms present a higher isosteric heat in relation to the adsorption isotherms. In both, the isosteric heat decreased as the moisture content increased.

## 1. Introduction

Habanero pepper is a variety of red pepper most popular in the Mexican territory, it has a high moisture content (> 80 % wet base) and the main characteristics of the habanero are color (carotenoids), aroma and mainly the pungencia due to the capsaicinoids [1,2]. Therefore, the export and conservation of fresh fruit have several disadvantages because habanero pepper is very perishable and has a limited shelf life. Convective drying is one of the most popular and efficient heat and mass transfer process that allows to prolong and preserve the useful life of foods by reducing water activity ( $a_w$ ) and decreasing moisture content [3]. The state of water plays an important role in the preservation of food. The degree of sorption of water from a food system depends on the vapor pressure of the water present in the food sample and in the surroundings. The equilibrium moisture content (EMC) is obtained when the vapor pressure of water present in food is equal to the vapor pressure of the surroundings. The water activity ( $a_w$ ) of a food is an equilibrium property of the water and its constituents present, which defines as the ratio of the partial pressure of the water vapor in the food ( $p$ ) and the partial pressure pure water vapor ( $p_0$ ) at the same temperature, as shown in equation 1:

$$a_w = \frac{p}{p_0} = \frac{HR}{100} \quad (1)$$

The relationship between EMC and  $a_w$  in a range of values at a constant temperature generates an evaluation tool very useful called "Moisture sorption isotherm", which relates the amount of water adsorbed or desorbed in equilibrium. An adsorption isotherm refers to the behavior of dehydrated foods, which tend to adsorb water against the surrounding relative humidity to have equilibrium pressures. While a desorption isotherm refers to the behavior of hydrated foods, which tend to eliminate water to have equilibrium conditions at a given temperature. These behaviors depend on the interaction between water and food components. Sorption isotherms provide information for a variety of processing applications and product stability, such as prediction of moisture transfer, determination of product stability and shelf life, storage conditions, selection of packaging systems [3, 4, 5]. Therefore, the aim of this study was to analyze the isotherms (adsorption and desorption) of the habanero pepper dehydrated powder.

## 2. Materials and Methods

### 2.1. Raw material and convective drying of habanero pepper

Habanero pepper was obtained from the city of Orizaba, Veracruz, Mexico. The selected fruits showed an orange color and similar size (4-7 cm length, 3-5 cm width). Samples of habanero pepper were cut into slices 0.6 cm wide and placed on metal trays of a convective

dryer (Polinox SEM-2). The convective drying process was performed at a temperature of 60°C and at an air velocity of 1.5 m/s for 360 min until moisture  $\geq 0.05$  g water/g dry solids is constant. The data obtained from drying at 60 °C was plotted as moisture ratio (MR) according to the equation 2:

$$MR = \frac{X - X_e}{X_0 - X_e} \quad (2)$$

Where  $X$  is the moisture content at any time  $t$ ,  $X_e$  is the equilibrium moisture and  $X_0$  is the initial moisture. These experimental sets ( $MR, t$ ) were fitted to different empirical models from literature applicable to agricultural products: Page, Newton, Henderson & Pabis, Logarithmic and Wang & Sing. These equations for drying kinetics are indicated below (equations 3 to 7), respectively.

$$MR = e^{-kt} \quad (3)$$

$$MR = e^{-kt^n} \quad (4)$$

$$MR = a \cdot e^{-kt} \quad (5)$$

$$MR = c + a \cdot e^{-kt} \quad (6)$$

$$MR = 1 + a \cdot t + b \cdot t^2 \quad (7)$$

Where  $n$ ,  $a$ ,  $b$  and  $c$  are constants of the models, and  $t$  is any time in the drying kinetics.

## 1.2. Physicochemical analysis

During the convective drying process of dehydrated habanero pepper, the evolution curves of water activity and color difference were performed. The water activity was determined at  $25 \pm 1$  °C using a water activity meter (AQUALAB series 3 model TE). The moisture content (g water/ g dry solids) of habanero pepper was measured with a halogen thermobalance (OHAUS, model MB35).

## 1.3. Moisture sorption isotherms

Habanero peppers were milled in a manual pulverizer of blades at laboratory scale, model GRT-20B of 3000 Watts and 25000 rpm for 3 min to obtain samples of habanero pepper powder to analyze moisture sorption isotherms. The sorption isotherms (adsorption and desorption) were determined by a vapor sorption analyzer (AquaLab VSA), which consists of an equipment that automatically generates moisture sorption isotherms in foods,

allowing the determination of the complex relationship between  $a_w$  at each reading and the EMC of the sample at a constant temperature. The isotherms were determined at 20, 25, 35, 45 and 55 °C. The VSA equipment generates the static isotherms in equilibrium by the Dynamic Vapor Sorption (DVS) method, which consists of monitoring the weight change of the sample as it is exposed to different controlled relative humidities. The sample is maintained at each humidity for a period of time until the sample reaches a steady state weight change, where the objective is to achieve the equilibrium between the  $a_w$  and the controlled humidity inside the generator chamber. The experimental sorption isotherms of the habanero chili powder were performed in duplicate.

#### 1.4. Prediction of mathematical models

The mathematical models GAB (Guggenheim & Anderson de Boer), BET (Branauer, Emmett & Teller) and Oswin represented by equations 8, 9 and 10 were used to adjust and predict the experimental values of sorption isotherms (adsorption and desorption).

$$EMC = \frac{CKX_m a_w}{(1 - Ka_w)(1 - Ka_w + CKa_w)} \quad (8)$$

$$EMC = \frac{CX_m a_w}{(1 - a_w)(1 - a_w + Ca_w)} \quad (9)$$

$$EMC = A \left[ \frac{a_w}{(1 - a_w)} \right]^B \quad (10)$$

Where: A, B, C and K are constants of the models,  $a_w$  is the water activity, EMC is the equilibrium moisture content (g water/g dry solids) and  $X_m$  is the moisture content in the monolayer (g water/g dry solids).

#### 1.5. Net isosteric heat of sorption

The net isosteric heat of sorption was determined from moisture sorption using the equation 11, derived from the Clausius Clapeyron equation:

$$\ln(a_w) = - \left( \frac{q_{st}}{R} \right) \frac{1}{T} + C_1 \quad (11)$$

Where  $a_w$  is the water activity,  $T$  is the absolute temperature (K),  $q_{st}$  is the net isosteric heat of sorption (J mol<sup>-1</sup>), R is the gas constant (J mol<sup>-1</sup> K<sup>-1</sup>).

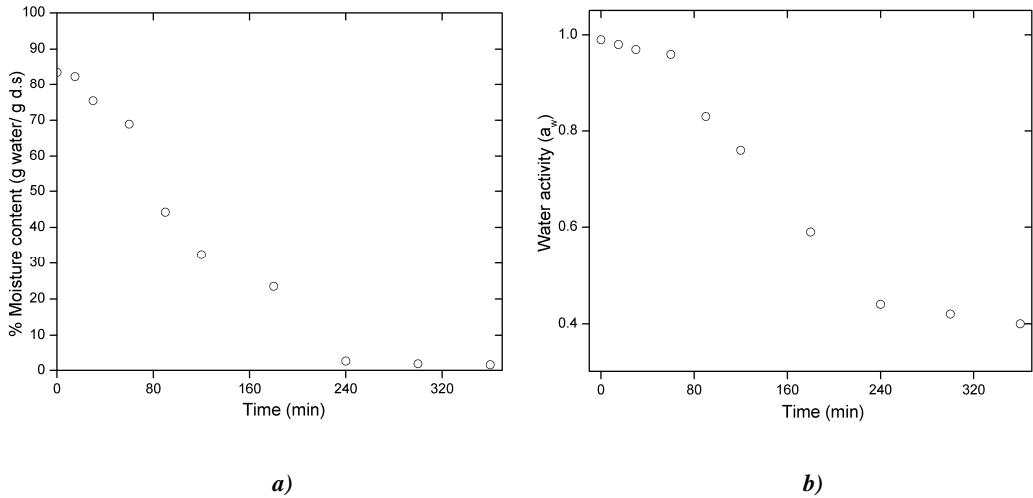

#### 1.6. Results and discussion

Figure 1 and 2 show the adjustment of the mathematical models of the drying kinetics and the evolution curves of  $a_w$  of habanero pepper during drying as a function of time, observing that the  $a_w$  and moisture content of the fresh fruit is relatively high. However, when the drying process is performed, the values of moisture content and  $a_w$  decreased significantly. A food with an  $a_w$  less than 0.60 and moisture content low is considered safe and stable during storage in relation to microbial growth [6]. The  $a_w$  is considered a parameter for the conservation and stability of food as well, it has been used as an important variable to evaluate and reduce the rate of microbial growth, chemical reactions, lipid oxidation and enzymatic activity in the food [5].

**Figure 1. Fitting of the experimental data with the different models tested**

Figure 1 shows the experimental data points obtained from temperature 60 °C of the drying process together with the plots corresponding to the fittings obtained for all the models tested. It is observed that the Page and Newton curves are better describing the habanero pepper drying process. On the other hand the models of Henderson & Pabis and Logarithmic do not represent the initial state ( $t=0$  min), while the Wang & Singh model does not exemplify the final state ( $t=360$  min). However, the best model to describe this drying kinetics process is the Page model because it shows a sigmoidal shape in the curve. In Figure 2(a), it is possible to observe how the moisture behavior follows a sigmoidal shape, which is characteristic of the drying process. The initial moisture content was 83.59% and the final content 1.56%. Regarding water activity in Figure 2(b), shows also a sigmoidal shape and it is possible to reach a safe range (below 0.6) at time 180 min.

**Figure 2. Drying curves for physicochemical parameters of habanero pepper: a) moisture content and b) water activity**

The shapes of the adsorption and desorption curves of habanero pepper dehydrated powder showed a behavior similar to the five temperatures (20, 25, 35, 45 and 55 °C) studied and presented a non-linear trend type II (sigmoid) typical shape for most foods [7], which is shown in Figure 3. As the temperature increases, the EMC decreased to a constant water activity, this change generates that the water molecules are activated due to a change in the increase in the pressure of the water vapor inside the particles of habanero pepper powder through a state of excitation, becoming less stable and consequently accelerating the moisture transfer of the food around it [8]. In addition, it was observed a simultaneous increase of the EMC because the food particles are saturated by water molecules according to an incremented in the values of water activity at a constant temperature. This is due to the decrease in the degree or capacity of sorption of water in habanero pepper powder when the temperature increases. In the process of desorption, it was observed that the high and intermediate values of the water activities in the desorption curves of habanero pepper powder present a remarkable decrease of the EMC due to the dissipation of the water molecules present in the surfaces towards the surroundings. This indicates the influence of temperature on the desorption isotherms. However, it is also shown that the desorption curves between low values of  $a_w$  (0.3-0.1) and the EMC are very close to each other. This means that the water molecules bind more firmly and the enthalpy of vaporization is greater due to the transition of the water that is strongly attached to the capillaries of habanero pepper powder.

Figure 3. Isotherms of habanero pepper: a) adsorption and b) desorption

The GAB, BET and Oswin models were fitted to evaluate the behavior of moisture sorption isotherms and the goodness of fit for each model was evaluated according to the coefficient of determination ( $R^2$ ), sum of the square error (SSE) and the residual mean square error (RMSE). The results of the non-linear regression analysis are presented in Table 1. The best fits were obtained with the GAB and Oswin models with a  $R^2 > 0.995$  and  $R^2 > 0.987$ ,  $SSE < 7.705$  and  $19.91$ , for  $RMSE < 1.133$  and  $1.687$  respectively for the sorption isotherms of habanero pepper dehydrated powder. However, the GAB model presents an advantage due to it presents theoretical bases and the value of moisture content in the monolayer ( $X_m$ ) whereby it is best model that empirical model of Oswin. The net isosteric heat of sorption ( $q_{st}$ ) decreased with increasing moisture content. The higher values of  $q_{st}$  were found at low moisture contents, this can be explained by the fact that the water molecules are tightly bound to the monolayer structure and food components; and therefore, the quantity of energy needed to adsorb or desorb these water molecules is very high. However, a rapid decrease in sorption isosteric heat was observed when the moisture content began to increase due to the sorption of water molecules in the multilayer. The isosteric sorption heat of habanero pepper powder, which was determined using the Clausius-Clapeyron equation, decrease with an increase of moisture content, ranging from  $4.86 \text{ KJ mol}^{-1}$  to  $1,07 \text{ KJ mol}^{-1}$  and  $7.59 \text{ KJ mol}^{-1}$  to  $1,43 \text{ KJ mol}^{-1}$  for adsorption and for desorption with an equilibrium moisture content ranging from 5 to 45% (g water/g dry solids).

## 2. Conclusions

The isotherms of adsorption and desorption of habanero pepper dehydrated powder presented a sigmoid shape (Type II) at five different temperatures: 20, 25, 35, 45 and  $55^\circ \text{C}$ . According to the results of this study, the GAB model presents a better fit of the

experimental results of the sorption isotherms of the habanero pepper powder with a  $R^2 > 0.995$ ,  $SSE < 7.705$  and  $RMSE < 1.133$ . Habanero pepper powder was less hygroscopic as the temperature decreased. This behavior of sorption can be attributed to the low solubility nature of carbohydrates and bioactive compounds present in habanero pepper powder with water molecules. Water activity values from 0.3 to 0.4 represent the optimum moisture content at which most dehydrated foods will have maximum shelf life. Therefore, considering 0.35 as the average water activity, among these values, the safest for dehydrated habanero pepper powder, the limit equilibrium moisture content for this product should be 7.38%, 7.13%, 6.79%, 6.50% and 6.04% at temperatures of 20 °C, 25 °C, 35 °C, 45 °C and 55 °C respectively, since above this moisture content, enzymatic oxidation, chemical instability and/or oxidation will begin proliferation of microorganisms. Regarding drying kinetics, according to the obtained results, it was concluded that the empirical models that best describe the dehydration kinetics for habanero orange bell pepper are Page and Newton.

### **Abstract**

*X-ray computed tomography technique was used to observe microstructure formation during freeze-drying. A specially designed vacuum freeze-drying stage was equipped at the X-ray CT stage, and the frozen and dried microstructures of dextrin solutions were successfully observed. It was confirmed that the many parts of the pore microstructures formed as a replica of the original ice microstructures, whereas some parts formed as a consequence of the dehydration dependent on the relaxation level of the glassy phases, suggesting that the post-freezing annealing is advantageous for avoiding quality loss that relates to the structural deformation of glassy matters.*

**Keywords:** freeze-drying; X-ray CT; ice microstructure; glassy state

## 1. Introduction

Freeze-drying is known as one of the best drying methods in terms of preservation of product qualities. Due to its higher processing cost than the other drying method, quality assurance is a critical issue to meet requirements of industries. Detailed knowledge on the phenomena occurring in a freeze-drying system plays an important role in further improvement of process design. Freeze-drying process consists of freezing and drying steps. When an aqueous solution is subjected to freezing, an ice crystal phase coincidentally forms with the freeze-concentrated phase. In most cases of freeze-dried formulations, the freeze-concentrated phase transforms into a glassy phase, and the water content in the glassy phase can be related to the temperature. The glass transition temperature ( $T_g$ ) of the maximally freeze-concentrated glassy phase is commonly denoted as  $T_g$ , and this temperature has a critical importance in terms of carrying out an appropriate freeze-drying run. During drying step, water is mainly removed from the ice crystal phase by sublimation (i.e. primary drying). The removal of water coincidentally forms dried layer, and the subsequently sublimated water vapor must transfer through the dried cake layer with porous microstructures. The mass transfer resistance in the cake layer is thus controlled by modifying the ice crystal morphologies.<sup>[1-3]</sup> Water is also removed from the freeze-concentrated glassy phase by vaporization (i.e. secondary drying) at above  $T_g$ . The viscous flow of the glassy phase may cause the loss of the dried layer structure that is called as collapse. The occurrence of collapse is thus provoked by the excessive increase of the product temperature and/or decrease of the evaporation rate.<sup>[4-8]</sup> Furthermore, it must be noted that the glassy phase in a rapidly frozen solution is not perfectly freeze-concentrated because of the formation of the non-crystallized water (i.e. vitrified water).<sup>[9-11]</sup> Annealing over  $T_g$  reduces the fraction of the amorphous phase toward the completion of the freeze-concentration; this is called as relaxation (glassy phase relaxation). The degree of the relaxation relates to the  $T_g$  and viscosity of the glassy state, and it would affect the dehydration rate from the glassy phase and consequently the strength of the dried layer. Therefore, the freeze-dried microstructure forms not only in the freezing step but also in the drying step. The formation of freeze-dried microstructure in the sufficiently freeze-concentrated frozen solution would be different from the one in the immature frozen solution. Our interest in this study was thus to investigate the influence of the glassy state relaxation on the microstructure formation during freeze-drying.

X-ray computed tomography (CT) is a powerful tool to visualize microstructure of a material without sample destruction. In this study, X-ray CT was used to observe microstructure formation during freeze-drying. Our interests in this study is to investigate the primary and secondary drying behavior by using in-situ CT technique with monochromatized X-ray from the synchrotron radiation. A freeze-drying system was set-up at the X-ray CT

stage, and the microstructure change during vacuum freeze-drying of dextrin solution was observed.

## **2. Materials and Methods**

### **2.1. Materials**

Millipore-purified water was used for the sample preparation. Sucrose was purchased from Wako Pure Chemical Industries (Osaka, Japan). Dextrin was donated by Matsutani Chemical industry Co., Ltd. (Hyogo, Japan). Dextrin of which dextrose equivalent (DE) equal to 11 was used in this study. Glass transition temperatures of the maximally freeze-concentrated aqueous dextrin solution ( $T_g$ ) measured by DSC was around  $-11^{\circ}\text{C}$ .

### **2.2. Frozen sample preparation**

Aqueous dextrin solution with a concentration of 20 % (w/w) was prepared and filled in a sample stage. Sample stage was composed of a metal base (made by stainless steel) and a plastic tube (diameter 6 mm, height 10 mm). The tube was attached on the metal base to make a space for putting a solution. The bottom of a solution contacts to the metal part. The sample stage with a sample solution was placed on a copper block pre-cooled in liquid nitrogen so as to freeze inner solution rapidly with keeping its direction of freezing from the bottom to the top. Frozen solutions were subsequently annealed at  $-5^{\circ}\text{C}$  in an electric cooling devise for selected duration (0–12 h). Frozen samples were then stored in a refrigerator at  $-90^{\circ}\text{C}$  until measurement.

### **2.3. Synchrotron X-ray computed micro tomography**

X-ray computed tomography was carried out at synchrotron facility SPring-8 (BL19B2, Hyogo, Japan). Monochromatized X-ray was used for this measurement in order to obtain X-ray attenuation linear coefficient from the tomograms. The X-ray energy was adjusted to 12.4 KeV by a double Si-crystal monochromator (net plane: (111)). As schematized in Fig. 1, the measurement stage was equipped with a turntable with a cold finger of which temperature was controllable by an external air blowing device in the range of  $-80$  to  $-10^{\circ}\text{C}$ . The sample stage with a frozen sample was rapidly fixed on the sample stage pre-cooled at around  $-15^{\circ}\text{C}$ . The sample stage on the turntable was then fully covered with a housing case, and the inner space was evacuated by connecting a vacuum pump in order to start freeze-drying. The top of this housing component was made by acrylic resin with a thickness of 0.5 mm. The X-ray passed through this acrylic window and the sample, and then exposed to X-ray camera that was set 100 mm behind the housing component. An X-ray imaging unit (AA40, Hamamatsu Photonics K.K., Japan) and CCD camera (C4880-41S, Hamamatsu Photonics K.K., Japan)

were used for image acquisition. 256 transmission images were acquired for one set of measurement by rotating the turntable from 0 deg to 180 deg at a speed of 1.2 deg/s. The exposure time of X-ray was set to 0.12 s for taking an image, and the pixel size in the image was 2.92  $\mu\text{m}$  square. A horizontal cross-sectional image (i.e. tomogram) was reconstructed from the transmission image by the filtered back projection method. Freeze-drying run was carried out with the sample stage temperature at around  $-14^{\circ}\text{C}$ , inner pressure around 12 Pa.

Fig. 1 X-ray CT measurement set-up equipped with freeze-drying stage.

### 3. Results and Discussions

#### 3.1. CT images during freeze-drying

The freeze-drying runs were carried out and CT images were successfully captured by the present system. First of all, CT images taken from the frozen zones were compared in Fig. 2. The boundary between the ice and freeze-concentrated phases was obviously formed in the sample prepared via longer annealing. One reason is due to the ice crystal size increase by Ostwald ripening mechanism. Another reason is the progress of the freeze-concentration due to the glassy state relaxation. The details of these kinetics during annealing were investigated in a former study of the authors [12], suggesting that both the glassy phase relaxation and Ostwald ripening jointly control the ice crystal growth/ripening kinetics, and the dominant mechanism was depending on the stage of annealing. Furthermore, the progress of freeze-concentration increases the density of the phase, this contribute to increase the attenuation level in the CT image and make clear contrast with the ice phase. It was also suggested that the dextrin-water system required more than 20 hours of annealing time for the completion of the glassy phase relaxation.

Fig. 2 X-ray CT images of frozen specimens (vertical cross sections); (A) Annealed for 0h, (B) Annealed for 12 h, (C) Annealed for 30 h.

Fig. 3 X-ray CT images of freeze-drying specimens (the duration under vacuum was stamped in the images); (A1-3) Annealed for 0 h, (B1-3) Annealed for 12 h .

3D reconstructed images of the samples during freeze-drying were shown in Fig. 3. It was visibly confirmed from the images of the sample via 12 h of annealing that the ice crystals were removed from the system by maintaining the original architectures made by the freeze-concentrated phase (Fig. 3A). This observation agrees with conventional explanation of a freeze-drying mechanism where a microstructure in a freeze-dried matrix is a replica of the frozen microstructure. On the other hand, this was hardly observed in the images of the sample prepared without annealing (Fig. 3B). Although extremely fine porous structures were formed at the top part, the formations of specific large pores were obvious in this drying system. These large pores were not visible in the frozen zone, and randomly distributed in the sample geometry. Considering that the glassy phase in the non-annealed solution was not perfectly freeze-concentrated, the apparent vapor pressure of this phase is higher than the perfectly freeze-concentrated phase. The apparent water vapor pressure, this is not equilibrium thermodynamic pressure, of the glassy phase is observed lower as the value of  $(T - T_g)$  become smaller. This is because the properties of glassy phase is kinetically controlled.<sup>[7]</sup> Therefore, in the drying of non-annealed solution, water removal from this phase would be accelerated and easily lost its original microstructure.

### 3.2. Fractal dimension and lacunarity

The previous section discussed about the microstructure formation that occurred simultaneously with dehydration. In order to evaluate the differences in microstructures, the fractal dimension and the lacunarity of the porous microstructures were calculated from the images. Fractal dimension is a measure of structural roughness, whereas lacunarity is a measure of inhomogeneity or texture. In other words, lacunarity is the ratio of void space filled in a fractal structure. Cross sectional images were selected from the dried zone, and converted into binary images (Fig. 3). Image analysis was carried out on the binary images by a software *FracLac version 2015 for ImageJ*. The fractal dimension values for the non-annealed and annealed samples were both calculated as 1.8. The lacunarity values, on the other hand, for the non-annealed and annealed samples were 0.14 and 0.12, respectively. These values suggested that the structural difference between the non-annealed and annealed freeze-dried matrix was mainly due to the formation of the void space. The difference in the lacunarity values implies that the obvious void spaces seen in the non-annealed sample were not casted by ice crystals. Annealing in freeze-drying process has been recognized as a technique to reduce primary drying time and also to alter crystallinity and/or aggregation degree of the components<sup>[9, 10, 13-15]</sup> The result of this study suggested that these advantages of annealing are realized by avoiding the structural deformation as seen in the freeze-drying of the non-annealed sample, and largely relate to the degree of the glassy phase relaxation.

*Fig. 4 X-ray CT images of freeze-dried specimens (horizontal cross sections); (A) Annealed for 0h, (B) Annealed for 12 h. Binary images converted from A1 and B1 are shown at the bottom.*

#### 4. Conclusions

*In-situ* computed tomography technique with X-ray from the synchrotron radiation was used to observe microstructure formation during freeze-drying to investigate the primary and secondary drying behavior. A specially designed vacuum freeze-drying stage was equipped at the X-ray CT stage, and the frozen and dried microstructures of dextrin solutions were successfully observed. It was confirmed that the many parts of the pore microstructures formed as a replica of the original ice microstructures, whereas some parts formed as a consequence of the dehydration. This would relate to the relaxation level of the glassy phases. When rapidly frozen and non-annealed solution was subjected to freeze-drying, obvious deformation of the original ice microstructures could be provoked by the water removal from both ice and freeze-concentrated phases. Considering that the glassy phase in the non-annealed solution was not perfectly freeze-concentrated, water was rapidly removed from this phase and lost its original microstructure. It was suggested that the advantages of

annealing are not only to reduce primary drying time due to the modification of ice crystal morphologies but also to avoid quality loss that relate to the structural deformation of the glassy matters.

### **Abstract**

*Green Coffee Products (GCP) consumption have been increased recently and is justified due its benefits to human health, as the antioxidant activity and thermogenic properties and ant mutagenic and ant carcinogenic capacity and also present alleged weight loss control. The aim this work was to elaborate a GCP with Coffea canephora by spray drying and compare its antioxidant capacity to commercial GCP samples by ORAC methodology. The results presented a range of 33.02 – 2,408.05  $\mu\text{mol Trolox/g}$  for commercial products and 1,861.91  $\mu\text{mol Trolox/g}$  for the product obtained in this work.*

**Keywords:** Antioxidant Activity; Green Coffee; Spray Drying; ORAC.

---

## 1. Introduction

In recent years, the studies on the biological activity of green bean coffee and their beverages has been more encouraged and explored [1]. Green coffee beans differ in chemical composition according to species and origin. Coffee beans are composed of polysaccharides, lipids and proteins and as secondary compounds caffeine, trigonellin, chlorogenic acids, free sugars (mainly sucrose), free amino acids, diterpenes, melanoidines, among others [2]. However, during the coffee roasting process, several chemical reactions occur at the same time, from which some compounds are degraded, such as proteins, polysaccharides, and chlorogenic acids [3].

A cup of the roasted coffee drink is rich in different and complex bioactive substances, which can present antioxidant activity, being the beverage an important source of the consumption of natural antioxidants [4].

The process and formulation to obtaining food supplements from green coffee may be the differential, as the commercial products of dietary supplements based on green coffee has different formulations which uses various food materials sources of bioactive compounds. Besides the formulation and choice of raw material, since it is known that the robusta coffee beans (*Coffea canephora*) contains more acids chlorogenic than *C. arabica*, which plays an important role in the antioxidant capacity [5]. The product obtained in this work was composed only by green coffee extract from *C. canephora* and maltodextrin.

In addition to the consumption of the traditional coffee beverage made by infusion of roasted and ground coffee, green coffee extract (GCE), commercialized in different forms, such as capsules, flours or liquid extract, has gained a market share by the appeal of antioxidant activity and for the help in the weight loss process [6], since it contains 6 to 12% of chlorogenic acids, of which during the roasting process of the grain for the preparation of the traditional coffee beverage undergoes degradation [7]. In this way the aim of our study was elaborate a GCP with *C. canephora* by spray drying and compare its antioxidant capacity to commercial GCP samples.

## 2. Materials and Methods

### 2.1 Green Coffee Products

It was evaluated nine different products of commercial dietary supplements based on green coffee, purchased directly from Rio de Janeiro trade, in the form of capsules or flours and one GCP imported from USA, Figure 1A. A GCP 10 was elaborated under our laboratory conditions, Figure 1B.

Fig. 1. Market GCP analysed (A), GCP produced by spray drying

## 2.2 Extraction of bioactives compounds and production of green coffee dietary supplement by spray drying

For extraction of bioactives compounds of robusta coffee (*C. canephora*) the grains were grounded in an IKA grinder (A11) and sieved (480-680  $\mu\text{m}$ ). Then, the aqueous extract was according to a methodology adapted from Liu et al., (2010) [8], using a ratio of 0.11 g/mL (mass/volume) between green coffee and distilled water for the extraction of bioactive compounds in Hielscher model tip ultrasound with 200 watts power for 10 minutes with a sample immersed in an ice bath. After extraction, the samples were taken to the refrigerated centrifuge ROUTINE 38 at 7000 rpm for 14 minutes at 25°C to separate the solid phase.

In spray drying a first step is to evaluate if it is necessary use of carrier's agents. Priors tests indicating it is indispensable for protection from heat and facilitate its flow into the tower to prevent adherence of product to the equipment walls. The most commonly carrier used is the maltodextrin, a hydrolyzed starch widely that has a property of aiding the dispersion of a product and preventing its agglomeration pipelines. Maltodextrin DE10 (10% equivalent dextrose) was mixed with GCP extract (7 oBrix) using an ultra turrex forming an emulsion to be atomized in a spray dryer. The percentage of maltodextrin was established according to the solids content of extract in this case 70 grams per liter of extract. The spray-drying process was performed using a laboratory-scale Mini Spray Dryer Buchi B-290 (Buchi Labortechnik AG). The emulsion was fed at a flow rate of 0.96 L/h, co-current air flow rate of 25 kg/h and air inlet and outlet with temperatures of 170 °C and 90 °C, respectively, C, using a nozzle of 0.7 mm diameter. The powder product was stored into sealed metallic packaging and conserved at 25 oC until the moment of analyses.

## 2.3 Extraction of bioactives compounds of commercial products

The extraction of bioactive compounds of the commercial products analyzed in this work followed the same procedures described in the section 2.2 only modifying the ratio mass/volum to (0.067 g/mL).

## 2.4 Determination of antioxidant capacity by ORAC

The determination of antioxidant capacity by the Oxygen Radical Antioxidant Capacity, equation 1, was done according to Zulueta and collaborators [9] that consisted on the transfer of hydrogen from the antioxidant material (samples or Trolox) to the AAPH radical [2,2'-azobis amidinopropane], avoiding attacking the fluorescein present in the reactional medium. Samples were diluted in sodium phosphate buffer pH 7.4 and transferred to a 96-well microplate 80 µL. It was built a calibration curve, in triplicate, as well as the same amount of the samples besides the blank of the reaction, where 80 µL of phosphate buffer was applied. The plate was taken to the Infinite 200 model Tecan Fluorimeter spectrum at 37 °C programmed with excitation wavelength of 485 nm and emission wavelength of 535 nm. It was dispensed 80 µL of fluorescein solution and performed the excitation e emission reading. After initial reading, it was dispensed 40 µL of the AAPH radical solution and read excitation e emission of all wells at every 5 minutes for 90 cycles. The area under the curve (AUC) was calculated by software (Prism), using the fluorescence reading over the 90 cycles of the analysis. A Trolox AUC values were subtracted from the blank AUC and the differences used for the construction of the Trolox calibration curve. The linear and angular coefficients obtained in the calibration curve were used to quantify the samples.

$$Orac (\mu\text{mol Trolox} \cdot \text{g}^{-1}) = \frac{(AUC_{\text{sample}} - AUC_{\text{blank}}) - b}{a \cdot CA} \quad (1)$$

AUC sample = Area Under the Curve of the sample

AUC blank = Area Under the Curve of the blank

b = linear coefficient

a = angular coefficient

CA = Concentration of the sample in solution given in mg/L

## 2.5 Determination of caffeine and chlorogenic acid contents in GCP

The determination of caffeine and chlorogenic acid were conducted in triplicates by HPLC Alliance 2695 with PDA detector 2996, with 280 nm and software Empower® (Waters,

Massachusetts, EUA). The chromatographic column used was a BDS Hypersil C18 (5cm x 4,6mm e 3 $\mu$ m – Thermo Scientific, Massachusetts, EUA), according Rosa and collaborators [10]. The quantification of both analytes were performed by external standardization base on calibration curves made with commercial analytical standards.

### **3. Results and Discussion**

The results of antioxidant capacity determined by the ORAC methodology ranged from 33.02  $\mu$ mol trolox/g to 2,408.05  $\mu$ mol trolox/g, which shows the heterogeneity of the products (Figure 2). The range of antioxidant capacity of the GCE likely to be due to variation in the formulation of products containing other sources of compounds that exert antioxidant function [11]. The products 2, 3 and 5 showed low range of antioxidant capacity. The GCE supplement elaborated in this study (sample 10) showed an excellent antioxidant potential when compared to commercial green coffee products, besides presenting only coffee and maltodextrin in its formulation. Compared to 9 products analyzed, the product obtained in this work (Sample 10) presented third best antioxidant activity against commercial products.

Liang and collaborators [12] analyzed the antioxidant capacity of green arabic coffee beans from the Dominican Republic, Peru, Sumatra, Papua New Guinea and Ethiopia and obtained values of 410; 450; 420; 380 and 410  $\mu$ g trolox equivalent/gram.

A great variation in the values of antioxidant capacity from GCP samples were observed, probably due to the different raw material, formulation and ways of processing to obtain each GCE. This information is emphasized through caffeine and chlorogenic acid results obtained by HPLC in our green coffee product. Since our GCP, sample 10, presented greater values for caffeine and chlorogenic acid (Figure 3).

The antioxidant capacity of dietary supplements based on green coffee plays an important role which refer to quality of this products since the marketing of this products is around the antioxidant capacity.

Figure 2. Antioxidant capacity of green coffee products

Figure 3. Caffeine (A) and chlorogenic acid (B) contents in green coffee products

#### 4. Conclusions

A product of green coffee extract was elaborated in this work (Sample 10) with great antioxidant capacity .

A great variation in the values of antioxidant capacity from GCP samples were observed, probably due to the different raw material, formulations and ways of processing to obtain each GCP.

The antioxidant capacity of dietary supplements based on green coffee plays an important role which refer to quality of this products since the marketing of this products is basen on their antioxidant activity.

### **Abstract**

*The aim of this work was to verify the influence of drying on physical and chemical characteristics of residues from rice milk production. Residues were from the production of white, red and black rice. They were dehydrated in an oven with air circulation at 60°C for 8h. Characterization of them were carried out by physical and chemical analyses. Residues have presented statistical difference for all parameters measured. Its characterization is necessary to justify its use in other process or application on new products. The residues from rice milk production have high content of nutrients and phenolic compounds, even after dehydration.*

**Keywords:** *Nutrients; Oryza sativa; waste.*

---

## **1. Introduction**

Rice is one of the most consumed cereal in the world, mainly in Asian countries<sup>[1]</sup>. Its success is related not only on its nutritional quality or its practicality and applicability on food industry, but also on some characteristics that this grain present, like absence of allergenic substances and gluten<sup>[2]</sup>. In addition, rice has presented in its composition a high amount of proteins, mineral salts and B vitamins, and a low percentage of lipids, which confer a great nutritional value to the grain and make it a source of energy<sup>[3,4]</sup>.

There are many variety of rices, and some of them, like red or black rice, are source of compounds important for human nutrition. Red and black rice can be considered a source of important compounds for human nutrition and health, such as phenolic compounds, anthocyanins, catechins, and fibers<sup>[5,6,7]</sup>.

Vegetable milk is considered an option for dairy products. It is defined as an aqueous extract made by vegetable raw materials<sup>[8]</sup>. Comparing with cow milk it stand out based on its composition, that presents low fat, cholesterol free, and high percentage of proteins and energy<sup>[9]</sup>. In addition it is lactose free<sup>[10]</sup> and made by vegetables, so lactose intolerants and vegans can drink it.

Although vegetable milk is an important food product for consumers, its process generate some residues. Those residues produced still has important compounds which can be used in human diet. An alternative is the dehydration of this material and its application in many other food products. Thus, food industries could reduce its waste of resources on the environment.

The dehydration of residues from food industries is a way to preserve this material by loss of water, however processing and storage conditions have to be studied with the aim of preserving nutrients and bioactive compounds. So, it can be inserted in formulations of many kinds of foods, such as cereal bars, cakes, biscuits, among others.

Thereby, the aim of this work was to verify the influence of drying on physical and chemical characteristics of residues from the production of rice milk.

## **2. Materials and Methods**

Residues were from the production of vegetable milk based on white, red and black rice. They were dehydrated in an oven with air circulation at 60°C for 8 hours. The characterization of them were carried out by analyses of moisture, ash, lipids, proteins, carbohydrates, total caloric value, Aw, pH, titratable acidity and phenolic compounds.

Moisture content was quantified according to AOAC<sup>[11]</sup>. Samples were submitted to an oven with air circulation (70°C for 24 hours) and results expressed in percentage of moisture in wet basis. Ash was carried out by incineration in muffle oven at 550°C<sup>[11]</sup>, and results expressed in percentage of ash. Lipid was carried out by cold extraction<sup>[12]</sup> and expressed as percentage of lipids. The determination of protein was done by micro Kjeldahl method and results calculated by conversion factor for rice (5.95) and expressed as percentage of proteins. Carbohydrate was calculated by difference (Nifext fraction). Total caloric value was calculated by multiplied values of lipid, protein and carbohydrate by Atwater constants and expressed in kcal/100 grams. Water activity (Aw) was carried out by direct measurement in digital hygrometer (Aqualab, Decagon, 3.0 Serie). pH was measured directly with potentiometer, by dilution of 10 g of sample in 100 mL of distilled water. Titratable acidity was determined by titulation with sodium hydroxid<sup>[11]</sup> and expressed in percentage.

For determination of phenolic compounds, extracts were made according to Rufino et al.<sup>[13]</sup>. The phenolic compounds were determined by Folin and Ciocalteu method<sup>[14]</sup>, developed by Singleton and Rossi<sup>[15]</sup>, with gallic acid as standart. Results were expressed as mgEAG/g.

All analyses were carried out in triplicate and datas were submitted to variance analyse and compared by Tukey test, with 5% of significance.

### 3. Results and Discussion

Residues from vegetable milk based on white, red and black rice (Fig. 1) have presented statistical difference ( $p \leq 0.05$ ) for all parameters measured (Table 1 and 2).

*Fig. 1 Dehydrated residues from processing of vegetable milk based on white (a), red (b) and black (c) rice.*

**Table 1. Characterization of residues from processing of vegetable milk based on white, red and black rice (part I).**

Rice	Moisture (%)	Ash (%)	Lipid (%)	Protein (%)	Carbohydrate (%)
White	4.11±0.10 <sup>b</sup>	0.45±0.01 <sup>c</sup>	0.45±0.07 <sup>b</sup>	7.56±0.32 <sup>c</sup>	87.43±0.49 <sup>a</sup>
Red	7.85±0.56 <sup>a</sup>	0.99±0.04 <sup>b</sup>	2.05±0.13 <sup>a</sup>	12.39±0.08 <sup>a</sup>	76.73±0.64 <sup>c</sup>
Black	2.13±0.04 <sup>c</sup>	1.19±0.07 <sup>a</sup>	1.81±0.16 <sup>a</sup>	10.75±0.02 <sup>b</sup>	84.12±0.06 <sup>b</sup>

Values in the same column followed by the same letter do not differ by Tukey test at 5% of probability.

According to the composition of residues, protein value is an important parameter that can be observed. Residue from red rice milk presented 12.39% of protein, and make it as a great source of this macronutrient.

**Table 2. Characterization of residues from processing of vegetable milk based on white, red and black rice (part II).**

Rice	Total caloric value*	Aw	pH	Titratable acidity (%)	Phenolic compounds**
White	384.05±0.10 <sup>b</sup>	0.248±0.005 <sup>b</sup>	5.93±0.07 <sup>b</sup>	1.65±0.07 <sup>c</sup>	19.30±0.60 <sup>c</sup>
Red	374.01±0.70 <sup>c</sup>	0.527±0.002 <sup>a</sup>	6.11±0.07 <sup>a</sup>	374.01±0.70 <sup>c</sup>	110.26±0.01 <sup>b</sup>
Black	395.13±0.63 <sup>a</sup>	0.195±0.000 <sup>c</sup>	6.20±0.02 <sup>a</sup>	3.98±0.09 <sup>a</sup>	123.41±0.50 <sup>a</sup>

\*kcal/100 grams; \*\*mg EAG/100 g. Values in the same column followed by the same letter do not differ by Tukey test at 5% of probability.

The characterization of residues from food industry is necessary to justify its use in other process or application on the development of new food products, such as cereal bars, cookies, breads, biscuits, cakes, and others. Using up all nutrients and reducing the waste of them and the environmental impact.

Dehydration process do not degraded the content of phenolic compounds present on the samples. Residue from black rice milk presented highest phenolic compounds content

(123.41 mg EAG/100 g), due to the difference on the variety of rices (white: 19.30 mg EAG/100 g; red: 110.26 mg EAG/100 g).

Even after dehydration, residues still presented a great content of nutrients and bioactive compounds. Many researchers use the dehydration of residues to make flours and use it in new food products. So all important nutrients and compounds is used and consumed by people.

#### 4. Conclusions

In conclusion, residues from rice milk production have high content of nutrients and phenolic compounds, even after dehydrated. Also they can be used on others process to improve the nutritional quality of new food products and reduce the waste of nutrients. Dehydration, at the studied conditions, of the residues from rice milk production is an indicated process for preservation of nutrients and bioactive compounds.

### ***Abstract***

*The MW heating at early or at final stage of drying process to obtain a crispy apple snack was studied. The effect of MW power and time of application was also evaluated on colour, texture, physico-chemical and sensory properties. Apple snack obtained with the MW heating (7.5 min at 3.000 W) at early stage after an osmotic pre-treatment resulted in apple slices more porous and with better sensory attributes than if it is applied at later stage of drying.*

***Keywords:*** *apple; snack; drying; microwaves*

---

## 1. Introduction

One of the main barriers for fruit consumption is convenience. The application of new preservation technologies allows developing new food concepts, such as snacks, which can fulfil the consumer demand of convenience and, as a result, increase fruit consumption.

Apple drying has been studied extensively during the few past decades [1-4] by means of processes which combine an osmotic treatment and a conventional convective drying. Results were acceptable and a stable shelf-life over 6 months [5] has been reached. However, these processes are very time consuming (4.5 h). Microwave drying (MW) combined with other drying conventional methods could decrease the processing time [6]. Therefore, including MW in the drying process, could be useful in order to save time and energy and, in addition, improve the snack quality. It is still not clear which is the best time to apply MW to obtain a crispy snack. Some authors [7] assert that MW heating applied at the earlier stage of drying leads to more porous product, whereas others [8,9] indicate that this parameter is enhanced when the MW heating is carried out at the final stage of drying process.

The present work aimed to compare the effect of the MW heating at early or at final stages of drying on the colour, texture, physico-chemical and sensory properties of an apple snack.

## 2. Materials and Methods

### 2.1 Sample preparation

Golden Delicious apples and apple juice from local suppliers were stored at 4°C. Quality of the raw material was relatively stable since all the experiments were completed in 1-2 weeks. Apples were washed and manually sliced at  $4\pm 0.3$  mm-thickness with a calibrated cork borer. Sugar content of the apple juice was  $12.2\pm 0.2^\circ$  Brix.

### 2.2 Apple snack processes

The preparation of the apple snack consisted in a three stage process. The stage was an osmotic pre-treatment (O) followed by a combined treatment of MW/Convective drying (C) or C/MW. Different MW power ratios were applied to the product (Table 1).

*Table 1. Treatments used to develop the apple snack*

Process	Drying Stage 1	Drying Stage 2	MW power ratio (W/g)	MW power (kW)	MW time (s)
1	MW	C	2.98	3.0	452
2	MW	C	5.56	6.0	226
3	C	MW	18.77	3.0	452
4	C	MW	40.76	6.0	226

### **Osmotic pre-treatment (O)**

Apple slices were dipped in apple juice at 4°C in a solution ratio 1:2 (w/w) for 60 min. Then, moisture content (MC) and water activity ( $a_w$ ) were measured. After the osmotic treatment and before starting the drying process, samples were blotted by gravity to remove the excess of water.

### **Microwave drying (MW)**

MW heating was carried out in an industrial MW continuous tunnel (F00003801A, MES Technologies, France; see Fig.1). Apple slices were placed onto the conveyor belt (single layer) at 0.45 m/min at 25 °C. Table 1 shows the MW power ratio applied.

### **Convective drying (C)**

Convective drying (C) was carried out in a conventional dryer placing the apple slices in a single layer onto a grid. Samples were dried at  $107\pm 3^\circ\text{C}$ ,  $\text{RH} < 3\%$  and 1.5 m/s air velocity for 60 min. Between drying stages 1 and 2 and at the end of the process, samples were cooled down during 5 min at  $15\pm 3^\circ\text{C}$ .

## **2.3. Parameters recorded or analysed**

### **Temperature (T)**

Temperature was measured with optic fiber probes (FOT-L-NS-484B, FISO Technologies, Canada). The probe was placed inside the apple slice, 15 mm from the surface and connected to a data logger (TMI, FISO Technologies, Canada).

### **Water activity ( $a_w$ )**

Water activity ( $a_w$ ) was measured at 25 °C with an AquaLab Series 3 instrument (Lab-Ferrer, Cervera, Spain). Three replicates per treatment were carried out.

### **Moisture content (MC)**

Moisture content (MC) of the samples was determined by drying until reaching constant weight (Association of Official Analytical Chemists [AOAC], 1990). Three replicates per treatment were carried out.

### **Density and porosity**

True density of dried apple slices was measured by means of a pycnometer using the volumetric displacement method [10]. The apparent density was measured using the solid displacement method [11] and a graduated burette of  $100\pm 0.5$  ml. Porosity ( $\epsilon$ ), was calculated according to Eq.1:

$$\varepsilon = 1 - \frac{\rho_b}{\rho_s} \quad (1)$$

where  $\rho_b$  and  $\rho_s$  are the bulk density and solid density expressed in  $\text{g/cm}^3$ . Three replicates per treatment were carried out.

### **Instrumental Colour measurements**

Instrumental colour measurements were carried out with the colorimeter Konica Minolta Chroma Meter CR-400 ( AQUATEKNICA, S.A.,Valencia,Spain) with illuminant D65 (2° standard observer and specular component included) in the CIE-Lab space: L\* (lightness), a\* (redness) and b\* (yellowness) (Commission Internationale de l'Éclairage [CIE], 1976). Colour measurements were performed on 8 samples per treatment and averaging 3 readings.

### **Instrumental Texture measurements**

Texture was measured using a TA.XT plus Texture Analyzer (Stable Micro System Ltd.,Godalming, UK) for force/displacement with a 5 kg load cell, using a spherical probe (P/0.25). Samples were placed onto the HDP/CFS (Crisp Fracture Support Rig and corresponding platform, SMS). Test settings were: speed 7 mm/s, trigger force 0.049 N, probe travel distance 5 mm. A force-time curve was recorded and maximum peak Force (N) was measured. Ten measurements per treatment were carried out.

### **Sensory analysis**

Six trained assessors [12] undertook the sensory analysis on dried apple slices. The generation and selection of the descriptors was previously carried out by 2 open discussion sessions. Product was evaluated for appearance, odour, flavour/taste, texture and overall sensory quality. A non-structured scoring scale [13] was used, where 0 means absence of the descriptor and 10 means very high intensity of the descriptor. Two tasting sessions were carried out. Samples were coded with three random numbers and were presented to the assessors balancing the first-order and carry-over effects.

### **Statistical analysis**

The analyses of variance were performed with the General Linear Model (GLM) procedure of the SAS statistical package (Statistical Analysis System [SAS], 9.4). The model for the physicochemical, instrumental colour, instrumental texture parameters and sensory attributes included the treatment as fixed effect. Differences among means were tested with the Tukey test ( $p < 0.05$ ).

### 3. Results and discussion

Apples used in the present study had  $83.3 \pm 0.3\%$  moisture content and  $5.7 \pm 0.8$  N firmness. The osmotic pre-treatment was studied only in terms of moisture gain; samples absorbed apple juice up to a moisture of  $85.1 \pm 0.04\%$ .

#### Moisture content (MC), water activity ( $a_w$ ) and porosity ( $\epsilon$ )

Table 2 shows that the application of MW treatment at the 1st drying stage (processes 1 and 2) reduced the MC by about 5 %, while the convective drying (2nd drying stage) reduced the MC by about 70 %. No significant differences were observed in MC and  $a_w$  between processes 1 and 2, therefore, the power ratio applied did not affect them. Slice porosity ( $\epsilon$ ) in process 2 was lower than in process 1. This could be explained by the temperature reached by the slices through the MW heating. In process 2, slices reached up to  $68^\circ\text{C}$ , while in process 1, up to  $55^\circ\text{C}$ . Some studies reported that high temperature causes damage in the porous structure and, as a consequence, porosity decreases [14].

*Table 2. Moisture content (MC), Water activity ( $a_w$ ) and porosity ( $\epsilon$ ) of the apple snack samples*

Sampling time	Variable	RMSE	Process			
			1	2	3	4
After stage 1	MC [%]	0.897	79.15 <sup>a</sup>	80.32 <sup>a</sup>	9.44 <sup>b</sup>	8.77 <sup>b</sup>
	$a_w$ [-]	0.0091	0.980 <sup>a</sup>	0.979 <sup>a</sup>	0.191 <sup>b</sup>	0.198 <sup>b</sup>
After Stage 2	MC [%]	0.796	7.31 <sup>b</sup>	7.40 <sup>b</sup>	9.91 <sup>a</sup>	9.05 <sup>a</sup>
	$a_w$ [-]	0.0022	0.165 <sup>b</sup>	0.167 <sup>b</sup>	0.221 <sup>a</sup>	0.201 <sup>a</sup>
	$\epsilon$ [-]	0.0084	0.545 <sup>a</sup>	0.423 <sup>b</sup>	0.494 <sup>ab</sup>	0.520 <sup>a</sup>

<sup>a b</sup> Means without a common superscript in a row are significantly different ( $p < 0.05$ ); RMSE: Root mean standard error; Process 1: MW (7.5 min at 3000 W)+C; Process 2: MW(3.75 min at 6000 W)+C; Process 3: C + MW (7.5 min at 3000 W); Process 4: C + MW (3.75 min at 6000W).

When convective drying was applied at the 1st drying stage (processes 3 and 4), the MC was reduced by about 76 % whereas the MW application at the 2nd stage of drying could not reduce it. The power ratio applied did not significantly affect the MC and  $a_w$ . No significant differences in porosity ( $\epsilon$ ) were observed between processes 3 and 4.

Treatments with the MW application at the 1st stage resulted in a significant reduction of both MC and  $a_w$  at the end of the process. Therefore, the MW application at earlier drying stage is more efficient than the MW application at later drying stage under the experimental conditions of the present trial.

### Colour and instrumental texture parameters

The driest samples (process 1 and 2) showed the lowest lightness ( $L^*$ ) and the highest redness ( $a^*$ ) (Table 3). This is attributed to the lower MC of these apple slices, although some studies reported that higher  $a^*$  is also related with the Maillard reaction, caramelization or pigment degradation [5].

These samples also showed the lowest Max. Force, which can be related to their lower MC. The lowest values were observed in samples from process 2, which also have the lowest porosity.

Several studies reported that the higher porosity requires greater compressive strength to fracture samples [15].

**Table 3. Instrumental colour and instrumental texture parameters of the apple snack samples**

Colour parameter	RMSE	Process			
		1	2	3	4
$L^*$	3.044	74.75 <sup>b</sup>	74.52 <sup>b</sup>	80.47 <sup>a</sup>	76.62 <sup>ab</sup>
$a^*$	1.494	6.23 <sup>a</sup>	4.37 <sup>a</sup>	2.16 <sup>b</sup>	2.16 <sup>b</sup>
$b^*$	2.180	33.47	32.71	32.41	34.07
Max.Force(N)	1.909	5.40 <sup>ab</sup>	3.52 <sup>b</sup>	7.43 <sup>a</sup>	6.74 <sup>a</sup>

<sup>a b</sup> Means without a common superscript in a row are significantly different ( $p < 0.05$ ); RMSE: Root mean standard error; Process 1: MW(7.5 min at 3000 W)+C; Process 2: MW(3.75 min at 6000 W)+C; Process 3: C + MW (7.5 min at 3000 W); Process 4: C + MW (3.75 min at 6000W).

### Sensory Analysis

Regarding appearance attributes, no significant differences were observed (results not shown). This fact indicates that, in spite of the differences observed in  $L^*$  and  $a^*$  parameters, these were not noticeable by the panelists. Similarly, no significant differences regarding taste/flavour attributes were observed (results not shown). However, samples obtained by process 1 showed a tendency to be scored with a high intensity of apple flavour, which is a desirable attribute.

Processing (MW/C or C/MW) significantly affected dried grass odour, crispiness and easiness to chew of the apple slices (Table 4). Samples obtained in process 1 (MW at the 1st drying stage and low power ratio), tended to be more crispy and more easy to chew. Differences are attributed to its lower MC and higher porosity. Samples of process 2 had lower porosity and these of processes 3 and 4 had higher MC. Other authors reported the effect of MC and porosity on crispiness and chewiness in the same direction [16,17].

Regarding dried grass odour, results showed that samples obtained with processes with higher power (2 and 4) were scored with higher intensity. This effect should be taken into account because this is an attribute not desirable for an apple snack.

Overall sensory quality showed a tendency to be higher in samples of process 1. This result could be explained by the fact that these samples were scored with higher intensity of apple flavour, crispiness and easiness to chew and with lower intensity of dried grass odour.

**Table 4. Sensory attributes**

Attribute	RMSE	Process			
		1	2	3	4
Dried grass odour	1.10	1.3 <sup>b</sup>	2.8 <sup>ab</sup>	1.1 <sup>b</sup>	3.3 <sup>a</sup>
Crispiness	1.81	7.0 <sup>a</sup>	4.8 <sup>ab</sup>	3.5 <sup>b</sup>	4.8 <sup>ab</sup>
Easiness to chew	1.49	6.3 <sup>a</sup>	3.8 <sup>b</sup>	3.5 <sup>b</sup>	3.5 <sup>b</sup>
Overall sensory quality	1.60	6.8	4.3	4.8	4.8

<sup>a b</sup> Means without a common superscript in a row are significantly different ( $p < 0.05$ ); RMSE: Root mean standard error; Process 1: MW(7.5 min at 3000 W)+C; Process 2: MW(3.75 min at 6000 W)+C; Process 3: C + MW (7.5 min at 3000 W); Process 4: C + MW (3.75 min at 6000W).

#### 4. Conclusion

The application time of MW treatment in the apple snack process affects their physico-chemical parameters and sensory attributes. The MW treatment (7.5 min at 3000 W) applied at the 1st stage of drying followed by convective drying results in more porous apple slices and with better sensory attributes.

### Abstract

*Citrus aurantium* flowers are high value aromatic and medicinal plants. The storage conditions and quality of dried *Citrus aurantium* flowers depends on their hygroscopic stability. The equilibrium moisture content was determined at temperatures (from 30 to 60 °C), and the sorption phenomenon is well described by Peleg model. The optimal water activity for the storage of the product was estimated at  $a_{wop}=0.373$ . Afterwards, the net isosteric heat was evaluated in the range of  $88 \text{ kJ}\cdot\text{mol}^{-1}$  for small values of the moisture content ( $X_{eq}=0.14 \text{ kg water/kg d.b}$ ), and it decreased along with the increase of  $X_{eq}$ . The experimental drying curves showed only a falling rate period. Finally, Midilli-Kucuk model was found to be the more suitable to describe the drying kinetic of *Citrus aurantium* flowers.

---

## 1. Introduction

Medicinal and aromatic plants have a crucial value in the pharmaceutical industry and traditional medicine. Drying is the most used preservation operation in the storage of medicinal and aromatic plants and it is a part of the extraction process of high value substances. The indirect solar drying is more adapted to developing countries; it is economic, fast and leads to a homogeneous and edible product [1].

*Citrus aurantium* flowers are known for their benefits on nervous balance and digestion [2]. They are often used for the extraction of the main assets. These flowers are very rich in essential oil that can be used in the composition of some perfumes. For the natural medicine, the leaf is used for its sedative and soothing properties. Indeed its essential oil, associated with other bitter principles gives him soothing and relaxing properties. Furthermore, they are usually prescribed to regulate mild sleep disorders and to treat nervousness. In this case, the preservation of this material by drying and the establishment of desorption isotherms are very useful for its conservation [3].

The sorption isotherms are a good way to describe how active water is bound to a wet product [4]. They are also an extremely valuable tool because it provides precious information about the hygroscopic equilibrium [5]. In other words, it is necessary to determine the optimum moisture content and the water activity that must be achieved during drying for better preservation of the dried product.

Only experimental studies allow determining the drying kinetics of products. Therefore, it is interesting to study variations of moisture content for different controllable aerothermal parameters. The mechanisms of these transfers are very complex and they lead to large physical, chemical and biological changes. Hence, the evolution of these parameters must be controlled in order to achieve the best quality [6,7].

The main objectives of this study are:

- To determine the effect of temperature on the moisture desorption and adsorption isotherms of *Citrus aurantium* flowers, and to find the appropriate model that describes its sorption curves.
- To determine the optimal storage condition of the product and the isosteric heat of sorption.
- To investigate the drying kinetics of *Citrus aurantium* flowers.

## 2. Materials and Methods

### 2.1. Sorption isotherms

The hygroscopic equilibrium was achieved by the static gravimetric technique [8]. The samples that were used for desorption were fresh and weighed around  $1\pm 0.1$ g. The ones that were used for adsorption had been dried for 24h in an oven at  $105^{\circ}\text{C}$  before putting them on the glass jars; their weight was around  $0.1\pm 0.01$ g. This process was performed at three different temperatures (30, 40 and  $50^{\circ}\text{C}$ ).

## 2.2. Description of the solar drying

The experimental apparatus consists of an indirect forced convection solar dryer. The solar dryer was described in detail in [9]. The same mass of fresh *Citrus aurantium* flowers ( $20\pm 1$ g) was used for each drying experiment. Drying experiments were performed for three temperatures (40, 50 and  $60^{\circ}\text{C}$ ) with the air flow rate of  $0.083\text{m}^3\cdot\text{s}^{-1}$ .

## 3. Results

### 3.1. Desorption and adsorption isotherms

Figs. 1 and 2 show the effect of temperature on desorption and adsorption of *Citrus aurantium* flowers.  $X_{eq}$  increases by decreasing temperature at constant water activity. This result may be explained by the higher excitation state of water molecules at higher temperature thus decreasing the attractive forces between them [10]. The sorption isotherms are type II of the IUPAC classification and exhibit a sigmoidal shape; this is consistent with the behavior of other medicinal and aromatic plants [11]. In the present study, the relationship between  $X_{eq}$  and  $a_w$  at 30, 40 and  $50^{\circ}\text{C}$  was predicted by applying mathematical models. The used models' equations (GAB, Modified Henderson, Modified Halsey, Modified Oswin, Enderby and Peleg) are given in [12]. The best model, describing sorption isotherms of the product, has the highest value of the correlation coefficient  $r$  and smallest values of  $SEM$  and  $MRE$ . These statistical errors are defined respectively by Eqs. (1) and (2):

$$SEM = \sqrt{\frac{\sum_{i=1}^N (X_{eq_{i,pre}} - X_{eq_{i,exp}})^2}{d_f}} \quad (1)$$

$$MRE = \frac{100}{N} \sum_{i=1}^N \left| \frac{X_{eq_{i,pre}} - X_{eq_{i,exp}}}{X_{eq_{i,exp}}} \right| \quad (2)$$

Where  $X_{eq_{i,exp}}$  is the  $i$ th experimental moisture content,  $X_{eq_{i,pre}}$  is the  $i$ th predicted moisture content, and  $d_f$  is the freedom degree of the regression model. The Peleg model gives the best fitting to the experimental data with a correlation coefficient  $r$  of 0.9847 and 0.9920, SEM of 1.0856 and 1.0562, and MRE of 9.3654% and 10.1268% respectively for desorption and adsorption isotherms.

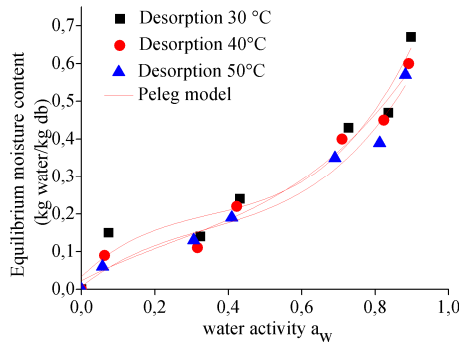

Fig. 1 Desorption isotherms of *Citrus aurantium* flowers at 30, 40 and 50 °C.

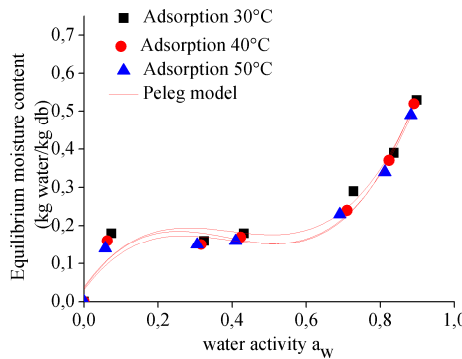

Fig. 2 Adsorption isotherms of *Citrus aurantium* flowers at 30, 40 and 50 °C.

### 3.2. Determination of the optimum conditions for the storage

All experimental data of desorption and adsorption at 30, 40 and 50°C were gathered on the same graph (Fig. 3). This curve allowed to determine the value at which the second derivative of  $X_{eq}$  equals to zero and consequently the optimum value of water activity for storage. The found value for *Citrus aurantium* flowers ( $a_{wop}=0.373$ ) is in agreement with the general stability domain of biological products that is between 0.2 and 0.4 [13].

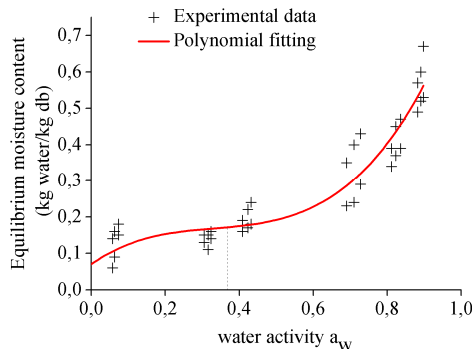

Fig. 3. Determination of the optimal water activity for storage of *Citrus aurantium* flowers.

### 3.3. Net isosteric heat

The net isosteric heat of sorption was calculated from the experimental data using the Clausius Clapeyron equation given by Eq. (3):

$$\left[ \frac{d(\ln a_w)}{d(1/T)} \right]_{X_{eq}} = \frac{-\Delta H_d}{R} \quad (3)$$

Fig. 4 presents the isosteric heat of sorption of *Citrus aurantium* flowers at temperatures ranging between 30 °C and 50 °C. This curves show that the isosteric heat is higher for small values of the moisture content (88 kJ.mol<sup>-1</sup> for  $X_{eq}=0.14$ kg water/kg d.b) indicating the highest binding energy for water removal, and it decreased along with the increase of the  $X_{eq}$  [14].

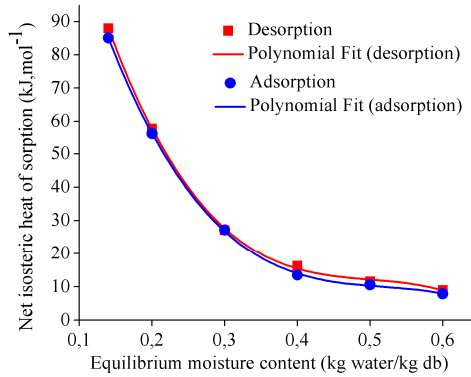

Fig. 4. Net isosteric heat of desorption and adsorption of *Citrus aurantium* flowers versus equilibrium moisture content.

### 3.4. Drying kinetics of *Citrus aurantium* flowers

An increase in the drying air temperature had led to a significant reduction in the drying time; from 340 min for a temperature of 40 °C to 220 min for a temperature of 60 °C (Fig. 5). It can be noticed the presence of only the falling drying rate period (phase 2) which is governed by the water diffusion in the material [15].

Several mathematical models are used to describe the macroscopic behavior of the products. In this work, the most models describing drying kinetics were used: Newton, Page, Henderson and Pabis, Logarithmic, Two term, Two term exponential, Wang and Singh, Diffusion approach, Verma et al. and Midilli-Kucuk. The models' expressions are given in literature [16]. The moisture ratio of *Citrus aurantium* flowers during the thin layer drying experiments was calculated by using Eq. (4):

$$X^* = \frac{X - X_{eq}}{X_0 - X_{eq}} \quad (4)$$

The appropriate model was selected according to the highest correlation coefficient ( $r$ ), the lowest  $MBE$  (Eq. (5)) and the lowest  $\chi^2$ .

$$MBE = \frac{1}{N} \sum_{i=1}^N (X_{pre,i}^* - X_{exp,i}^*) \quad (5)$$

Where  $X_{exp,i}^*$  stands for the experimental moisture ratio found in the measurements;  $X_{pre,i}^*$  is the predicted moisture ratio for this measurement.

Midilli-Kucuk model was selected as the most convenient model to represent the drying behavior of *Citrus aurantium* flowers with  $R$ ,  $\chi^2$  and  $MBE$  respectively of 0.9991, 0.00037 and 0.00017. These result highlighted the ability of this model to better simulate the change in water content in the solar drying *Citrus aurantium* flowers. Hence, this product presents a weak external resistance to heat and mass transfer [17].

Fig. 5. Variation of moisture content as a function of time.

#### 4. Conclusions

The storage conditions and the quality of dried *Citrus aurantium* flowers depend to a great extent on their hygroscopic stability. Hence, the equilibrium moisture content was investigated at three temperatures in the most convenient range for plants (from 30 to 60 °C). The sorption phenomenon is well described by the semi-empirical Peleg model. The optimal water activity for the storage of the product was estimated at  $a_{wop}=0.373$ . Then, the net isosteric heat of sorption of the samples was computed from the predicted sorption data. It was evaluated in the range of  $88\text{kJ}\cdot\text{mol}^{-1}$  for small values of the moisture content ( $X_{eq}=0.14$  kg water/kg db), and it decreased along with the increase of the  $X_{eq}$ ; this thermodynamic quantity estimates the required energy for dehydration processes. Drying experiences were conducted in Marrakech (Morocco) by using an indirect forced convection solar dryer at three temperatures (40, 50 and 60°C). The experimental drying curves showed only a falling rate period. Finally, Midilli-Kucuk model was found to be the more suitable to describe the drying kinetic of *Citrus aurantium* flowers.

## 5. Nomenclature

$M_d$	Mass of dry matter	kg
$M_{eq}$	Mass at the hygroscopic equilibrium	kg
$X$	Moisture content at any time during drying	(kg water/kg db)
$X_0$	Initial moisture content	(kg water/kg db)
$X_{eq}$	Equilibrium moisture content	(kg water/kg db)
$X^*$	Moisture ratio	
$a_w$	Water activity	
$r$	Correlation coefficient	
$SEM$	Standard Error of Moisture	
$MRE$	Mean Relative Error	%
$MBE$	Mean bias error	
$\Delta h_d$	Net isosteric heat of sorption	$\text{kJ}\cdot\text{mol}^{-1}$
$\Delta H_{vap}$	Heat of vaporization of pure water at 35 °C	$43.53 \text{ kJ}\cdot\text{mol}^{-1}$
$R$	Universal gas constant	$8.3145 \text{ J}\cdot\text{mol}^{-1}\cdot\text{K}^{-1}$

### **Abstract**

*Organic dried apples are common snacks fulfilling functional as well as nutritional aspects. However, appearance of dried slices does not always satisfy consumer requirements, thus, improvements are needed. In this study, partial least squares (PLS) regression models were successfully developed to monitor changes in colour and moisture content in apple slices during the drying process over the Vis/NIR spectral range. The regression vector analysis results suggested that features at 580, 750 and 970 nm are better for predicting moisture content, while 580 and 680 nm allow to measure the ( $a^*/b^*$ ) colour ratio.*

**Keywords:** *Drying; Dried apple slices; Moisture content; Colour; PLSR modelling*

## **1. Introduction**

The demand for organic dried agricultural products is increasing globally due to their health promoting aspects, ecological protection and biodiversity maintenance. [1,2] Organically grown fruits and vegetables contain a higher polyphenol content compared to conventionally grown ones, having anti-carcinogenic, anti-inflammatory, antimicrobial, antioxidant, antihypertensive, immune modulating, cardio protective, vasodilatory and analgesic proprieties. [3] The majority of people prefer fresh produce; however, it is difficult to preserve perishable foods owing to their high moisture content and high metabolic activity. Thus, drying is one of most important techniques to produce foods with an improved shelf-life, organoleptic quality, and nutritional value and to widen product availability and diversify the market throughout the years. Amongst food commodities, apple is the most common commercial fruit consumed globally [4] due to its nutritional properties. Dried apples be used as raw material in the production of snacks, integral breakfast foods, flour, chips and more, thus increasing in the global market. [5] However, maintaining a proper structure and appearance of dried organic products has been challenging.

Convective hot-air drying is one of the most common and energy intensive drying methods in the food industry. This leads to a dried product with a reduced weight making it suitable for transportation and a prolonged shelf-life with minimal nutrient deterioration during storage. However, the potential negative outcomes of this process are several physical and biochemical changes which might occur leading to quality degradation such as changes in colour, texture, size and shape as well as the organoleptic, nutritional and functional properties during the drying process. This will impact on the consumer acceptability. [6] Most of the quality parameters are highly temperature dependent. [5]

Moisture content measurement is a labour intensive and time consuming during the drying process. Therefore, a non-invasive and non-destructive method is both more useful and favourable to detect quality metrics in a production line setting. The presented method is based on models that were developed from measured data and hyperspectral data relating the products and quality parameters. Many studies have been carried out estimating dried apple quality characteristics. [7-10] However, very few studies have been carried out in the organic sector. Thus, the aim of this study was to determine the impact of the drying temperature on the drying behaviour and colour parameters of organic apple slices, as well as to investigate quality metrics predictions such as moisture content and chromaticity using the visible/near-infrared (Vis/NIR) spectroscopy during the drying process.

## 2. Materials and Methods

Apples (cv. *Elstar*) were purchased from the Hessische Staatsdomäne Frankenhausen, (Grebenstein, Germany) on the evening before each trial, where they had been stored at  $8 \pm 1$  °C. Fruits of uniform size and colour were used and stored at room temperature overnight until the experiments were conducted. Apples were cored using an apple stainless steel corer of 2.5 cm (lurch, Schineklstrasse 6, Germany) and sliced to 4-mm thickness using an electrical slicer (Graef, Alleschneider Vivo V 20, Arnsberg, Germany). Apple slices were cut into equal diameter using a cookies dicer of 62-mm diameter (Flammable, Germany).

During drying experiments, the samples were dried at  $60 \pm 2$  °C and  $70 \pm 2$  °C for 6 and 4 h, respectively, in a tray dryer (HT mini, Innotech Ingenieursgesellschaft mbH, Germany). The dryer was pre-heated until set temperature was reached before being loaded with the sample. Four replications were performed for each assessment. Batch sampling was performed at 0, 15, 30, 60, 90, 120, 180, 240, 300 and 360 min for 60-°C drying temperature, while at 0, 15, 30, 60, 90, 120, 150, 180, 210 and 240 min for 70-°C drying temperature. In each drying interval, sample weighting, chromaticity and hyperspectral scans were performed and analysed following the procedure mentioned by Crinchton et al., 2017. In addition, the  $a^*/b^*$  ratio was calculated in this experiment.

The spectral data were analysed using Partial least squares regression (PLSR) in relation to the moisture content (gw/gDB) and the CIELab coordinates. PLSR is a regression technique used to find linear relationships between the reflectance spectra and specific qualitative measurement values. The train-test (calibration-prediction) split for the complete dataset was on a 70:30 basis. The classification performance of each PLS model was determined in terms of regression vector (RV).

One-way analysis of variance (ANOVA) was performed to evaluate statistical differences among the drying times. The Tukey's pairwise comparison method was performed, and the Honestly Significant Difference (HSD) was calculated for an appropriate level of interaction ( $P < 0.05$ ). Results were reported as the mean and standard error of the mean.

## 3. Results and Discussion

### 3.1. Drying Behaviour

Fig 1. shows the moisture content of the organic apple slices as a function of drying time at 60-°C and 70-°C drying temperatures. As expected, the moisture content decreases gradually with drying time and the drying rate is higher at the highest temperature. [8- 10] The drying time to reach the final moisture content of 0.11 g H<sub>2</sub>O/ g D.M were 360 min and 240 min at the drying air temperatures of 60 and 70 °C, respectively. ANOVA indicates

significant effect of drying time on moisture content. The free water content reduced significantly at higher temperature causing higher internal moisture diffusion resistance during the drying process. [4-6]

Fig 1. Effect of drying air temperature on moisture content of slices over drying time

### 3.2. Colour changes

Table 1 depicts the  $a^*/b^*$  ratio of slices at two different drying temperatures. Tukey's test of comparison revealed significant differences at different stages of the drying process for  $a^*/b^*$  value. The greatest change loss occurred at 210 min which was significantly different to that at 0-, 15-, 30- and 60-min drying times. At 210 min, Maillard reaction might occur causing the slices to brown faster (Table.1). Moreover, the enzymatic reaction due to polyphenol oxidase (PPO) is first very likely to occur and afterwards non-enzymatic browning that contributing to changes in colour. The browning reactions occurring during drying can have a significant impact on the final colour of the product. [6]

**Table 1. Effect of drying time on a\*/b\* ratio of organic apple slices. Mean values with no common letters are statistically different according to HSD of ( $p \leq 0.05$ ).**

Drying at 60- °C and 70- °C	
Drying time (min)	a*/b ratio
0	-0.23 <sup>d</sup> ± 0.007
15	-0.14 <sup>c</sup> ± 0.006
30	-0.13 <sup>bc</sup> ± 0.006
60	-0.12 <sup>bc</sup> ± 0.005
90	-0.11 <sup>abc</sup> ± 0.006
120	-0.10 <sup>abc</sup> ± 0.009
150	-0.09 <sup>abc</sup> ± 0.011
180	-0.09 <sup>abc</sup> ± 0.006
210	-0.07 <sup>a</sup> ± 0.010
240	-0.08 <sup>ab</sup> ± 0.007
300	-0.09 <sup>ab</sup> ± 0.010
360	-0.09 <sup>abc</sup> ± 0.006

### 3.3. Spectral Analysis

PLS regression models with excellent predictability were obtained to monitor changes in moisture content and colour parameters of apple slices during drying process. The model performances for moisture content and a\*/b\* ratio are presented in Table 2. The prediction model on the test (prediction) set achieved good moisture content predictions with highest R<sup>2</sup> (0.98) and lower RMSEP (0.27 g Water/g D.M) and for a\*/b\* ratio with R<sup>2</sup> (0.82) and lower RMSEP (0.23). The selection of optimal wavebands was performed using Regression vector (RV) to find the most vital information for moisture content distribution (Fig 2b) and a\*/b\* ratio (Fig 2c). For moisture content prediction, the highest peak was observed at wavelengths 580 nm and two downward peaks at 750 nm and 970 nm. At 970 nm, there might be the non-bonded O-H stretching second overtone vibration in water and free water molecules in the apple slices. [11,12] In case of the a\*/b\* ratio, 580 nm and 680 nm were found to be important wavelengths using RV analysis (Fig 2c). Specifically, 680 nm is related to change in chlorophyll content. [9] Moreover, as moisture evaporates during drying, different pigments such as anthocyanins concentration might increase leading to a

change in colour. Noteworthy, moisture content in the product and changes in colour seem to be correlated to each other which have to be optimised during the drying processes to produce acceptable dried slices.

## 4. Conclusions

Drying temperature, time and product quality are the important considerations for drying processes. Lowering the drying temperature reduces the drying potential and increases drying time. Colour ( $a^*/b^*$  ratio) parameter changed periodically as the onset of drying. RV of moisture content showed the importance of three wavelengths (i.e. 580, 750, 970 nm) and for colour change ( $a^*/b^*$ ) ratio at 580 and 680 nm. RV had a higher prediction accuracy indicating that wavelengths selected are more powerful in predicting the MC and  $a^*/b^*$  colour of organic apple slices. Thus, using this Vis/NIR based technique, can provide an efficient means of quality metric estimation such as moisture content and  $a^*/b^*$  colour prediction information of organic apple slices.

## 5. Nomenclature

Vis/NIR	Visible to near infrared
PLS	Partial Least Squares regression

### **Abstract**

*This study presents the consumer acceptance of coffee beverages made from espresso coffee pods (CCE) and american coffee pods (CCA), six quality attributes were evaluated by a sensory panel conformed to judges of different experience level. A physicochemical characterization was made for the coffee powder in CCA and CCE. The beverage preparation via different machines was made for to observe the influence on the consumers acceptance. The coffee powder in CCA showed high aw and high moisture content, this factors should affect the consumer perception; in general, a low acceptance level of coffee beverages made from CCE and CCA was observed, maybe because of the strong habit of consuming filtered coffees.*

**Keywords:** *Coffee; Espresso; American; sensory; physiochemical.*

---

## **1. Introduction**

During the preparation of a coffee cup there is a solid-liquid extraction process in which the following steps occur: 1. the water absorption of the ground coffee; 2. the massive transfer of soluble from coffee grinds to hot water; and 3. the separation of the beverage extract and the spent coffee solids. [1]

Among the various processing techniques, filter coffee (drip filter) is the most used coffee obtained by the infusion method, while espresso coffee is the most appreciated coffee produced by the pressure method. In drip filtration methods, water at 92-96 ° C flows through a bed of hardly compressed ground coffee and the extract drips vertically. The turbulence generated in the processing prevents the water from saturated [2]. The sensory properties of coffee prepared by dripping hot water through the ground grain on a filter are affected by particle size, solid / water ratio, contact time and temperature [3]. While an espresso coffee is obtained by the pressure method, water at approximately 9 bar and 88-92 ° C is forced to pass through the compacted coffee beans in a small preparation chamber [2], a fast preparation time and a fine particle size is necessary [4] since the result is strongly affected by the physical condition that controls the filtration process (grinding degree, temperature and water pressure and time) of percolation. The espresso is produced by professional machines and after specific operations carried out by expert hands that define the quality and quantity, the degree of grinding and compression of the coffee to obtain a cup of espresso with specific sensory properties. [5]

The Coffee pods, prepared in single-use (single-use) for coffee machines, have gained considerable popularity due to their end-use convenience and longer shelf life than conventional coffee [1]. The key point of this success is to allow any person, expert or non-expert, to prepare it at any time and in all places (home, car, office and plane) where the limited quantities consumed do not justify or allow the use of professional machines [5]. The pods compatible with Keurig® are composed of a thermoformed multilayer high-barrier capsule, in which a paper or other filtering medium is attached to the side wall near the top of the capsule, forming a filter that separates the capsule into the pods. upper and lower compartments. The roasted and ground coffee beans are introduced into the upper compartment, and then sealed with an aluminum foil lid to form the final product of the PODS [1]. The preparation time in individual coffee is considerably shorter than conventional coffee (30-60 seconds versus 8-12 minutes), and as a result, the contact time with water is relatively shorter. In addition, since the preparation time, the water temperature, the pouring volume and the flow parameters are controlled by the microprocessor and controller of the coffee machine, and the coffee grinds are of portion size in the capsule, the intervention of the user is largely eliminated during the preparation process [1]. The pods compatible with Nespresso used by a simple technology that includes pre-packaged individual doses containing pre-measured and pre-stamped ground coffee.

The ground coffee is hermetically sealed between two thin layers of filter paper, in aluminum or plastic pods [5]. Despite the considerable popularity, the information on the elaboration of coffee pods, the preparation of the drink and the acceptance by consumers is not available in the literature. The objective of this study is to investigate the influence of physicochemical parameters on the encapsulation and acceptance by coffee consumers.

## **2. Materials and Methods**

Five commercial espresso coffee pods (CCE) and five commercial american coffee pods (CCA) were characterized in powder coffee and the beverages made from CCE in single-dose machines C50-US-CW-NE coffee machine (Nespresso®, Switzerland) and CCA extracted in the K50 CLASSIC SERIES coffee machine (Keurig®, United States) were characterized too. For CCE beverages the double-distilled water temperature was  $70\pm 2$  °C and for CCA beverages it was  $80\pm 2$  °C. The extraction volume for espresso coffee was 40 ml (35 ml of prepared coffee and 5 ml of foam) and for american coffee it was  $177\pm 2$  ml (6 oz). the extraction time for espresso coffee was  $14\pm 2$  seconds and for american coffee it was  $25\pm 2$  seconds. The water-coffee ratio was 20 g/100 ml for espresso and 7 g/100 ml for american coffee.

The physicochemical parameters evaluated in powder coffee and in the beverages included moisture content from wet basis (%) in infrared balance OHAUS-MB45 (Parsippany, USA) (105 °C for 5 min) according to Zanin et al. [6]; water activity using the AQUALAB VSA (Vapor Sorption Analyzer) equipment from Decagon Devices, Inc.; color (L) in powder coffee and color (L) of the beverages, using the digital colorimeter CR-410 (Konica Minolta Sensing Inc., Japan). Refractive indexes (expressed in ° Brix) were measured with the Atago PR-201 $\alpha$  digital refractometer, the titratable acidity (expressed as chlorogenic acid) was determined by titration and pH with the digital potentiometer BP- 3001 (Trans Instruments, Singapore). Measures was made in triplicate.

The sensory attributes of the beverages were evaluated using a QDA quantitative descriptive analysis, a sensory panel conformed to judges of different experience level: Colombian experts in tasting by SCAA methodology (p1), Colombian inexperienced coffee consumers (p2) and Colombian habitual specialty coffee consumers (p3) . The acceptance scale of 6 discrete values in which "I dislike extremely" was evaluated with 0 and "I like extremely" corresponded to 5.

Anova tests were performed ( $p < 0.05$ ) to observe the statistically significant differences in the physicochemical parameters and on the quality attributes evaluated in the sensory panel for espresso coffee and american coffee. The statistical package StatGraphics Plus 5.1 for Windows (Manugistics, Inc., Rockville MD) was used.

### 3. Results and discussion

#### Physicochemical characterization

Table 1 presents the results of the comparison of the powder coffee contained in CCE and CCA, in addition the comparison of the parameters obtained in the CCE and CCA beverages. The moisture content,  $a_w$ , color, in powder coffee from CCE presented statistically significant differences ( $P < 0.05$ ) compared to CCA; likewise, in the analysis of the beverages, pH, oBrix and color presented statistically significant differences ( $P < 0.05$ ) in the two types of drinks.

**Table 1. Physicochemical parameters in powder coffee and beverages coffee extracted for espresso and american pods.**

Samples	Parameters	CCE	CCA
Powder coffee	Moisture content (%)	2.71±0.62 <sup>a</sup>	4.51±1.52 <sup>b</sup>
	Water activity ( $a_w$ )	0.25±0.11 <sup>a</sup>	0.38±0.11 <sup>b</sup>
	Roasting degree (L)	23.20±0.53 <sup>a</sup>	24.79±1.5 <sup>b</sup>
	Titrateable acidity	1.68±0.4 <sup>a</sup>	1.85±0.36 <sup>a</sup>
Beverages	pH	5.21±0.13 <sup>a</sup>	4.92±0.11 <sup>b</sup>
	Refractive index (°Brix)	3.92±0.53 <sup>a</sup>	1.66±0.45 <sup>b</sup>
	Color (L)	32.04±2.89 <sup>a</sup>	29.80±1.15 <sup>b</sup>

(n = 3) mean ± SD. Different letters, in the same row indicate significant difference ( $P < 0.05$ ).

The moisture content (%) and  $a_w$  in CCA is significantly higher than in CCE, this result may be influenced by the storage process that depends mainly on factors related to environmental conditions and technological factors such as the availability of oxygen and moisture, the exposed surface area, temperature and packing material [7]; the CCE moisture content (2.71±0.62%) is similar to that found by Lee et al. [8] for roasted and ground coffee. Apparently the result indicates that the CCE allow less water vapor exchange between the inside of the pods and the surrounding environment. Additionally, taking into account that Cardelly and Labuza [9] reported  $a_w$  of 0.106% for roasted and ground coffee, the values of  $a_w$  found for CCA (0.38±0.11%) were much higher, unlike the values of  $a_w$  for CCE (0.25±0.11%) that were closer to that found by the same author.

The color of roasting in the powder coffee of CCE and the CCA, showed significant differences ( $p < 0.05$ ), the magnitudes of the coordinate L obtained (23.1±0.5 and 24.1±1.7 respectively) correspond to the degree of dark roasting according to the classification proposed by Franca et al. [10], this result is linked to the generalized concept for the preparation of espressos and American coffee; although L in CCA is significantly higher than in CCE, indicating less roasting degree and higher moisture content.

The refractive index in the beverages, result higher in espresso than in american coffee as shown in Table 1, similar results were obtained by Gloess et al. [11] who determined that espresso coffee has a refractive index closer to 4.0%, the author evaluated this parameters in different machines: a semi-automatic espresso machine, an automatic machine and a Nespresso brand single-use machine. In the american coffee, the same author determined refractive index slightly higher than 1.0%; finding for the filtered coffee extract a refractive index of  $1.03\pm 0.01\%$  and for the French press  $1.43\pm 0.01\%$ , these results are similar to those found for the CCA.

The pH in beverages is a characteristic that could suggest sensory acidity, according to the results shown in table 1, the pH for the CCE is  $5.2\pm 0.1$  and for CCA of  $4.9\pm 0.1$ , these results are similar to those found by Ludwig et al [2] who presented for the filtered coffee extract (water-coffee ratio of 6.0% and time extraction time of 75 seconds) a pH of  $5.12\pm 0.01$  and for espresso (15% water-coffee ratio and 16 seconds of extraction) a pH of  $4.9\pm 0.01$ . Other results such as those obtained by Fujioka et al. [12] showed that the pH in extracted coffee is related to the presence of chlorogenic acids; this author found that the pH in seven types of commercial coffees (with a water-coffee ratio of 3% and filtered) varies from  $4.95\pm 0.01$  to  $5.99\pm 0.01$  results very similar to those shown in table 1.

#### **Sensorial analysis in espresso beverages and american coffee beverages.**

Table 2 shows the sensory acceptance of coffee beverages made from CCE and CCA, the crema (foam) was evaluated only in espresso coffee since american coffee does not generate it; statistically significant differences ( $P<0.05$ ) between CCA and CCE was obtained only in Color (L), expressed by P2; while statistically significant differences by panelist type was obtained in all quality attributes, indicating higher strictness in the evaluation expressed by P1 and P3, maybe because they have most experience and knowledge in coffee quality.

In the cream evaluation in CCE, the panelists criticized because this is disperse and not homogeneous. According to Gloess et al. [11] that compared several methods of preparation of espresso coffee, found that the crema of the espresso coffee pods was noticeably bigger and of a more intense color compared with other espressos coffees and that the espresso of the semiautomatic machine had the best foam.

**Table 2. Sensory Evaluation in beverages made from CCE and CCA**

Quality attributes	Panelists	Type	
		CCE	CCA
Color	P1-P3	3.1 ± 0.8 <sup>a</sup>	3.1 ± 1.0 <sup>a</sup>
	P2	3.8 ± 0.9 <sup>b</sup>	3.6 ± 0.8 <sup>a</sup>
Aroma	P1-P3	2.2 ± 1.2 <sup>a</sup>	1.6 ± 0.9 <sup>a</sup>
	P2	3.4 ± 1.0 <sup>b</sup>	2.7 ± 0.8 <sup>b</sup>
Flavor	P1-P3	1.9 ± 0.9 <sup>a</sup>	1.6 ± 0.9 <sup>a</sup>
	P2	3.0 ± 1.3 <sup>b</sup>	3.0 ± 1.2 <sup>b</sup>
Balance	P1-P3	1.9 ± 0.9 <sup>a</sup>	1.8 ± 0.8 <sup>a</sup>
	P2	3.2 ± 1.3 <sup>b</sup>	2.6 ± 1.2 <sup>b</sup>
Aftertaste	P1-P3	1.7 ± 1.1 <sup>a</sup>	1.2 ± 1.2 <sup>a</sup>
	P2	3.1 ± 1.8 <sup>b</sup>	2.9 ± 1.1 <sup>b</sup>
Score global	P1-P3	1.8 ± 0.9 <sup>a</sup>	1.4 ± 0.9 <sup>a</sup>
	P2	2.8 ± 1.3 <sup>b</sup>	2.8 ± 1.3 <sup>b</sup>
crema	P1-P3	2.9 ± 1.2 <sup>a</sup>	-----
	P2	4.6 ± 0.5 <sup>b</sup>	-----

n = 3 mean ± SD. Different letters, in the same row for each treatment, indicate significant difference (P<0.05). Different letters, in the column for each quality attribute indicate significant difference (P<0.05).

According to the observations expressed by panelists in the sensory questionnaire, they described greater sensory acidity in espresso coffee, while the results in table 1, the highest titratable acidity and pH concentration occurs in american coffee, which would lead to thinking that it is possible to relate it to sensory acidity. To demonstrate this, it is necessary to do in-depth research of titratable acidity, pH and sensory acidity in an expert panel. The objective of this research was not to evaluate only expert tasters for this reason, we can not assure that the acidity in American coffee is directly due to the sensory acidity perceived by the panel .

#### 4. Conclusions

A high moisture content and aw was found in powder coffee in commercial pods of CCA type, this can significantly affect sensory acceptance since high moisture contents can be indicators of product interaction with the environment given the high degree of hygroscopicity of the coffee. Likewise, the physicochemical parameters studied did not allow demonstrating the correlation between pH and acidity titratable versus sensory acidity, is recommended to deepen the subject by evaluating the acidity content through chemical analysis, titratable acidity, pH and sensory acidity.

In all cases, it was found that the panelists evaluated separately the attributes of color and foam in relation to the other attributes associated with the senses of smell and taste.

In general, the american coffee and espresso coffee pods had low acceptance, perhaps due to the accentuated custom of consumption of filtered coffee in Colombia

### **Abstract**

*Ethnic foods are healthy products interesting for the new societies. Mesquite flour offers another option for making gluten-free recipes as part of a diet for people with celiac disease. The physicochemical properties of mesquite flours (*Prosopis laevigata*) were characterized. The mesquite pods were dried at 60°C, 15% RH and 2 m/s airflow; then a grinding and sieving process were applied. The nutritional composition and the sorption isotherms were obtained at 30, 35, 40 and 45°C for water activities of 0.07-0.9. The particle-size distribution, morphology and thermal stability of the flours were determined by different methods.*

**Keywords:** *Mesquite Flours; drying; isotherms; chemical properties; morphology.*

---

## 1. Introduction

Mesquite (*Prosopis spp*) are extremophile trees, comprising 44 species around the world [1]. In Mexico, mesquite trees are distributed in northern, central and southern states of the country. In ancient times, the indigenous peoples of Mexico used mesquite pods as food, to produce flour, sirups and bread [2]. The pods having a high protein content in addition to the sucrose content offers a wide potential for the development of new ethnic products [3]. For example, flours of *Prosopis pallida* and *Prosopis juliflora* were obtained from the fractions of different grinds, then a bread was elaborated with 25% wheat flour [4]. In the last years, different studies have analysed the properties of flours of *P. alba*, *P. chilensis* and *P. flexuosa* for the elaboration of bakery products. Nevertheless, mesquite flours must satisfy the culinary requirements and the storage conditions must be well established [5]. In this work we determine the physicochemical properties of Mexican mesquite flours (*Prosopis laevigata*) in order to characterize the flour and to identify the storage conditions.

## 2. Materials and Methods

### 2.1. Mesquite flours

*Prosopis laevigata* pods were harvested between April and August 2016 in the community of Santiago Suchilquitongo, In Oaxaca (Mexico). The pods in stage three of maturity were used. Pods were dried in a tunnel dryer at 60°C, relative humidity of 10% and air velocity of 2.6 m/s. The pods were milled by two methods: a) in an Osterizer blender model 465-15 for 20 seconds, and b) in a mill pulverizer for legumes Model HC-2000Y, during intervals of 5 seconds until 20 seconds. The milled material was sieved through #40 (0.420mm) and #60 (0.250mm) sieves. After the sieving process the powder was stored in a vacuum desiccator for 24 hours.

### 2.2. Physicochemical characterization

The moisture content of pods was determined by the oven-dry method (105°C, during 24 hours). The total raw protein content was determined by the Kjeldahl method (AOAC 960.52, 1997). For the determination of reducing and direct sugars, the Lane-Eynon volumetric method was followed. Total fat extraction was carried out by the Soxhlet method (AOAC 920.3, 1990). Raw fiber (NMX-F-090-S-1978) was obtained by using the flour residues, which were dried at 130 °C in an electric oven for 2 hours. The ash content was obtained by calcining in crucibles at 550°C for 30 min in a muffle oven model KLS 03/10.

The particle size distribution of mesquite flour obtained from the pulverizer was analyzed using the principle of blue laser light diffraction measurement (ISO13320, 2009) by the Microtrac Blue-ray M3551-1W-BU00 in a humid medium, with a measuring range of 10 nm up to 2000 microns. An ultrasound was applied for 30 seconds with a power of 30 watts to

800 grams of flour, then it was divided in three samples to facilitate the dispersion of the particles.

The mesquite flours were analyzed by Scanning Electron Microscope (SEM) in a JEOL brand microscope, model JIB-4601F, with a spatial resolution of 1.2 nm. Secondary electron detector E-T (Everhart-Thornley) and a range of magnification were taken from 50x to 2500x.

The sorption isotherms of mesquite flour were determined by the gravimetric static method with water activities ranging from 0.07 to 0.97 and temperatures of 30, 35, 40 and 45°C. The used salts were the following: NaCl, MgCl<sub>2</sub> \* 6 H<sub>2</sub>O, KOH, KCl, KI, K<sub>2</sub>SO<sub>6</sub>, Mg(NO<sub>3</sub>)<sub>2</sub> \* 6H<sub>2</sub>O [9]. For high water activities, vials were prepared with an antifungal agent, which were introduced into the equilibrium systems. The samples were weighed every 2 days until constant weight was observed. The experimental data was fitted to the GAB (Guggenheim-Anderson-Deboer) model (Equation 1). The parameters of this model were estimated by using the solver tool in excel [6].

$$X_{eq} = \frac{X_m \cdot C \cdot K \cdot a_w}{(1 - K \cdot a_w) \cdot (1 - K \cdot a_w + C \cdot K \cdot a_w)} \quad (1)$$

The isosteric heat of sorption (Q<sub>st</sub>) was determined by solving the equation derived from the Clausius Clapeyron formulation [6] (Equation 2):

$$\left[ \frac{\partial \ln(a_w)}{\partial (1/T)} \right]_{CHE} = - \frac{Q_{st} - \lambda}{R} = - \frac{q_{st}}{R} \quad (2)$$

Samples of mesquite flours conditioned at relative humidity of 7%, 32%, 51% and 67% at 45°C were prepared for a DSC analysis (TA Instruments, model Q2000). The samples started at an initial temperature of 0°C, followed by a heating rate of 2°C /min up to a final temperature of 250°C. The thermogram was obtained by using the TA Instruments Universal Analysis DSC software.

### 3. Results and Discussion

The nutritional compositions of flours presents a high content of sugars, fiber and protein. It was observed that the carbohydrates increased according to the type of milling, which increases the flour hygroscopicity (Table 1).

Table 1. Nutritional composition of mesquite flours obtained by the two grindings.

Components	Blender		Mill pulverizer	
	Average (g / 100 g)	Standard deviation	Average (g / 100 g)	Standard deviation
<b>Energy content (kcal / 100 g)</b>	170.97	0.07	198.72	0.50
<b>Carbohydrates (g)</b>	24.27	0.09	26.18	0.08
<b>Sugars (g)</b>	7.48	0.03	10.18	0.02
<b>Proteins (g)</b>	12.4	0.08	11.77	0.12
<b>Fats (Lipids) (g)</b>	2.16	0.03	2.90	0.06
<b>Fiber (g)</b>	16.9	0.2	17.25	0.11
<b>Ashes (g)</b>	3.12	0.01	3.45	0.05
<b>Humidity (g H2O / g dry matter)</b>	0.1	0.01	0.10	0.01

The particle size distribution (Fig. 1) showed a smooth and Gaussian distribution. The flour presented a homogeneous distribution with an average particle size of 148 microns, which is adequate to be considered as flour for bakery and confectionery products.

Fig. 1 Particle size distribution.

The SEM images show the morphological characteristics of flours. Figure 2 reveals a surface rounded particle, without rocky parts, or forced cuts. Figure 3 shows a particle organized with smaller particles, forming a tortuous, irregular form, porous, and rocky agglomerate; a strong attraction was observed between the particles with different sizes.

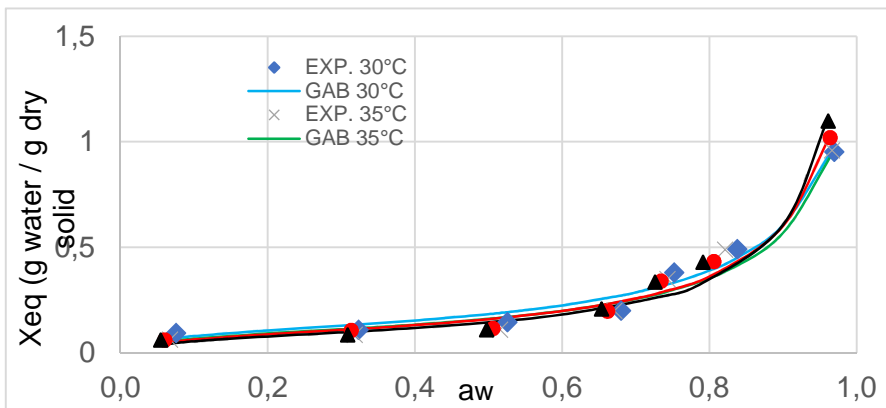

**Fig. 2** Micrograph of mesquite flour (Mill pulverizer), 2500x.

**Fig. 3** Micrographs of mesquite flour (Blender), 160x.

The experimental and simulated sorption isotherms at 30, 35, 40 and 45°C are shown in Figure 4, which display a type II form. The shape of the curve indicates a probable small adsorption force in the monolayer [7]. An increase in  $X_{eq}$  was identified when  $a_w$  is near from 0.65, at this water activity a degradation of flour was observed. This type of isotherm has been obtained in materials containing fibers (wheat, rice, potato, soybean, corn) [8]. Also an interlacing of the curves was observed, indicating a non-dependence on temperature. The GAB model correctly describes the experimental data.

**Fig. 4** Adsorption isotherm of mesquite flour (*Prosopis laevigata*) at the four working temperatures.

Table 2. Parameters obtained from the GAB model

Model	Parameters	30°C	35°C	40°C	45°C
GAB	<b>X<sub>wa</sub></b>				
	(g H <sub>2</sub> O /g dry matter)	0.1039	0.0905	0.0894	0.0824
	C	22.1997	19.9075	16.6142	15.2432
	k	0.9219	0.9355	0.9475	0.9656
	r <sup>2</sup>	0.9898	0.9772	0.9817	0.9773
	s	0.0555	0.0741	0.0592	0.0703

X<sub>wa</sub> = Monolayer value; C and k = constants for the model; r<sup>2</sup> = correlation coefficient; s = standard error

Figure 5 shows the isosteric heat (Q<sub>st</sub>). Q<sub>st</sub> increases as X<sub>w</sub> decreases; At X<sub>w</sub>=0.25 the value of Q<sub>st</sub> is 47.69 kJ/mol and at X<sub>w</sub>=0.05 Q<sub>st</sub>=81 kJ/mol. This fact indicates a low availability of active sites and liaison forces on the surface of the flour [9]. Q<sub>st</sub> indicates a requirement of 81 kJ/mol in order to remove 0.05 g water/g dry solid, without affecting the stability of the flour.

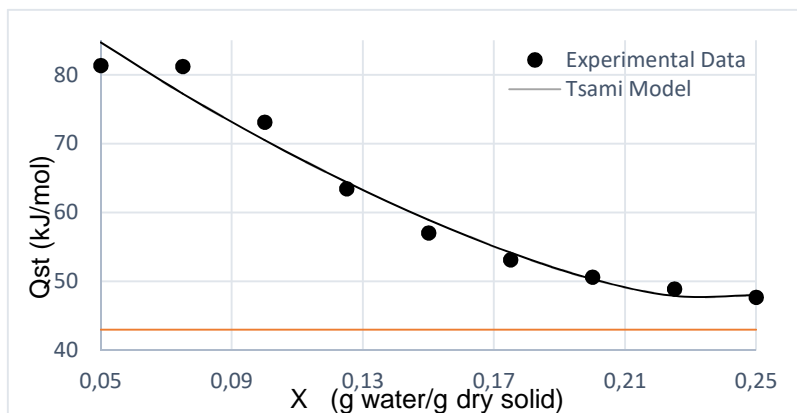

Fig. 5 Isosteric heat of sorption as a function of the moisture content of mesquite flours subjected to constant temperatures of 30, 35, 40 and 45°C.

Figure 6 shows the DSC curves for mesquite flours. A glass transition (T<sub>g</sub>) of the mesquite flour was not observed, due to a probable flexibility and mobility of the glucose and fructose chains, as well as the presence and increase in the water content of the sample [10]. The flours displayed a wide thermal stability (0-130°C). The phase transition observed in all the flours were melting points from 148°C to 158°C and crystallizations at 170°C due to the presence of simple sugars, such as fructose.

Fig. 6 DSC curves. Flours conditioned at different aw, at 45°C.

#### 4. Conclusions

The nutritional content of the powders reveals important properties for the mesquite flours. Flours have a high content of sugars and fiber, and an important content in protein. Flours are highly hygroscopic, and this fact can be explained by the sugar content. Microscopic images reveal irregular, agglomerated and porous structures. Flour displays a type II isotherm, a water activity higher than 0.6 provokes a degradation of the powders. According to the isosteric heat, 81 kJ/mol are required in order to remove 0.05 g water/g dry solid, without affecting the stability of the flour. The calorimetric data showed a wide thermal stability (0-130°C) of this material. The flour reveals a potential use for the food industry.

### **Abstract**

*Developing a technique to disperse hydrophobic ingredients homogeneously in a water-soluble solid matrix (solid dispersion) is one of the topics that have been extensively investigated in the pharmaceutical and food industries. Recently, we have devised a novel solid dispersion technique (surfactant-free solid dispersion), in which a preliminarily amorphized sugar was dissolved in an organic media containing hydrophobic component, without using any surface active substances, and then vacuum dried into the amorphous solid mixture [Food Chem., 197 (2016) 1136; Mol. Pharm., 14 (2017) 791]. In this study, the physicochemical properties, especially thermal stability of the surfactant-free amorphous solid dispersion, were investigated.*

**Keywords:** *solid dispersion; amorphous sugar; surfactant-free; vacuum drying; glass transition temperature*

---

## **1. Introduction**

To date, many attempts have been made to improve the solubility of hydrophobic drugs in physiological fluids [1,2]. One promising approach for improving the water solubility of a hydrophobic drug is the use of an “amorphous solid dispersion (ASD)”[3-5], in which hydrophobic drug molecules are dispersed at the molecular level in the carrier matrix comprised of water-soluble substance. When a medicine in the ASD is taken into a human body, the dissolution of the carrier matrix is accompanied by the release of hydrophobic drug molecules [6]. The concentration of the dissolved drug temporarily increases much above the equilibrium solubility (over-dissolution), possibly resulting in the improvement of the bioavailability of the hydrophobic drug [6]. In the solid dispersion of hydrophobic drugs, an amphiphilic polymer such as polyvinylpyrrolidone and hydroxypropyl methylcellulose is frequently used as the carrier matrix [6,7], and a combination of a surfactant with an amorphous carbohydrate matrix has also been reported to be effective for the stable dispersion of drugs [8,9]. On the other hand, we recently developed a new ASD technique that does not involve the use of a surface active agent [10]. In this method, (i) sugar is amorphized and (ii) added to an organic solvent containing a hydrophobic substance, followed by homogenization. (iii) The homogenized solution is then dried to a solid (surfactant-free solid dispersion). The amorphized sugar can be dissolved in an organic solvent such as methanol to a greater extent than a crystalline one. Hydrophobic drugs (Indomethacin, ibuprofen, gliclazide, nifedipine) can be stably embedded in the surfactant-free solid dispersion without any detectable segregation and exhibited marked over-dissolution at the initial stage of the dissolution in water [11].

The stability of the dispersion state of drug molecules in an amorphous carrier matrix is also an important quality aspect of the ASD besides the drug dissolution behavior in water: When hydrophobic drug molecules segregate from the amorphous carrier matrix, the over-dissolution of the drug is mostly precluded. The segregation of hydrophobic drug molecules is caused by the glass-to-rubber transition of the carrier matrix, and the glass transition temperature ( $T_g$ ) of amorphous carrier matrix therefore is considered to correspond to the drug dispersion stability. In this study, first the  $T_g$  values of the surfactant-free solid dispersion were measured and compared to those for authentic freeze-dried ones. As a result, the  $T_g$  value of amorphous sugar matrix obtained from an organic solvent (methanol) was found to be significantly lower than that from an aqueous solution and furthermore indicated to be increased, as the result of a heat treatment, to as high as that for the water-originated one. Hence, at the next step, the methanol-originated amorphous sugars were heated under different conditions, including temperature and period, and analyzed for the  $T_g$  value and the drug dissolution behavior in water. The mechanism of the markedly low  $T_g$  for the methanol-originated amorphous sugars as well as what happens in the heat-treatment were investigated.

## 2. Materials and Methods

### 2.1. Materials

$\alpha$ -Maltose, maltitol, palatinose, and trehalose were purchased from Wako Pure Chemical Industries, Ltd., (Osaka, Japan). Indomethacin ( $\gamma$ -form of the crystal) and ibuprofen (Wako Pure Chemical Industries) were used as hydrophobic drugs. Methanol was obtained from Wako Pure Chemical Industry.

### 2.2. Methods

***Vacuum Foam Drying and Heat Treatment*** The amorphous sugar cake that had been freeze-dried from an aqueous solution [12] was added to a methanol solution, containing a model hydrophobic drug, at the concentration of 100 mg/mL. Immediately thereafter, a 100  $\mu$ L aliquot of the mixture solution was transferred to a 1.5 mL-polypropylene tube and the resulting solution was then dried under a reduced pressure of around ca. 1 Torr and centrifugation at  $30\pm 1^\circ\text{C}$  for 60 min (methanol-originated sample), using a TOMY Micro Vac MV-100 centrifugal concentrator (TOMY SEIKO Co., Ltd., Tokyo, Japan). At this initial drying stage, foaming was minimal. After a 60 min period of initial drying, the residue was punctured with a steel needle, followed by the secondary vacuum drying for an additional 30 min [11]. The subsequent vacuum drying reliably resulted in foaming [11]. These series of procedures had preliminarily been indicated to be indispensable for drying the sample sufficiently ( $< 0.01$  g-MeOH/g-dry matter) within a convenient drying period [11].

The obtained dried sample was alternatively transferred in a glass vial and then heated in a drying oven. The sample vials were sealed with heat-resistant caps to avoid the water sorption in the drying oven. The heating temperature and period were varied from 30 to  $120^\circ\text{C}$  and from 0 to 120 min.

***Differential Scanning Calorimetry*** Differential scanning calorimetry (DSC) analyses of amorphous sugar matrices, obtained from methanol as well as water, were carried out, using a TA Q2000 calorimeter (TA instruments Co., New Castle, DE) equipped with RCS90 cooling system (TA instruments Co.) in the same procedures as was used in our previous study [11]. From the obtained DSC curves, the  $T_g$  of the sample was determined as the onset of the corresponding thermal event.

***Fourier Transform Infrared Ray Spectroscopy*** IR spectra for amorphous sugar samples were measured by means of a diffuse diffraction method using an FTIR in the same ways as was used in our previous study [13]. In order to semi-quantitatively estimate the degree of formation of hydrogen bonding in an amorphous sugar matrix, the peak wavenumbers of sugar O-H stretching vibration bands of amorphous sugar samples were analyzed. The IR

band due to sugar O-H stretching vibration (3200~3500 cm<sup>-1</sup>) was smoothed at 80 points to determine the peak wavenumber.

**Specific Molar Volume Analysis** A ten mL of methanol or water was put in a 20 mL graduated cylinder, and 0.1~2 g (0.3~6 mmol) of amorphous sugar cake that had been freeze-dried from water and then thoroughly dehydrated over P<sub>2</sub>O<sub>5</sub> [12] was then added to the methanol. α-Maltose was used as a sugar since it can be highly dissolved in methanol from amorphous state compared to the other sugars [10]. The freeze-dried amorphous α-maltose was absolutely dissolved by gently inverting the graduated cylinder several times. After removing bubbles on the cylinder wall, the change in the volume (*dV*) was determined and converted into the apparent partial mole volume of sugar (*v*<sub>sugar</sub>) by being divided by the amount of the added sugar (*n* g) (Eq. (1)).

$$v_{\text{sugar}} = dV/n \quad (1)$$

**Dissolution Behavior of Hydrophobic Drugs from Solid Dispersion Samples** The prepared surfactant-free solid dispersions of model hydrophobic drugs were added to a known amount of water (final drug conc.: 50 µg/mL for indomethacin, 500 µg/mL for ibuprofen) and the suspension was stirred at 200 rpm with a 1.5-cm magnetic stirring bar at 37±1°C. A 200~1,000 µL aliquot of the suspension was withdrawn and then filtered with 0.2 µm pore size filter (Nihon Millipore K.K., Tokyo, Japan). The concentration of the dissolved model drug was typically measured by UV-vis absorption at specific wavelengths (indomethacin: 318 nm; ibuprofen: 233 nm).

### 3. Results and Discussion

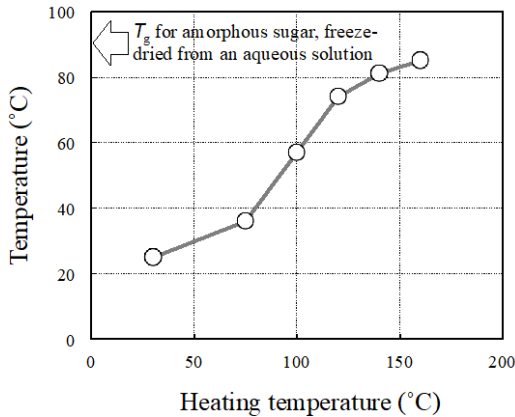

The DSC thermograms for the surfactant-free solid dispersion sample, obtained by vacuum foam drying from methanol solution, showed single heat capacity shift due to glass-to-rubber transition but no endothermic peak. This demonstrates that the surfactant-free solid dispersion sample was fully amorphous and methanol was fully removed during the vacuum foam drying.

**Table 1. Glass Transition Temperatures (*T*<sub>g</sub>) for amorphous sugar matrices, dried from methanol, as well as for Freeze-Dried from water**

sugar	<i>T</i> <sub>g</sub> (°C)	
	from water	from methanol
α-maltose	90±1	36±1 (1 <sup>st</sup> scan)
		72±2 (2 <sup>nd</sup> scan)
palatinose	62±2	21±1
trehalose	102±3	37±3
maltitol	46±2	9±2

Table 1 compares the *T*<sub>g</sub> values of differently dried matrices of sugars. The *T*<sub>g</sub> values for the sugar matrices dried from methanol are ~50°C lower than those for the samples dried from

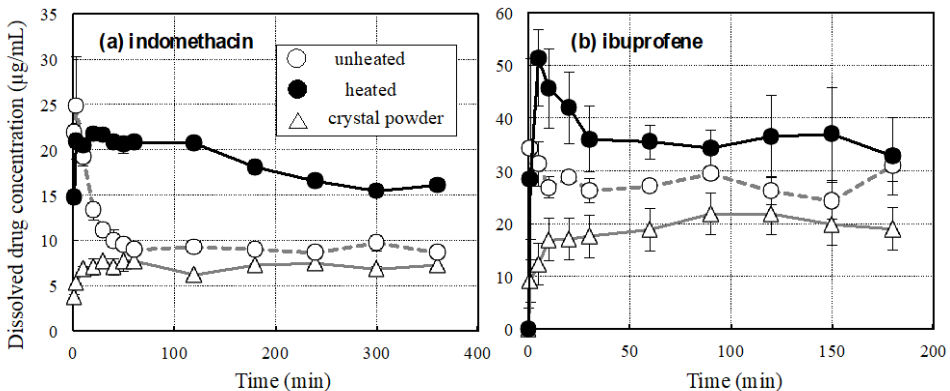

**Fig. 1.** Influences of heating temperature on  $T_g$  values for surfactant-free solid dispersion, obtained from methanol.  $\alpha$ -Maltose and indomethacin (1% v/v) were used as sugar and hydrophobic drug, respectively.

Figure 1 shows the  $T_g$  values for different heating temperatures. As the heating temperature (Fig. 1) and period (data not shown) increase, the  $T_g$  increases and appears to reach the value for the water-originated sample.

The dissolution of hydrophobic drugs in water from the heat-treated solid dispersion sample as well as from the unheated ones were measured (Fig. 2). Both the heated and unheated solid dispersion samples show typical “spring and parachute” dissolution curves [14]. Namely, the concentration of dissolved drug jumps up to much above the equilibrium solubility at the early stage (“spring”) and then decreases to reach the equilibrium value (“parachute”),

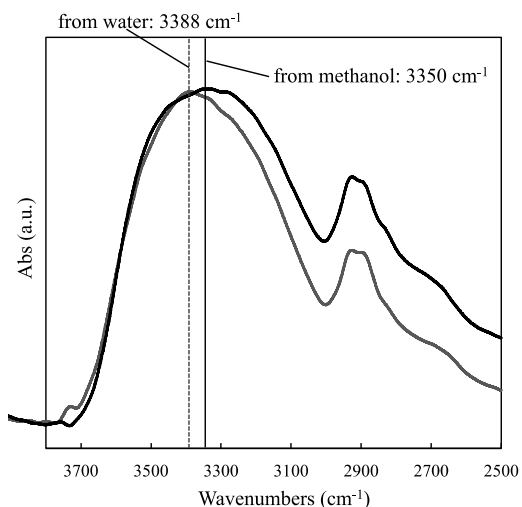

**Fig. 2.** Dissolution profiles of (a) indomethacin and (b) ibuprofene in water from unheated and heated surfactant-free solid dispersion as well as crystalline powders of model drugs.  $\alpha$ -Maltose was used as sugar, and the drug content in the solid dispersion sample was 1% w/w. The amounts of model drug added to the water were 50  $\mu\text{g/mL}$  for (a) indomethacin and 500  $\mu\text{g/mL}$  for (b) ibuprofene. The heat-treatment was conducted at 120°C for 60 min.

whereas the crystalline drug exhibits gradual increase toward the saturation concentration. When compared between the heated and unheated solid dispersions of indomethacin, the decrease in the dissolved indomethacin concentration after the over-dissolution is markedly slowed down as the result of the heat-treatment although the attained maximum dissolved concentration of indomethacin is slightly lowered. On the other hand, in the case for ibuprofen, the attained maximum dissolved concentration is slightly increased as the result of the heat-treatment while the slowing down of the "parachute" process is less significant than in the case for indomethacin. Considering these, the heat-treatment of the surfactant-free solid dispersion, originated from methanol, can be deduced to serve to improve the aqueous dissolution of hydrophobic drug, the effect and extent of which vary depending on the drug type.

At present stage, the mechanism for the improvement of aqueous dissolution of hydrophobic drugs by heating is obscure. However, this study indicates that the heat-treatment can overcome the low  $T_g$  of amorphous sugar (carrier) matrix, dried from methanol, and possibly the instability of over-dissolution of hydrophobic drugs. Hence, the possible mechanism for the markedly low  $T_g$  for the methanol-originated amorphous sugars and what happened in the heat-treatment were further investigated.

The IR spectra for the amorphous sugar matrices dried from methanol and water were compared (Fig. 3), indicating that the peak position of the absorption due to O-H stretching vibration for the methanol-originated sample ( $3350\text{ cm}^{-1}$ ) was much lower than that for the water-originated one ( $3388\text{ cm}^{-1}$ ). Accordingly, more sugar-sugar hydrogen bondings may be formed in the amorphous sugar matrix dried from methanol than in that from water. On the other hand, when the methanol-originated sample was heated (at  $120^\circ\text{C}$  for 60 min), the peak frequency of O-H stretching vibration was positively shifted toward the value for the water-originated sample (Fig. 3).

**Fig. 3.** IR bands for sugar O-H stretching vibration for amorphous matrices, dried from methanol and water. The peak wavenumbers of the IR bands are shown in the figures.

From the volumetric measurements of the methanol and aqueous solution containing different amount of amorphous sugar ( $\alpha$ -maltose), the occupied volume of sugar molecule in methanol and water were calculated to be 133 mL/mol and 188 mL/mol, respectively. This

indicates that a sugar molecule may have considerably compact conformation in methanol relative to in water.

Sugar molecule in a poor solvent may change its conformation so as to decrease the solvent-contacting surface area. The lower permittivity of methanol than that of water may allow intramolecular hydrogen bonding in the disaccharide molecule, which would also reduce the occupied volume of a sugar molecule. Consequently, the partial molar volume of  $\alpha$ -maltose in methanol is considered to be markedly smaller than in water, as shown above.

When assumed that the sugar molecules in the matrix dried from methanol, more or less, maintain their compact conformation before being drying, the methanol-originated matrix is considered to have smaller mean intermolecular distance and thus greater extent of hydrogen bondings, as indicated by the lower frequency of sugar O-H stretching vibration. It would also follow that the smaller volume assigned to each sugar molecule provides the lower  $T_g$  where the free volume of sugar molecule reaches a critical value (Table 1). Furthermore, the markedly small occupied volume of sugar molecule in the matrix obtained from methanol may be accompanied by the distortion of the sugar molecule. The relaxation of sugar molecule to less awkward conformation is thus considered to be time-dependent and accelerated with increasing temperature, as shown in Fig. 1.

#### **4. Conclusion**

Amorphous sugar can be temporarily dissolved in methanol and dried into amorphous powders from methanol, which was applied to the surfactant-free solid dispersion of hydrophobic drugs (surfactant-free solid dispersion). However, the  $T_g$  of the methanol-originated sample was much lower than that of amorphous sugar dried from water. More hydrogen bonds are formed in the amorphous matrix dried from methanol than in the matrix dried from water. The specific characteristics of the methanol-originated sample were reduced as the result of heating: The  $T_g$  and degree of hydrogen bonding for the surfactant-free solid dispersion sample were respectively increased and reduced close to those for amorphous sugar dried from water by heating under appropriate conditions. The heat treatment was indicated to improve aqueous dissolution of hydrophobic drugs (indomethacin and ibuprofen) from the surfactant-free solid dispersion. The comparison of the apparent sugar molar volumes in methanol and water suggested that the occupied volume of sugar molecules in methanol was ~30% smaller than that in water. The markedly lower  $T_g$  and higher extent of hydrogen bonding for the methanol-originated amorphous sugar matrix were deduced to closely relate to the highly compact and possibly awkward conformation of sugar molecules in methanol.

### **Abstract**

*In this study, the effects of drying temperature (70, 80, 90°C) and air velocity (0.5, 1.8 m/s) of hot air drying (tray drying) on quality of dried 2-phase olive pomace and system's energy efficiency were investigated. The drying experiments were carried out in a tray dryer. The effects of drying conditions were evaluated with analyzing drying time, the primary and secondary oxidation and calculating specific moisture extraction rate (SMER), moisture extraction rate (MER) and specific energy consumption (SEC). The results showed that increase in drying temperature and decrease in air velocity led to decrease in quality of dried olive pomace.*

**Keywords:** Waste valorization, 2-phase olive pomace, Tray dryer, Energy efficiency, oxidation stability

---

## **1. Introduction**

The differences in olive oil production methods in terms of 2-phase and 3-phase extraction result in varies wastes in terms of property and quantity [1]. The olive mill waste water and olive pomace (35-40 % moisture) are obtained as wastes in 3-phase extraction, while 2-phase extraction only consists of olive pomace with higher moisture content (60-70 %) as waste. The pollution degree with respect to COD (chemical oxygen demand) and BOD (biological oxygen demand) of olive pomace in 3-phase system are considerably high compared to 2-phase system [2]. Although olive pomace is presented as a waste, it can be used as an ingredient in animal feed additives, fertilizer and source of alternative fuel [3]. Moreover, lipase enzyme by fermentation, activated carbon by hydrolysis and biodiesel are also obtained from olive pomace [3]. It is necessary to dry the olive pomace in order to be evaluated as a high-value-added by-product. The drying process improves the processability and durability of the olive pomace. Drying of olive pomace is generally carried out in rotary dryer at a range of 400 to 800°C in the industry [4]. Unfortunately, 2-phase olive pomace (2-POP) cannot be easily dried in rotary dryer at this temperature range due to high moisture content and low thermal stability [5]. For these reasons, 2-POP is mixed with different amounts of 3-phase olive pomace to regulate the moisture content and to avoid the adhesion on dryer wall [4]. However, the quality of 2-POP decreases due to high drying temperature and long drying time. New drying methods should be taken into consideration to overcome this issue.

The aim of this study was to determine the effects of drying temperature and air velocity of tray drying as an alternative drying method on the quality of dried 2-POP and the system's energy efficiency.

## **2. Materials and Methods**

### **2.1. Materials**

2-phase olive pomace (2-POP) was purchased from a factory where 2-phase olive oil is produced by 2-phase extraction system in Aydın, Turkey. Then, it was stored at -25°C until drying experiments. Prior to drying, the samples were thawed at 4°C in a refrigerator. The moisture content of 2-POP was determined as 66.4 % (wb.).

### **2.2. Drying Procedure**

Due to high moisture content, 2-POP was pre-dried in a drum dryer whose conditions were selected as vapor pressure~3 bar (133.52°C), drum rotational speed:~6 rpm, drums gap:~3 mm in order to decrease the moisture content from 66.4% to 50% (wb.). After pre-drying, 1 kg of pre-dried 2-POP having 50% moisture content was dried in a tray dryer (Eksis make,

Isparta, Turkey) until 8% moisture content at different conditions. Drying temperature (70, 80, 90°C) and air velocity (0.5, 1.8 m/s) were selected as independent variables of tray dryer. Drying experiments of 2-POP were performed at each drying temperature and air velocity, while the sample thickness (0.5 cm) and drying area (25x25 cm) were kept constant for all experiments. All drying experiments were done in duplicate for each drying condition and all analysis was applied triplicate.

### 2.3. Analysis

#### 2.3.1. Moisture Content

Moisture content of raw, pre-dried and dried olive pomace was determined by vacuum oven at 65°C and 0.25 bar [6]. Moisture content of samples was identified as wet basis.

#### 2.3.2. Oxidation Level

For determination of oxidation level of dried samples, the oil was extracted from 2-POP by cold extraction with chloroform/methanol as solvent. After that, this mixture was evaporated at 50°C by a rotary evaporator (Heidolph, Germany). Peroxide value, free fatty acid and ultraviolet (UV) absorbance ( $K_{232}$  and  $K_{270}$ ) were analyzed to determine oxidation level. *Peroxide value* of samples was analyzed by titration method given in AOAC (1990) [7]. *Free Fatty Acid* analysis was performed by titration used KOH according to Sun-Waterhouse et al. (2011) [8]. *Ultraviolet (UV) Absorbance ( $K_{232}$ ,  $K_{270}$ ) value* of oil obtained from samples was measured by spectrophotometer after that oil was diluted in iso-octane (2,2,4-trimethylpentane).

#### 2.3.3. Drying system efficiency

Criteria of Specific Moisture Extraction Rate (SMER), Moisture Extraction Rate (MER) and Specific Energy Consumption (SEC) were calculated to determine drying efficiency of system. *Specific moisture extraction rate (SMER)* (kg water/kWh) shows that the mass of water removed from the product to be dried for consuming per unit the energy kWh. According to Hawlader ve Jahangeer (2006), SMER values were calculated [10]. *Moisture Extraction Rate (MER)* (kg water/h) is defined as the mass of moisture removed from the dryer at the unit time. This proportion is calculated according to Gürlek et al. (2015)[9]. *Specific Energy Consumption (SEC)* (kJ/kg water) is described as the amount of energy required to remove per unit moisture (kg) from the samples during drying. According to Sadi et al. (2015), these values were calculated [10].

#### 2.3.4. Statistical analysis

ANOVA test was conducted to determine the effect of drying temperature and air velocity on dried 2-POP. The statistical analyses were performed using SPSS (Statistical Package for the Social Sciences, SPSS Chicago, Illinois, USA) software version 15.0.

### **3. Results and Discussion**

As a result of drying experiments at different temperatures and air velocities, drying time changed between 74 and 170 min. Drying at high temperature and air velocity (90°C and 1.8 m/s) had a short drying time (74±1.4 min), while drying time (170.0±2.1 min) at low temperature and air velocity (70°C, 0.5 m/s) was longer than other experiments (Table 1). Increase in drying temperature and air velocity caused a decrease in drying time due to the increase heat transfer rate. Increase in air velocity gave rise to accelerate the mass transfer from the surface of samples. Thus, drying time also decreased at high air velocity. Moreover, the process conditions of tray dryer in terms of temperature and air velocity had significant effect on the drying time as given in Table 2 ( $p < 0.05$ ).

Olive pomace, which is rich in poly unsaturated fatty acids, is easily exposed to oxidative degradation. Oxidative degradation is one of the important factors for limiting the shelf life of products and causing quality losses [11]. Hence, it is necessary to examine oxidation mechanism during drying of 2-POP.

The drying temperature and air velocity were considerably effective variables on dried olive pomace's peroxide value, free fatty acid,  $K_{232}$  and  $K_{270}$  values (Table 1). Increase in drying temperature and decrease in air velocity caused an increase in peroxide value, free fatty acid,  $K_{232}$  and  $K_{270}$  values showing the quality loss of product. Long drying time caused an increase in oxidation level of samples [12]. Although drying at high temperature resulted in a decrease in drying time, the oxidation level of samples dried at high temperature were higher compared to those dried at low temperature (Table 1). According to the literature, oxidation mechanism accelerates with heat treatment. Application of heat treatments at high process time and temperature causes an increase in quality loss of samples [13]. The peroxide,  $K_{232}$  and  $K_{270}$  values of samples were significantly affected by temperature and air velocity. Although free fatty acid values of samples were affected by drying temperature and velocity, free fatty acid values only changed with drying temperature at significant level (Table 2;  $p < 0.05$ ).

Energy consumption of drying process constitutes 10-25 % percentage of industrial energy consumption [14]. Thus, drying processes and systems which are provided to use efficient energy are necessary to develop [4]. SMER, MER and SEC values were calculated and compared to determine tray dryer's system efficiency at different conditions in this study.

PV: Peroxide value; FFA: Free fatty acid

Results of SMER (kg water/kWh), MER (kg water/h) and SEC (kJ/kg water) values are given Table 1 while their ANOVA results are shown in Table 2. It is necessary to reach maximum SMER and MER value and minimum SEC value in order to operate the dryer with high drying performance and energy efficiency. Motevali et al. (2011) investigated the effect of drying temperature on drying system efficiency. They found that drying system efficiency in tray dryer decreased with increasing temperature at constant air velocity [16]. Increasing drying temperature resulted in increase in SMER and MER values; a decrease in SEC values (Table 1). Although high-energy consumption needed to reach high temperature in tray dryer, energy efficiency of dryer system was increased at high temperature due to shorter drying

time. With increasing air velocity, SMER and MER values had an upward tendency whereas SEC values had a downward tendency. An increase in air velocity caused a decrease in drying time so dryer system's performance was increased. It was determined that SMER and SEC values were significantly affected by temperature (Table 2;  $p < 0.05$ ) in contrast to air velocity (Table 2;  $p > 0.05$ ). Moreover, temperature and air velocity were effective variables on MER values (Table 2;  $p < 0.05$ ).

#### 4. Conclusion

In this study, the effects of temperature and air velocity on quality of dried 2-POP and the system's energy efficiency were determined. Increase in temperature and decrease in air velocity caused an increase in the peroxide value, free fatty acid and specific absorption value at UV light ( $K_{232}$ ,  $K_{270}$ ) of 2-POP whereas decrease in the drying time. It was determined that drying at low temperature and high air velocity led to increase in oxidation stability of olive pomace dried in a tray dryer. Maximum SMER, MER and minimum SEC values were expected to determine for high performance and energy efficient dryer system. The effective conditions of tray dryer were specified at high drying temperature and air velocity (90°C and 1.8 m/s). As a conclusion, this study showed that it was necessary to examine the quality of product and energy efficiency of dryer systems together in drying applications.

#### 5. Nomenclature

### **Abstract**

*Potential factors leading to surface oil were investigated by analyzing the impact of emulsion properties, atomization and drying conditions separately. An increased oil load, droplet size and in particular the size of droplet aggregates led to significant more surface oil. Increasing the viscosity, inlet temperature and relative humidity resulted in larger particles with a higher encapsulation efficiency. The results indicate that the probability of oil droplets being in contact with the particle surface determines the amount of surface oil. Oil diffusion towards the surface was excluded due to the short residence times and high viscosities.*

**Keywords:** *microencapsulation; encapsulation efficiency; emulsion properties; atomization; drying conditions*

## **1. Introduction**

Polyunsaturated fatty acids are susceptible to oxidation. Microencapsulation is a strategy to protect lipids against environmental oxygen by embedding oil droplets in a solid matrix acting as an oxygen diffusion barrier. Some droplets are not fully covered and are in contact with the particle surface. This so-called surface oil is not protected and directly exposed to environmental oxygen.

In literature several hypotheses about surface oil creation during spray drying are stated. Apart from emulsion stability, oil droplet disruption during atomization and oil diffusion towards the particle surface are believed to be the main factors leading to surface oil [1]–[3]. Experimental confirmation is partly lacking due to the high number of potential factors interacting with each other and influencing the encapsulation efficiency (EE).

In this study it is hypothesized that the probability of oil droplets being in contact with the particle surface determines the surface oil concentration. The aim of this study is to identify key factors determining the EE by investigating the impact of emulsion properties, feed atomization and drying rate separately.

## **2. Materials and Methods**

High quality fish oil (Omega Oil 1812 TG Gold) was kindly provided by BASF Personal Care and Nutrition GmbH (Illertissen, Germany). Rapeseed oil, maltodextrin DE21 (AGENABON) and Soy Protein Isolate (Vegacon 90) were obtained from Hery Lamotte Oils GmbH (Bremen, Germany), Agrana GmbH (Frankfurt am Main, Germany) and Eurosoy GmbH (Hamburg, Germany), respectively.

### **2.1. Emulsion and Powder Preparation**

Soy protein and maltodextrin DE21 were hydrated in distilled water for 12 h. Oil was dispersed by operating an IKA SPP25 (Staufen, Germany) for 10 min. The emulsion was homogenized in four passes using the homogenizer HL 1.3-400KX (HST Maschinenbau GmbH, Dassow, Germany). Emulsions were spray dried using a pilot plant dryer (type FSD 4.0, GEA-Niro, Copenhagen, Denmark) with a maximum water evaporation capacity of 30 kg/h operated at an airflow of 200 kg/h in the closed loop mode. The feed was atomized using a two fluid nozzle set to 1 bar (ex GEA-Niro). Inlet and outlet temperature were set to 180°C and 85 °C, respectively.

### **2.2. Analysis**

#### *2.2.1. Oil droplet size*

Static light scattering: A Mastersizer 2000 (Malvern Instruments Ltd, UK) was used to analyze the oil droplet size according to Mie-Theory. Three samples of each emulsion were measured in triplicate.

Pulsed field gradient: A Bruker minispec mq 20 NMR Analyzer (Bruker, Rheinstetten, Germany), operating at 20 MHz and equipped with a controlled pulsed gradient unit with a probe head H20-10-25-AVXG (Bruker, Rheinstetten, Germany) was operated at 20 °C. The oil droplet size of emulsions and within the powder was determined according to the procedure described by Linke et al. (2017) [4].

### 2.2.2. Particle Size Distribution

A Mastersizer 2000 (Malvern Instruments Ltd, UK) was used to determine the particle size by dispersing the powder in ethanol. Data were analyzed according to Fraunhofer theory. Three samples of each powder were measured six times.

### 2.2.3. Oil Load, Surface Oil and Encapsulation Efficiency

The surface oil was removed applying a procedure described by Bae and Lee (2008) with some modifications [5]. Approximately 1 g powder and 10 mL n-Hexane (ROTISOLV® HPLC) were shaken for 2 min. The powder was separated by filtration and washed three times with 10 mL n-Hexane. The oil load of the untreated and washed powder was determined according to a method described by Linke et al (2017). Briefly, a Bruker Minispec MQ20 NMR Analyzer (Bruker, Rheinstetten, Germany) with an absolute probe head H20-18-25-A1 was operated at 40 °C with a resonance frequency of 19.95 MHz. The powder was weighed into tubes and tempered at 40°C for 45 min. The instrument was calibrated with standards consisting of 0.07 and 0.9 g fish oil. The surface oil was calculated by subtracting the remaining oil from the total oil. The encapsulation efficiency was determined by dividing the amount of encapsulated oil by the total oil times 100.

## 3. Results

### 3.1. Impact of emulsion properties on the encapsulation efficiency

In order to vary the emulsion properties in terms of viscosity, oil content and oil droplet size the homogenization pressure, oil load, dextrose equivalent (DE) of the maltodextrin and the soy protein concentration were modified (Figure 1). With increasing ratio of soy protein to oil the  $d_{3,2}$  of oil droplets decreased (Figure 1A). Additionally, the diameter measured by static light scattering (SLS) and nuclear magnetic resonance (NMR) differed at concentrations below 0.07 g (w/w) protein per oil. Due to different measurement principles, the latter method measures the size of individual droplets, whereas SLS determines the average diameter of droplet clusters [6], [7]. Insufficient concentrations of soy protein lead to droplet flocculation, which was confirmed by light microscopy (data not shown). Using maltodextrin with a higher DE led to a significant reduction of viscosity, due to shorter glucose chains (Figure 1B). Homogenizing emulsions at higher pressure decreased the oil droplet size, whereas the viscosity remained constant (Figure 1C). In case of an higher oil content the droplet size and viscosity slightly increased (Figure 1D).

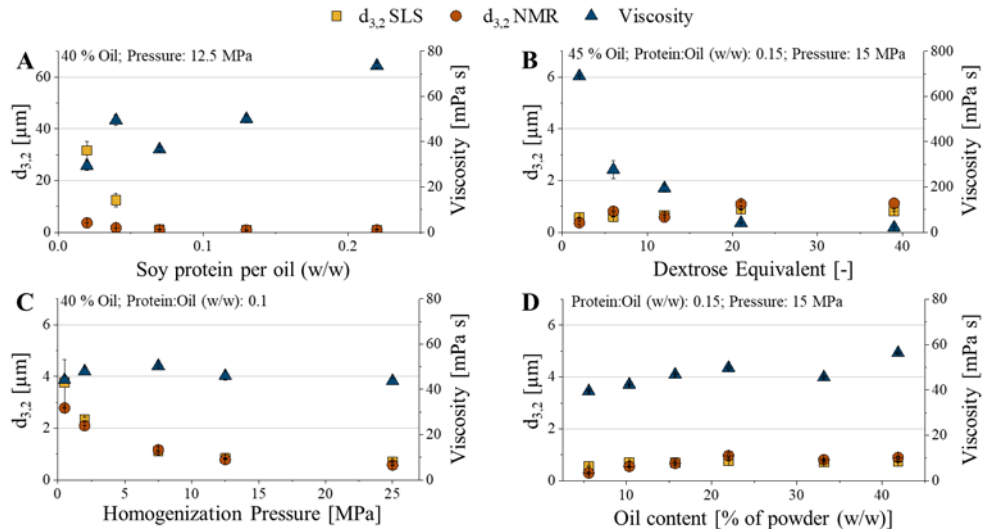

Figure 1: Emulsion viscosity and Sauter mean diameter  $d_{3,2}$  of oil droplets determined by static light scattering (SLS) and nuclear magnetic resonance (NMR) as a function of the soy protein concentration (A), dextrose equivalent of maltodextrin (B) homogenization pressure (C) and oil content (D); default settings were set to a solid content of 45% and maltodextrin DE21

### 3.1.1. Impact of the droplet size on the EE

Modifying the emulsifier concentrations and homogenization pressure resulted in a change in the Sauter mean diameter of oil droplets (Figure 1). Plotting the  $d_{3,2}$  as a function of the EE shows that larger droplets lead to a less efficient encapsulation (Figure 2).

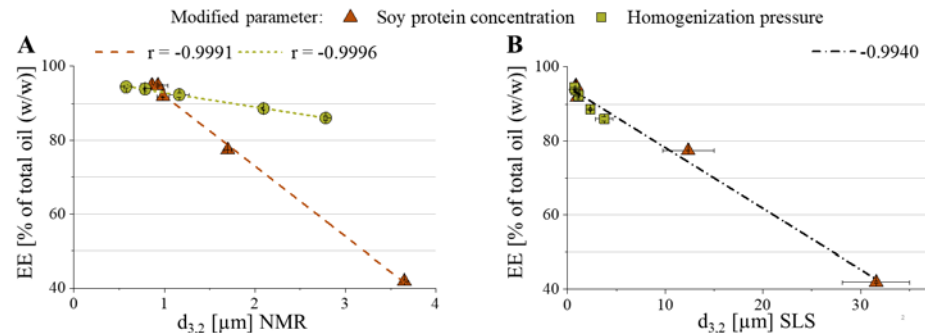

Figure 2: EE [% of total oil] as a function of the Sauter mean diameter  $d_{3,2}$  of oil droplets [ $\mu\text{m}$ ], determined by nuclear magnetic resonance (NMR) (A) and static light scattering (SLS) (B)

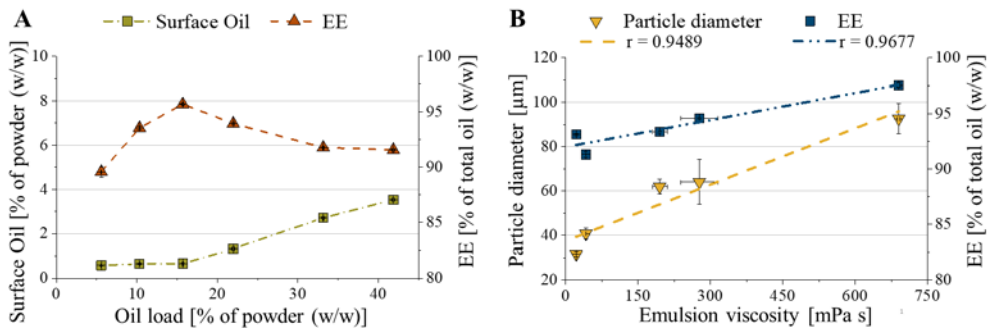

In case of the  $d_{3,2}$  determined by NMR, the droplet size modified by the homogenization pressure affects the EE less compared to the protein concentration (A), whereas the impact of the diameter measured by SLS is aligned for both samples sets (B). As SLS measures the

size of droplet clusters it is concluded that apart from the individual size, oil aggregates lead to more surface oil. As droplet clusters are larger compared to individual droplets, it is more likely for them being in contact with the powder particle surface and contributing to surface oil.

### 3.1.2. Impact of the oil load on the EE

The EE and the amount of surface oil is plotted as a function of the oil concentration in the emulsion (Figure 3, A). A higher oil load leads to more surface oil supporting the hypothesis, as the likelihood for droplets being in contact with the particle surface is higher if more oil is present. However, the EE increases up to oil loads of 15 % and decreases at higher concentrations. Even though less oil is located at the particle surface, the ratio to the amount of encapsulated oil fraction is smaller leading to a decreased encapsulation efficiency.

**Figure 3:** EE [% of total oil] and surface oil as a function of the oil concentration in the emulsion (A); EE and particle diameter  $d_{50,3}$  as a function of the viscosity for samples containing maltodextrin with a different dextrose equivalent (B)

### 3.1.3. Impact of the viscosity

Modifying the dextrose equivalent of the maltodextrin resulted in a change in the emulsion viscosity (Figure 1). With increasing viscosity larger particles and a more efficient encapsulation is obtained (Figure 3, B). It is assumed, that larger particles increase the EE due to a lower ratio of particle surface to particle volume. Thus, the viscosity is affecting the EE indirectly by changing the size of encapsulated lipid particles.

## 3.2. Impact of drying conditions and particle properties

Figure 4 shows the particle diameter and the EE as a function of the solid content, inlet temperature and relative humidity of the drying medium. A higher solid content and inlet temperature resulted in larger particles, due to a higher viscosity and faster crust formation preventing shrinkage, respectively. A higher humidity in the drying air resulted in slightly

larger particles. This is unexpected, as the drying rate is supposed to decelerate enabling particle shrinkage.

**Figure 4:** Particle diameter  $d_{50,3}$  [µm] and EE [% of total oil] as a function of the solid content, inlet temperature and relative humidity for samples differing in oil concentration and solid content, the default settings were set to a solid content and oil load of 35% and 30%, respectively.

Plotting the EE as a function of the particle diameter shows an increase until a plateau is reached (Figure 5). Apart from the modified drying conditions, particles containing different dextrose equivalent are following the same trend. Larger particles have a lower particle surface to volume ratio. Thus, it is more likely for oil droplets being embedded in the particle center and not being in contact with the particle surface. Particles above approximately 100 µm are powder aggregates. The EE might reach a plateau as aggregates consist of a number of individual particles, which determine the particle surface. Hence, the surface is not decreasing further with increasing aggregate size.

**Figure 5:** EE [% of total oil] as a function of the particle diameter  $d_{50,3}$  [µm]; Samples contain different solid content (SC) and maltodextrin dextrose equivalent (DE) and are spray dried at different inlet temperatures ( $T_{in}$ ) and relative humidity (rH).

## 4. Discussion

In this study the impact of potential factors on the encapsulation efficiency during the production of encapsulated lipid particles was investigated. In order to do so, the influence of emulsion properties and spray drying conditions on the surface oil creation was analyzed separately. Due to the number of potential factors and their interaction with each other it is challenging to identify the main contributors causing surface oil.

Smaller particles, oil droplets and in particular oil droplet clusters decreased the encapsulation efficiency significantly. This supports the hypothesis, that the probability of oil droplets being in contact with the particle surface determines the amount of surface oil. This might explain that encapsulated lipid particles produced by a benchtop spray dryer generally have a lower encapsulation efficiency compared to powders obtained on pilot plant scale as the obtained particles are smaller.

Larger particles were obtained at a higher solid content and inlet temperatures. Due to the increased viscosity and the fast drying the mobility of oil droplets was reduced, so that the likelihood of oil diffusing towards the particle surface is decreased. In terms of the increased humidity, the drying medium is more polar, which might prevent oil diffusion additionally. However, due to the short residence times and high viscosity it is suggested that oil droplet diffusion has no significant impact on the encapsulation efficiency.

Increasing the oil load up to 15% resulted in a higher efficiency even though the amount of surface oil was raising. Maximizing the concentration of lipids being fully embedded in the matrix increases the efficiency, but does not necessarily enhance the shelf life, as the absolute amount of surface oil being exposed to environmental oxygen may also increase. Additionally, to the investigated properties the volume of vacuoles in the particles should be considered, as it decreases the ratio of outer particle surface to the effective matrix volume. This might reduce the encapsulation efficiency, due to a higher likelihood of being in contact with the particle surface.

## 5. Conclusions

In this study the impact of the emulsion properties and spray drying conditions on the encapsulation efficiency was investigated. An increased oil load, smaller particles and larger oil droplets and droplet aggregates led to more surface oil. It supports the hypothesis, that the probability of oil droplets being in contact with the particle surface determines the success of the encapsulation.

## 6. Nomenclature

$d_{3,2}$	Sauter mean diameter	$\mu\text{m}$
EE	Encapsulation Efficiency	%
DE	Dextrose Equivalent	-

### **Abstract**

*Gluten-free (GF) dry egg pappardelle was prepared with tigernut flour (50%), chickpea flour (50%) and pregelatinized TNF (0, 5, 10%), and compared to plain pasta (100% durum wheat semolina). The GF pasta may have a significant higher content of insoluble fibre, minerals and fat rich in oleic acid and a similar protein content. It was not found any clear relationship between the flour functional properties and its proximate composition. The use of PG did not imply an improvement on the firmness but did provide some continuity to the pasta structure.*

**Keywords:** *Gluten-free pasta, tigernut flour, chickpea flour, texture, cooking properties.*

---

## **1. Introduction**

The celiac disease is one of the most common food induced disorders worldwide with an estimated mean prevalence of 1% of the total population [1]. To date, the only efficacious treatment for celiac disease affected patients is a gluten-free diet. However, many GF products based on cereals exhibit lower nutritional quality [2] and, not less important, higher glycemic index [3] than their gluten containing counterparts. Since pasta is one of the products that is most demanded by people with celiac disease [4], the aim of this study was to evaluate the chemical composition, the cooking characteristics and microstructure of GF pappardelle prepared with tiger nut and chickpea flours. Chickpea flour is a source of proteins, carbohydrates, dietetic fibre and oligosaccharides. Tigernut flour is a rich source of dietary fibre, high-quality fatty acid profile oil, which is similar to olive and hazelnut oil, minerals and vitamins such as phosphorus, potassium, iron and calcium, as well as vitamins E and C. Therefore, the combination of these flours may lead to an improved nutritional value of the resulting pasta, with a high fibre content and a lower glycaemic index. Despite the great efforts made in the last few decades to produce GF pasta with sensory characteristics similar to durumwheat products (good texture, minimum cooking losses, surface resistance to disintegration, without surface stickiness), the GF pasta currently on the market is still far from what the consumer is looking for [4]. The role of gluten could be replaced by choosing suitable formulations to achieve the desirable quality attributes and also making the dough easy to handle under industrial conditions [5]. Frequently, GF products are formulated using sintetic additives to improve the textural characteristics. Nowadays, both industry and consumer preference is to use other additives from natural sources. Previous studies have demonstrated the positive impact that the use of pregelatinized starch from rice [6] or cassava [7] has on the GF pasta texture. Pregelatinized flour can act as a binder [8] that may lead to the development of a viscoelastic and compact dough, which may contribute to obtain suitable palatability and textural characteristics on the pasta products. In this sense, this work assess the feasibility of replacing chickpea flour by tiger nut pregelatinized flour to improve the cooking behavior and final textural characteristics of dry GF pappardelle based on tiger nut and chickpea flours.

## **2. Materials and Methods**

### **2.1. Raw materials and characterisation**

Commercial durum wheat semolina –DWS– (Harinas Villamayor. S.A., Huesca. Spain). tiger nut flour –TNF–(Tigernuts Traders S.L., Valencia. Spain) and chickpea flour (CP) were used. Fresh eggs, CP and mineral water were purchased in a local market. PG was obtained by hot treatment (80°C, 20 min, 1:7.5 g/mL deionized water) followed by drying (40°C, 24 h) and grinding. DWS, TNF, CP and PG were analysed for their water, protein,

fat and ash contents according to the American Association of Cereal Chemists' approved methods [9] and for their total, soluble and insoluble fibre, amylose/amylopectin ratio and damaged starch according to the corresponding Megazyme methods K-TDFR, K-SDAM and K-AMYL (Megazyme Ltd., Ireland). Digestible carbohydrates were determined by difference (100 – percentage of estimated proximate chemical composition). The particle size distribution (PSD) of DWS, TNF, CP, PG and their mixtures (TNFCPPG0, TNFCPPG5, TNFPPG10) was determined by using a MasterSizer® Laser Diffraction Particle Size Analyser (Malvern Instrument Ltd., Malvern, England). equipped with a PS 65 (dry sample). For each sample, 10–20 g of flour mixture was used. Size distribution was quantified as the relative volume of particles in size bands, presented as size distribution curves (Malvern MasterSizer Micro software v 5.40). The PSD parameters recorded included mean particle diameter/volume mean diameter (D[4.3]) and span value (measurement of the width of the size distribution). The functional properties of DWS, TNF, CP, PG and their blends (TNFCPPG0, TNFCPPG5, TNFPPG10). were determined as follows. The water-holding capacity (WHC) was determined by using the modified methods from [10] and [11]. The fat adsorption capacity (FAC) was determined according to [12]. Each analysis was made in triplicate.

## **2.2. Pasta preparation**

The S formulation, used as the control sample, was obtained by mixing durum wheat semolina (72% w/w), fresh egg (13% w/w) and water (15% w/w). For the GF formulations, TNF and CP were used at 50/50 weight (76% w/w) and mixed with fresh egg (13% w/w) and water (11% w/w). Three GF formulations were assessed, considering three levels for chickpea replacement by pregelatinized TNF (0, 5 and 10% w/w, named henceforth as TNFCPPG0, TNFCPPG5 and TNFCPPG10 respectively). All raw materials were mixed and kneaded in an electric cooking device (Thermomix TM-31, Vorwerk Spain M.S.L., S.C., Madrid). The dried (CP/TNF/PG) and liquid (egg/water) components were separately blended and then kneaded together (10 min for S and 20 min each for GF pasta) with a rest period in between. The resulting doughs were rested for 20 min at 4 °C inside a plastic bag in order to enable sample relaxation. Afterwards, the fresh pasta sheets (1.0±0.03 mm thick) were formed by using a domestic pasta making machine (Simplex SP150, Imperia, Italy) coupled with a specific motor (A2500, Imperia, Italy). The pappardelle (4.4 cm width) were obtained by using the Duplex reginette 12/44 mm device (Imperia, Italy). Samples of 7 cm ± 0.03 mm length were then dried for 5.5 h (SCC 62, Rationel, Germany) under controlled temperature (55°C) and relative humidity (60%) conditions (until the pasta reached a water content of 10-12% (similar to that of dried commercial pasta). Once dried, the pappardelle were packed in vacuum bags and stored at 4°C temperature until further analysis.

### **2.3. Uncooked pasta structure**

FESEM (ULTRA 55, Carl Zeiss AG. Oberkochen. Germany) was used in order to observe the microstructure of dry GF pappardelle (TNFCPPG0, TNFCPPG5 and TNFCPPG10). The samples (cross-section) were fixed on copper stubs, platinum coated and observed using an accelerating voltage of 2 kV.

### **2.4. Pasta cooking**

Dried pappardelle (25 g) was cooked in 300 ml deionised water (98°C) according to the American Association of Cereal Chemists' approved method 16-50 [9]. To avoid evaporation losses and maintain the 90% of the initial volume, the flask was partially covered and boiling water was added during cooking. Once reached the optimal cooking time (9 min for S and 5 min for the rest ), the pappardelle were removed from the flasks and the cooking process was immediately stopped with 50 ml of cold deionised water. Finally, the pappardelle were drained for 2 min and immediately analysed for its firmness and cooking properties. Cooking trial was made in duplicate for each pasta formulation.

### **2.5. Cooking properties and cooked pasta firmness**

The water absorption index –WAI– (g/g) was calculated from the mass gain and the increase in water content after cooking. The water content in dry and cooked pasta was determined according to the AACC 44-40 method [9]. Cooking loss –%CL– (g/100 g) is the amount of solid substance lost to cooking water and it was determined according to the AACC-approved method 16-50 [9]. The swelling index –SI– was expressed as the relative volume changes ( $\text{cm}^3/\text{cm}^3$ ) between the uncooked and cooked pasta. The measurements of the pappardelle (thickness, width and length) were determined with a caliper (PCE-DCP 200N, PCE Ibérica S.L., Albacete, Spain). A TA.XT2 Texture Analyser (Stable Micro Systems. Godalming. Surrey. UK) was used to perform the AACC method 16-50 [9] at a rate of 0.17 mm/s until total sample deformation. Each analysis was made in triplicate for each pasta formulation.

### **2.6. Statistical analysis**

Analysis of variance (ANOVA) was carried out by using Statgraphics Centurion XVI software version 16.1.17 (StatPoint Technologies. Inc., Warrenton, VA) The significance level was  $p = 0.05$  in all cases.

## **3. Results and discussion**

### **3.1. Characterization of raw solid materials**

The chemical composition of the solid raw materials (DWS, TNF, CP and PG) are shown in Table 1. As expected, the TNF and CP fibre (specially insoluble) content was much higher than that of DWS. Fat content was also much higher for TNF, while the highest protein

content was obtained for CP. On the other hand, the highest amount of digestible carbohydrates was obtained for DWS, followed by TNF and CP, being the amylose content lower for TNF. Damaged starch was significantly higher for PG.

**Table 1. Proximate chemical composition of solid raw materials (g/100 g). Mean values of three replicates (standard deviation).**

	DWS	TNF	CP	PG
<b>Water</b>	13.43 (0.13) <sup>b</sup>	12 (0.7) <sup>c</sup>	11.48 (0.95) <sup>c</sup>	16.8 (0.3) <sup>a</sup>
<b>Protein</b>	13.18 (0.7) <sup>b</sup>	3.7 (0.2) <sup>c</sup>	23.7 (0.07) <sup>a</sup>	-
<b>Fat</b>	0.9 (0.05) <sup>d</sup>	21.44 (0.06) <sup>b</sup>	4.31 (0.03) <sup>c</sup>	23.59 (0.04) <sup>a</sup>
<b>Ash</b>	0.27 (0.03) <sup>c</sup>	2.29 (0.07) <sup>b</sup>	3.298 (0.007) <sup>a</sup>	2.32 (0.03) <sup>b</sup>
<b>Fiber</b>				
<b>-Soluble</b>	2.99 (0.13) <sup>b</sup>	3.5 (1.3) <sup>b</sup>	6 (3) <sup>ab</sup>	7.5 (0.8) <sup>a</sup>
<b>-Insoluble</b>	7 (3) <sup>c</sup>	16.6 (0.8) <sup>b</sup>	24 (0.6) <sup>a</sup>	24 (4) <sup>a</sup>
<b>-Total</b>	9.1 (0.4) <sup>c</sup>	20 (2) <sup>b</sup>	30 (3) <sup>a</sup>	32 (3) <sup>a</sup>
<b>DC*</b>	63.3 (0.2) <sup>a</sup>	40 (2) <sup>b</sup>	28 (4) <sup>c</sup>	-
<b>Amylose (%)</b>	27.2 (1.4) <sup>a</sup>	17 (2) <sup>b</sup>	28 (2) <sup>a</sup>	-
<b>Damaged starch</b>	3.31 (0.12) <sup>b</sup>	0.622 (0.109) <sup>c</sup>	0.6717 (0.005) <sup>c</sup>	20 (3) <sup>a</sup>

Means with different letters in the same row indicate significant differences ( $p < 0.05$ ).

\* Digestible carbohydrates calculated by difference

Concerning PG, its chemical composition was near to that of TNF, except for the fibre (due to a higher extraction capacity) and the damaged starch (due to gelatinization) contents. These results suggest that the use of TNF and CP at 50% w/w may allow to obtain GF pasta with a similar protein content and a higher presence of fibre, minerals and fat than the DWS formulation. It can be observed in Table 2 that the average particle size (expressed as the mean diameter of the equivalent volume) was significantly lower for CP, followed by TNF and DWS. Fibre hydration and starch gelatinization could be the responsible for the significantly higher particle size of PG. Furthermore, the uniformity in the particle size distribution (span) was higher in DWS (from industrial milling) and PG (obtained after grinding). The greater presence of fibre in TNF (20 (2)%) and CP (30 (3)%) compared to 9.1 (0.4)% in DWS) -with a much higher insoluble/soluble ratio- (16.6/3.5% in TNF and 24/6% in CP compared to 7/2.99% in DWS) could be responsible for the greater heterogeneity in TNF (span 2.39) or CP (span 6.9). Water holding capacity (WHC) reports the ability of a protein matrix to absorb and retain bound, hydrodynamic, capillary and physically entrapped water against gravity. The results show a significant lower value for DWS, which can be attributed to the higher fibre content of TNF and CP and the smaller particle size of TNF and CP, which implies a larger surface area available for water absorption [13]. The highest WHC obtained for PG may be due to its higher damaged starch content; however, no effect was observed on the mixture when PG was added at 5

and 10%. The fat absorption capacity (FAC) is attributed to the ability of proteins to bind lipids. Only TNF presents a significant higher value of this parameter.

**Table 2. Particle size distribution and Functional properties of solid raw materials and their blends. Mean values of three replicates (standard deviation).**

Sample	D[4.3]( $\mu\text{m}$ )	Span	WHC (g water/g flour)	FAC (g fat/g flour)

Means with different letters in the same column indicate significant differences ( $p < 0.05$ ).

### 3.2. Cooking properties and cooked pasta firmness

Cooking loss, a measure of the amount of solids lost in the cooking water, is considered to be an important indicator of pasta quality [14]. As reported by [15], cooking losses for GF pasta can reach 20-25 % values as compared to those of a wheat semolina pasta due to the better weaker gluten network in which swelled starch granules are worse entrapped. Obtained values in this work (Table 3) are similar to those obtained for other GF pasta based on legume flours [16] and quinoa [17]. No significant differences could be observed for WAI and SI with the percentage of PG used, but both parameters were significant higher for control samples.

**Table 3. Cooking properties of pasta formulations. Mean values (standard deviation).**

Sample	WAI (g/g)	%CL	SI	F (N)
S	1.74 (0.02) <sup>a</sup>	2.9 (0.2) <sup>c</sup>	0.80 (0.02) <sup>a</sup>	20.6 (0.2) <sup>a</sup>
TNFCPPG0	0.82 (0.05) <sup>b</sup>	11.7 (0.2) <sup>a</sup>	0.62 (0.06) <sup>b</sup>	8.8 (0.5) <sup>b</sup>
TNFCPPG5	0.79 (0.03) <sup>b</sup>	8.7 (0.2) <sup>b</sup>	0.58 (0.03) <sup>b</sup>	7.6 (0.3) <sup>c</sup>
TNFCPPG10	0.81 (0.02) <sup>b</sup>	12.0 (0.2) <sup>a</sup>	0.37 (0.02) <sup>c</sup>	6.5 (0.4) <sup>d</sup>

Means with different letters in the same column indicate significant differences ( $p < 0.05$ ).

A good quality pasta product should present certain degrees of firmness and elasticity, absence of stickiness, appearance uniformity and structural integrity. As expected, the firmness of GF formulations was significantly lower than that of control pasta (Table3), decreasing with higher contents of PG (although variations were small for this parameter). Although the use of PG at 5 or 10% did not imply an improvement on the firmness of cooked pasta, it did provide some continuity to the pasta structure (Figure 1).

*Fig. 1 FESEM dry pasta TNFCPPG0 and TNFCPPG10 (500x).*

#### 4. Conclusions

The consumption of gluten free pappardelle formulated with tiger nut and chickpea flours can have positive implications for human health, due to their increased nutritional quality. Cooking losses were acceptable and a certain structural continuity was obtained when pregelatinized tiger nut flour was used, thus further investigations are required.

### **Abstract**

*The aim of this work was to investigate the convective drying process of malt bagasse and to evaluate the influence of this process on the application of this residue as adsorbent in methylene blue removal by adsorption process. The experimental system for drying was a fixed bed dryer with parallel airflow, with operating conditions: air temperature in the range of 40 to 90 °C and air velocity of 2 m/s. The adsorption experiments were performed with solution of methylene blue at 70 ppm concentration. The drying kinetics showed a constant drying rate period followed by a falling drying rate. The results obtained for the dye removal efficiency were 56% for in natura sample and in the range of 81.69% to 93.99% for dried samples.*

**Keywords:** *dryin; malt bagasse; adsorption*

---

## **1. Introduction**

Nowadays, environmental problems and energy demands have demanded the search for energies renewable and clean. The use of biomass is part of the concept of sustainable development, besides reducing costs and not harming the environment [1]. Adsorption is a unit operation commonly used to separate solid-liquid, and can be efficient and low cost, using different adsorbents [2]. Solid residues from the agroindustry, such as sugarcane bagasse, coconut mesocarp and wood sawdust, are available in large quantities and can be considered as potential adsorbents due to their low cost due to not receiving any previous treatment and their physical- chemical properties [3].

In the process of brewing many solid wastes are generated, such as malt bagasse. According to Ferrari [4], the malt bagasse is the main byproduct resulting from the fermentation process formed by the solid part of the filtration of the fermentation must before boiling. One of the applications of the malt bagasse is the use as low-cost biosorbent in the sorption of dyes. These residues have limitation related to their high moisture content, which has a negative influence on transport, storage and for applications. Thus, the drying of malt bagasse is the first step for the biomass preparation. Piffer et al. [5] studied the adsorption of textile dye on malt bagasse in order to evaluate the efficiency of the process and Zanette et al.[6] reported the adsorption of 5G blue dye using the malt bagasse, verifying the influence of the agitation speed in the process.

The aim of this work was to investigate the convective drying process of malt bagasse and to evaluate the influence of this process on the application of this residue as adsorbent in removal efficiency of methylene blue by adsorption process.

## **2. Materials and Methods**

The raw material was supplied from artisanal beer producers from Bagé, Rio Grande do Sul, Brazil, and was packed in plastic bags at -18 °C until analysis. The moisture content was determined by the oven method at 105 °C for 24 h.

Figure 1 illustrates the experimental system used in the drying experiments. The experimental system involved a fixed bed dryer. The air flow coming from the blower [a] was monitored by psychrometer [b] and was heated by an electrical heater (c). Measurements of air velocity were performed by an anemometer [f]. In order to monitor mass of samples during the drying experiments a digital balance [e] was used, connected with a tray in the drying chamber.

**Fig. 1** Experimental system.

The malt bagasse samples were distributed uniformly as a thin layer onto the stainless steel tray of size 12x0.5 cm and dried. The ranges of operating conditions were defined in preliminary tests. The inlet air temperature ( $T_{air}$ ) were 40, 60, 75 and 90 °C and air velocity ( $v_{air}$ ) was 2 m/s. Drying curves ( $(M-M_e)/(M_0-M_e)$ ) as a function of time) were obtained and the equilibrium moisture content was assumed as the final moisture content, when the drying rate was practically null, for each drying condition.

The calibration curve of methylene blue dye was obtained from different concentrations and their respective absorbances in UV-VIS spectrophotometer at the wavelength of 664 nm. The calibration curve obtained for methylene blue is presented in Equation 1.

$$ABS = 0,1175 [MB] \quad (1)$$

where [MB] corresponds to the concentration of the dye in ppm and abs the absorbance.

The adsorption process was performed in a batch system. 2 g of the malt bagasse in natura and dried were first placed in a Erlenmeyer flask. 50 mL of methyle blue solution at a concentration of 70 ppm was added to the flask. The mixture were stirred continuously using a shaker at speed of 150 rpm for 60 min in a constant temperature at 25 °C. After adsorption, each sample containing the solution and adsorbent was subjected to centrifugation at 3000 rpm for 10 min. Then, the concentration of methylene blue were measured using UV-VIS spectrophotometer. The removal efficiency of methylene blue (% Rem) was determined using the Equation 2.

$$\%Rem = \frac{C_0 - C_{eq}}{C_0} \times 100 \quad (2)$$

where  $C_0$  is the initial concentration of the dye,  $C_{eq}$  is the final concentration.

Experimental data were analyzed by Statistica 7.1 software. Mean comparasions were carried out by Tukey test ( $p < 0.05$  was considered as significant).

### 3. Results and discussion

Figure 2 shows the typical drying curves obtained for malt bagasse.

Fig. 2 Drying kinetics at different operation conditions.

In all experiments, the drying kinetics showed a constant drying rate period followed by a falling drying rate period. As expected, an increase in air temperature also significantly increased the drying kinetics and resulted in lower final moisture contents. The moisture content for *in natura* malt was  $74.25\% \pm 0.43$  (% w.b.) and after the drying process the results were in the range of 2.6 to 6.9%, similar with results showed by Gonçalves et al. [7]. According to Lopes et al. [8] the final moisture content of the material is directly related to the drying time and temperature. According to Wang and Chen [9] the temperature and moisture content of the material play a very important role in the heat and mass transfers during the drying. At lower temperatures it was necessary a longer time for the removal of water from the material because, according to Vilela and Silva [10], drying requires gradients that help as the driving force for the mass flow of water into the air drying.

Table 1 shows the results to the removal efficiency of the methylene blue dye using malt bagasse samples before and after drying.

Table 1. Removal efficiency of methylene blue.

	<i>in natura</i>	Dried samples			
		40 °C	60 °C	75 °C	90 °C
<b>Rem (%)</b>	56.00±0.87 <sup>a</sup>	93.60±0.25 <sup>b</sup>	93.71±0.26 <sup>b</sup>	93.48±0.13 <sup>b</sup>	93.99±0.32 <sup>b</sup>

Average±deviation (n=3)

Different letters indicate significant differences between samples ( $p < 0.05$ )

It can be observed that drying of the adsorbent material favored the adsorption process because it allowed the reduction of moisture content of the adsorbent material, and, consequently, the increase of the intraparticle porosity and adsorption sites as mentioned by Geankoplis [11] and Arim et al. [12]. There were no significant difference ( $p < 0.05$ ) between the removal efficiency using dried samples at different conditions. Then, the results indicated that the adequate drying condition for malt bagasse is at 90 °C, since the drying can be faster with lower cost of energy.

#### 4. Conclusion

The malt bagasse drying showed a constant drying rate period followed by falling drying rate period, which is typical of materials with high moisture content. The dried malt bagasse showed to be efficient in the removal efficiency of methylene blue, with no significant difference between samples dried at different temperatures. The results showed promising results, and it was possible to affirm that malt bagasse can be used as adsorbent for adsorption of dye, reducing the environmental impact and showing a new application for this residue.

---

### **Abstract**

*Vitamin C is one of the constituents of pequi pulp. It is a natural antioxidant, capable of sequestering free radicals. The present study aimed to freeze dry a pequi pulp encapsulated with maltodextrin and whey protein and analyze vitamin C content. Vitamin C loss was lower in the experimental run that did not use encapsulating agent. Whereas, the run that used 15% of whey protein concentrate as encapsulant agent in relation to pequi solids presented the highest value (220.74 mg vitamin C / g pequi solids). Freeze drying of pequi pulp is a technique for vitamin C conservation independently of the variation in maltodextrin and whey protein proportion.*

**Keywords:** *drying; encapsulating agent; ascorbic acid.*

---

## 1. Introduction

The pulp of pequi (*Caryocar brasiliense* Camb.) is rich in vitamin C, which present antioxidant capacity [n1]. This fruit is produced in the regions that compose the Brazilian Cerrado biome and because of this, it is an extractive product. The lack of adequate methods of conservation and perishability of the fruit result in great loss [n1]. New technologies allow the aggregation of value to the product and among them is freeze drying. This technique minimizes losses of nutrient compounds during the drying process based on the dehydration by sublimation of a frozen product resulting in a dry material [n2, n3]. Microencapsulation is a technique that maintains product properties as stable as possible and extends its shelf-life. Encapsulating agents protect the core material from interaction with environmental factors such as light, oxygen, temperature and humidity, and among them are maltodextrin and whey protein concentrate (WPC). Maltodextrin is a partially hydrolyzed starch widely used in the food industry as it has a mild and long-lasting flavor [n4]. WPC is an excellent protein isolate in the edible coating, as well as in food enrichment and edible film production [n5]. The objective of this work was to dry the pequi pulp encapsulated with maltodextrin and WPC and to analyze the composition of vitamin C after freeze drying process.

## 2. Materials and Methods

### 2.1 Materials

Pequi fruits from a single batch production of the state of Minas Gerais, Brazil, were purchased at the Campinas Supply Center (Ceasa-Campinas) and used on all the experiments. After processing, the samples were stored in a freezer at  $-60 \pm 3$  °C and dried by a laboratory freeze dryer (Edwards High Vacuum, Super Modulyo model, Great Britain). Maltodextrin (MOR-REX® 1910, Ingredion, Mogi-Guaçu, Brazil) and whey protein concentrate (WPC 80, Alibra, Campinas, Brazil) were used as encapsulating agents.

### 2.2 Methods

#### 2.2.1 Preparation of pequi pulp

The fruits were stored in a Biochemical Oxygen Demand (B.O.D.) chamber at 5 °C until their processing stage. The pequi pulp processing followed the subsequent steps: selection, washing, sanitization, peeling, second sanitization, pulping, packaging, homogenization. Homogenization was carried out by a domestic mixer, adding distilled water in the

proportion 1: 1 (pulp:water, m/m) to the pequi pulp and different encapsulants in different concentrations, according to Table 1.

A central composite experimental design with two independent variables and three central points, totalling 11 experimental runs, was performed. The independent variables were the maltodextrin/why protein concentrate proportion and total concentration of encapsulating in relation to total solids content of pequi pulp.

Vitamin C content after freeze drying were considered the dependent variable (response). Table 1 presents the encoded and real values of independent variables of the experimental design. In Table 1,  $C_{total}$ : total concentration of encapsulants in relation to the total solids of pequi pulp.  $C_{WPS}$ : why protein concentrate concentration.  $C_M$ : maltodextrin concentration.

**Table 1. Experimental design**

Run	Independent variables				
	Encoded		Real		
	CM %	Ctotal [%]	CM %	CW %	Ctotal [%]

*Variation of the parameters encapsulant concentration, maltodextrin / WPC ( $C_{enc}$ %) and relation between the encapsulant and ST of the pulp ( $Total_{ratio}$ %).*

### 2.2.2 Freeze drying

The samples were previously prepared with the addition of the encapsulants according to the planning design, forming distinct treatments and, later, placed in stainless steel trays of the freeze-dryer with capacity of 200 g each one and submitted to freezing in a freezer at -

60°C before starting the freeze-drying process. After freezing, the samples were taken to the freeze dryer, which consists of a vacuum chamber, condenser, refrigeration unit, and vacuum pump. The average time for freeze drying of the samples was about 72 hours. Then, the porous plates obtained in this process were broken using a porcelain mortar and pestle and, after that, homogenized.

### 2.2.3 Vitamin C

For the analysis of vitamin C, absorbance readings were performed in a spectrophotometer at 760 nm using trichloroacetic acid and Folin-Ciocalteu Phenol 2.0N as reagents, described by Jagota and Dani [n6]. Vitamin C was quantified based on a standard curve fitted from various dilutions of vitamin C (5 to 70 µg). The values were expressed as mg of vitamin C in 100g of pequi pulp.

### 2.2.4 Statistical analysis

Significant differences between average results were evaluated by analysis of variance (ANOVA) and Tukey test at 5% of level of significance, using SAS software (Cary, NC, USA).

## 3. Results and discussion

The vitamin C results of the pequi pulp encapsulated with maltodextrin and whey protein are shown in Table 2. Vitamin C for fresh pequi pulp was  $311.72 \pm 1.25$  mg of ascorbic acid g<sup>-1</sup> solids of pequi. The vitamin C values of the experimental runs ranged from 99.03 to 220.74 mg of ascorbic acid g<sup>-1</sup> solids of pequi being within the values found by [n7] for spray dried pequi pulp. Run 7, with no encapsulating agent, presented lower vitamin C content compared to the other runs. It is believed that the use of encapsulating agent had a significant effect on the conservation of vitamin C, especially when the percentage of whey protein in the total solids of the pulp was used (run 5). The pequi pulp encapsulated with maltodextrin and whey protein concentrate, after freeze drying process, suffered losses of vitamin C when compared to the fresh pulp. However, when compared to the non-encapsulating agent run, the losses were not pronounced, showing that the technique of encapsulation has protected the oxidation of ascorbic acid from a number of biochemical mechanisms, which are responsible for the loss of vitamin C activity.

Even the lowest content of vitamin C found in experimental runs is superior to that of raw avocado fruit, 'Maçã' banana, 'Nanica' banana, cupuassu, jackfruit, 'Red Delicious' apple,

‘Fuji’ apple, watermelon, ‘Williams’ pear, ‘Aurora’ peach, pomegranate, tamarind, umbu and ‘Ruby’ grape [n8].

**Table 2. Vitamin C for freeze dried pequi pulp using maltodextrin and WPC as encapsulant agent.**

Run	C <sub>M</sub> (%)	C <sub>WPS</sub> (%)	C <sub>total</sub> (%)	Vitamin C (mg / g solids of pequi)
1	14.6	85.4	4.4	183.48±2.77g
2	14.6	85.4	25.6	191.06±0.98ef
3	85.4	14.6	4.4	186.59±1.07gf
4	85.4	14.6	25.6	213.14±2.25bc
5	0.0	100.0	15.0	220.74±2.54a
6	100.0	0.0	15.0	196.62±0.41ed
7	50.0	50.0	0.0	99.03±2.73h
8	50.0	50.0	30.0	202.33±1.47d
9	50.0	50.0	15.0	210.76±3.14c
10	50.0	50.0	15.0	196.06±2.16ed
11	50.0	50.0	15.0	219.41±2.14ba

\*Same letters in the column show no statistical difference ( $p > 0.05$ ).

Experimental data of vitamin C for freeze dried pequi pulp using maltodextrin and WPC as encapsulant agent are shown in Table 2. The experimental values of vitamin C oscillated from 99.03 to 220.74 mg vitamin C/ g solids of pequi.

The determination coefficient ( $R^2$ ) for the fitted model was 0.75. The model was tested for adequacy and fitness by the analysis of variance (ANOVA) without considering the non-significant terms ( $p > 0.05$ ). The coded second-order polynomial model (Equation 1) was considered significant and predictive.

$$Vit. C \left[ \frac{mg}{g_{solids\ of\ pequi}} \right] = 211.98 + 22.53C_{total} - 26.57C_{total}^2 \quad (1)$$

Fig. 1 shows the contour plot generated by the proposed model. It is observed that there is no influence of maltodextrin/WPC proportion on Vitamin C values.

*Fig. 1 Response surface for vitamin C content of microencapsulated pequi powder.*

#### 4. Conclusions

The experimental run using no encapsulant agent on freeze drying process has a lower vitamin C value because of the absence of protection against ascorbic acid oxidation. The runs that showed the best protection against oxidation of ascorbic acid were those encapsulated with 15% independent of the encapsulant used. Drying of pequi pulp by freeze drying is an excellent technique for the protection of ascorbic acid, regardless of variation (proportion) in the use of maltodextrin and/or whey protein concentrate (WPC).

### **Abstract**

*The objective of this work was to optimize the drying conditions in order to obtain acerola powder and to focus on the product aroma quality. Acerola fruits were selected, washed and sanitized before extracting the pulp. An emulsion was obtained by adding maltodextrin in the pulp. The dehydrated powders were obtained in spray dryer by drying at inlet temperatures of 128 and 152 °C. Twenty five volatile compounds were identified in fresh acerola pulp and in the dehydrated powder. These results prove that use of maltodextrin in spray drying of acerola pulp helps in retention of key aroma compounds in acerola powder.*

**Keywords:** *Acerola, Spray drying, dehydration, volatiles, aroma, GC-MS.*

## 1. Introduction

The aceroleira is a fruit tree native to the Antilles, North of South and Central America, that showed good adaptation in several countries being mainly cultivated in Brazil.<sup>[1]</sup> Its potential as a natural source and capacity for industrial use has attracted the interest of fruit growers and it has attained economic importance in several regions of Brazil.<sup>[2]</sup> The acerola (*Malpighia glabra*) is a fruit species widely accepted by consumers, which has been prominent in Brazil and the world, mainly because it is one of the main natural sources of vitamin C and carotenoids and it is widely industrialized in the form of frozen pulp, characterizing as functional foods, since it confers benefits in reducing the risk of some non-transmissible chronic diseases such as cancer.<sup>[1]</sup>

The transformation of acerola fruit into an industrial product will allow its preservation for a prolonged period, but it is also required that the beneficial properties and the fruit's sensorial characteristics will be maintained to its maximum.<sup>[3]</sup> Among the techniques used to maintain post-harvest quality of fruit, dehydration, besides being used as a conservation method, prevents deterioration and losses of commercial value and adds value to the product giving rise to a new option in the market.<sup>[4]</sup>

The spray drying consists of the transformation of the product from the fluid state to dry particles in the form of powder. The dried powder should retain maximum initial characteristics of the fruit pulp and protect it from the adverse conditions of the external environment. For this purpose wall materials or microencapsulants are incorporated into the pulp before drying.<sup>[5]</sup> Thus, the present work had as objective to optimize the drying conditions of the parameters for atomization of the acerola pulp in spray dryer and evaluate its effect on the volatile compounds of acerola pulp.

## 2. Materials and Methods

### 2.1. Fruits purchase

The ripe fruits of acerola were acquired from the Central Market of Supply (CEASA) in the city of Aracaju/SE. The fruits were then taken to the Laboratory of Processing of Vegetable Origin (LPOV), located in the Department of Food Technology (DFT) at the Federal University of Sergipe (UFS).

### 2.2. Sanitation and pulp extraction

The selected fruits were submitted to selection, sanitization in a solution of 200 ppm of residual chlorine (Sumaveg®) for 10 minutes to eliminate possible microorganisms that

withstood the previous step. The rinse was carried out in solution at 3ppm of active chlorine for 10 minutes. After the rinsing the fruits were washed in water for 10 minutes to remove all chlorine and pulped in a stainless-steel pulp (ITAMETAL), using a 1.5mm diameter screen. The pulp was weighed and packed in polyethylene packages. The packages with the pulps were stored in a freezer at freezing temperature (-21 ° C).

### 2.3. Spray Drying Process

For the Spray dryer atomization process, tests were carried out by varying the drying air temperature and the carrier agent concentrations, as detailed in Table 1.

*Table 1. Formulations and Temperatures used in spray drying process in obtaining dried powder from acerola pulp.*

Sample code	Pulp (%)	Maltodextrin (%)	Input Temperature (°C)	Output Temperature (°C)
AC 1	86	14	128	65
AC 2	86	14	152	78
AC 3	74	26	128	65
AC 4	74	26	152	78

The spray drying was performed in a spray dryer (LABMAQ, model MSDi 1.0, Riberão Preto-SP, Brazil) with injector nozzle having the orifice of 1.2 mm diameter, air flow of 4.00 m<sup>3</sup> / min and air pressure of 4 kgf/cm<sup>2</sup>. The dryer was fed through a peristaltic pump, with rotation speed adjusted as a function of the maximum speed; the flow was 0,44 L/h. Samples were produced with 14 and 26% of maltodextrin and the two inlet temperatures used were 128 and 152 °C (Table 1).

### 2.4. Determination of Volatile Compounds

The volatile composition of the acerola fresh pulp and dried powder was determined using the purge and trap (P&T) technique by varying 3 different dilutions of the pulp with water (4g:10mL, 4g:20mL and 4g:30mL). The volatiles were captured and concentrated in the P&T system (Tekmar, Model ATOMX, Mason-45040, USA) under the following conditions: 4 g of pulp were diluted with 10 mL of distilled water and taken to the purge and trap system, operating with helium gas flow of 40 mL/min, purging time of 11 min, desorption time of 5 min in a trap containing Tenax/silica gel/charcoal.

## 2.5. Separation and Identification of Volatile Compounds

The P&T system used the Vocarb3000 trap and analyzed in the gas chromatography system coupled to a mass spectrometer (GC-MS QQQ Agilent 7000). The compounds were separated on carbowax capillary column (30 m x 0.25 mm x 0.25  $\mu$ m) using helium as the carrier gas (1.0 mL/min). The temperature of the injector was 220°C and the column temperature programming was: 35°C for 2 min, increase at 10°C/min to 100°C, maintaining for 1 min followed by an increase of 3°C/min to 250 °C, totaling 59 min of analysis.

The identification of the volatile compounds was performed by comparing the mass spectra of the sample compounds with those in the NIST (National Institute of Standards & Technology), containing approximately 150,000 reference spectra and by comparing the linear retention index (LRI) of the compounds with those of publications in the literature and LRI calculated on the basis of the retention times of a series of n-alkanes mixtures of C8-C30, C8-C40 and C8-C17, injected at identical analytical conditions.

The linear retention index (LRI) was calculated based on the retention time of the authentic alkane standards versus the number of carbon atoms of the respective alkane standards, multiplied by 100.

The quantification of volatile compounds was related to the percentage area of the peak of each compound and to the total area of all peaks normalized in the chromatogram.

## 3. Results and Discussion

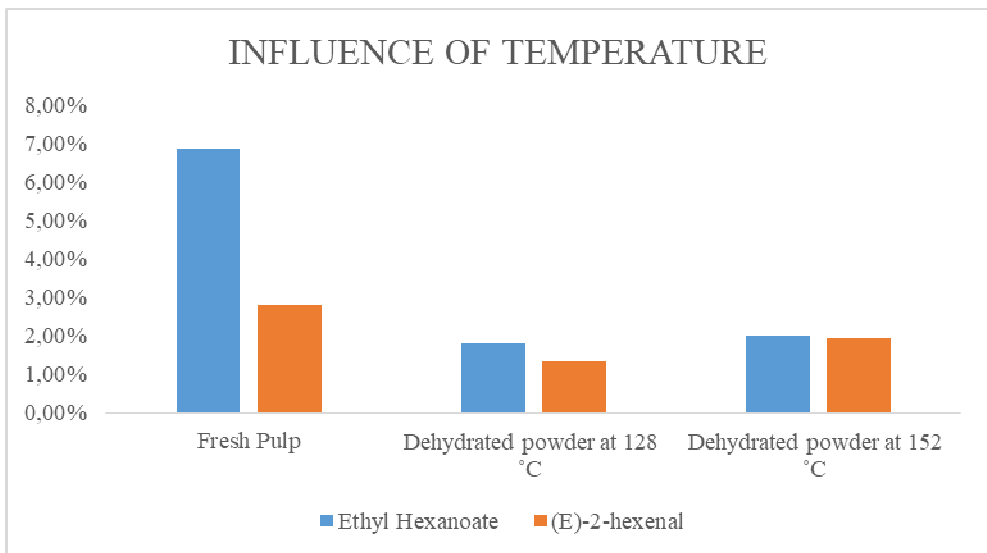

### 3.1. Volatile compounds in the fresh pulp and dehydrated powder of acerola.

Aroma is one of the most important attributes in food and it is used to mainly relate the sensory quality of fruit and fruit products. In the determination of volatile compounds of acerola pulp, 25 compounds were found from the sample containing 4g:10mL (Pulp:Water) and the main compounds identified were: ethanol (10.96%), ethyl acetate (9.61%), pent-4-en-1-yl propyl carbonate (8.20%), ethyl hexanoate (6.88%), ethyl butanoate (6.36%), 4-pentenyl butanoate (3.57%), (*E*)-2-hexenal (2.82%) and 4-pentenol (2.32%). For the dilution (4g:20mL) of the pulp, the number of identified compounds decreased, being only the compounds found in the first dilution consisting of ethyl acetate (5.73%), ethanol (11.32%), ethyl butanoate (5.52 %). However, in the third dilution (4g:30mL) only ethyl acetate (11.23%) and ethyl butanoate (2.34%) were identified. The P&T technique generally provides a higher extraction yield, which may be associated with a larger surface of the adsorbent trap in relation to other techniques such as SPME.<sup>[6]</sup>

In the dried acerola powder, 20 compounds were found in the samples dried at the two temperatures of 128 and 152°C while using a maltodextrin concentration of 26%. This concentration of maltodextrin showed a retention of 80% of aroma in the dried powder. The powder obtained using 14% concentration of maltodextrin did not show a better retention of volatile compounds and only 12 compounds were retained. The main compounds identified in the dried powder were ethyl hexanoate (2.01%), (*E*)-2-hexenal (1.95%), methyl hexanoate (1.2%) and methyl acetate (0.8%). These volatile compounds were reported previously in other studies on acerola aroma.<sup>[7,8,9,10,11]</sup> Ethyl hexanoate was the main contributor to acerola aroma and its odor quality resembled that of apple peel, being fruity and sweet.<sup>[12,13,14]</sup>

The concentration of ethyl hexanoate decreased from 6.88% in the fresh pulp to 2.01% in the dried powder as showed in the Figure 1. Nunes et al.<sup>[15]</sup>, studying the effect of drying temperatures in the volatile compounds of guava, reported in spray drying the volatile compounds could be affected by solubility in pulp of fruit lipids and/or residual water, which is probably the major factor contributing to volatiles retention.<sup>[16]</sup> Therefore, compounds with high vapour pressure and/or low liposolubility tend to be loose the components during drying, whereas compounds with low vapour pressure and/or high liposolubility tend to concentrate in dried powders.

**Figure 1: Influence of temperature on the key aroma compounds from acerola pulp**

Tong Chin et al.<sup>[17]</sup> studied the influence of temperature on the retention capacity of the volatile compounds of the dried Durian pulp by atomization process and monitored the key aroma compounds, propanethiol and ethyl propanoate, at two temperatures (170°C and 130°C), noting that at a temperature of 170°C a reduction in the number of volatile compounds occurs.

Other compound that showed reduction was (*E*)-2-hexenal that are reported that together with hexanal it is strongly related to the flavour of fresh guava fruit, providing an herbaceous and fresh aroma note.<sup>[18]</sup>

The retention of volatile compounds can be influenced by maltodextrin. Maltodextrins with higher DE are more hydrolyzed, and these provide more hydroxyl groups for the interactions with volatile compounds.<sup>[19]</sup> This interpretation is in accordance with one proposed by Reineccius<sup>[20]</sup>, who found that more volatile compounds were retained in the system containing maltodextrins of higher DE values.

#### 4. Conclusions

The various combinations used for spray drying of acerola pulp by varying drying air temperature and maltodextrin concentrations had influence on volatile compounds. The concentration of 26% of maltodextrin preserved more volatile compounds than the concentration of 14% maltodextrin. Compounds classified as key aroma compounds such as ethyl hexanoate and (*E*)-2-hexenal in fresh acerola pulp were retained in the acerola dried powder. These results prove that use of maltodextrin in spray drying of acerola pulp helps in retention of key aroma compounds in dried acerola powder.

### **Abstract**

*This study was aimed to obtain and characterize the dried powder of cajá-umbu (*Spondias spp*) fruit pulp obtained by spray-drying and lyophilization. Spray-drying of the pulp was done at different temperatures. Analysis of bioactive compounds and volatile compounds was performed. The total phenolic compounds content was high in the dried powder obtained at the temperature of 140 °C. The volatiles analysis of dried powders revealed that the powder dried at 140°C contained a larger number of compounds. The cajá-umbu powder showed that it is a better alternative for storage and conservation since it retained the majority of volatile compounds.*

**Keywords:** *Cajá-umbu, volatile compounds, gas chromatography, mass spectrometry.*

## 1. Introduction

Aroma is an important characteristic in exotic tropical fruits, which has increasingly attracted consumers due to their peculiar sensorial attributes. Brazil is one of the countries that have a large variety of these fruits, which are usually produced widely and are mostly consumed in fresh form or in the form of juices, ice cream, jams and jellies. Among the large variety of tropical fruits grown mainly in the Brazilian northeast region, fruits belonging to the genus *Spondias*, involving umbu (*Spondias tuberosa* Arruda Camara), yellow mombin (*Spondias mombin* L.), cajá-umbu (*Spondias spp*), purple mombin (*Spondias purpurea* L.) and amberella (*Spondias dulcis* L. syn. *Spondias cytherea* Sonn.) are prominent. The volatile composition of these fruits pertain to several chemical classes, such as tannins, terpenoids (sesquiterpenes and monoterpenes), flavonoids, etc.<sup>[1,2]</sup>

The cajá-umbu (*Spondias spp.*) owing to its particular sensorial characteristics, such as aroma and flavor, is a fruit which is very much appreciated in the northeastern region of Brazil. It is native to the semi-arid regions and is cultivated between the states of Rio Grande do Norte, Ceará, Piauí, Pernambuco and Bahia. Its sensorial characteristics possessing strong acidic exotic aroma and attractive color, make this fruit to be highly demanding in the regions of the country where it is found.<sup>[3,4,5]</sup>

Being a climacteric fruit, the shelf life of cajá-umbu fruit is low and thus it is commercialized in the near by places where it is produced. It is therefore a great challenge to transport and commercialize this fruit to places far from its cultivation. In order to preserve this fruit and to develop new products with increased commercial value, dehydration techniques such as freeze drying and spray drying can be used.

To the best of the author's knowledge no studies have been performed until the present moment on drying of cajá-umbu fruit and also to identify volatile and bioactive compounds in cajá-umbu dehydrated by these two techniques of drying. Thus the objective of this study was to evaluate the effect of two drying processes - freeze-drying and spray-drying of cajá-umbu pulp (*Spondias spp*) on the retention of volatile and bioactive compounds.

## 2. Materials and Methods

### 2.1. Fruit purchase and pulp extraction

The ripe mature fruits of cajá-umbu were acquired from the Center of Supply (CEASA) of the city of Aracaju/SE. These were then taken to the Laboratory of Processing of Vegetable Origin, located in the Department of Food Technology at the Federal University of Sergipe (UFS). The selected fruits were submitted to selection, sanitization pulping and packaging in polyethylene packages.

## 2.2. Spray Drying

For the Spray dryer process, experiments were performed by varying the drying air temperature (100, 120, 140 and 160°C) while maltodextrin concentration was maintained at 15%. The atomization was performed in a spray dryer with a nozzle atomization system of the brand LABMAQ (model MSDi 1.0, Brazil) with injector nozzle having 1.2 mm diameter orifice, air flow of 4.00 m<sup>3</sup>/min and pressure of air of 4 kgf/cm<sup>2</sup>. The spray dryer was fed through a peristaltic pump, with rotation speed adjusted as a function of the maximum speed; this flow being 0.52 L/h. The dried powder was stored in glass containers with a screw cap, then sealed and stored in a desiccator at room temperature (25 ± 2 °C).

## 2.3. Lyophilization

The drying of pulp was also performed in a Christ Freeze Dryer, (model Alpha 1-4 LSC, Germany). The pressure used was 0.42 mbar, at a sublimation temperature within the chamber was - 58°C.

## 2.4. Separation and Identification of Volatile Compounds

The volatile compounds were captured through the purge and trap system (Tekmar Mark, Model ATOMX), using the Vocarb3000 trap and analyzed in the gas chromatography system coupled to a mass spectrometer (GC- QqQ MS, Agilent 7000) according to the method with adaptations reported by Narain et al.<sup>[5]</sup> The volatile compounds were analyzed in GC-MS system using a Carbowax column (30 m x 0.25 mm x 0.25 µm). The oven temperature was programmed: initiation at 35°C (held for 2 min) then raised at a rate of 10°C to 100°C (held for 1 min) and finally increased at 3°C/min to 250°C. Volatile compounds were tentatively or positively identified by comparing their mass spectra with the compounds from NIST (National Institute of Standards & Technology) database and comparing the linear retention index (LRI) of the standards and compounds with those of literature publications and other databases (Flavornet, PubChem, Pherobase).

## 3. Results and Discussion

### 3.1. Volatile compounds of dehydrated powder

Dehydration reduces the moisture content and therefore can result in the loss of volatile compounds in the final product at the end of the process.<sup>[6]</sup> Studies on the influence of temperature are very important to guarantee the quality of the final dehydrated product.<sup>[7]</sup> When developing a powder obtained by spray drying or lyophilization it is necessary to always standardize the best temperature where a powder can be obtained with the aroma very close to that of the fresh fruit. Thus, it is important to study the volatile composition of the product obtained by dehydration at various temperatures in order to define the best condition for obtaining an aromatic product at the end of the process.

In the Table 1 presents the data on number of peaks obtained on the analysis of dried powders obtained at different temperatures used for spray drying and by lyophilization. The volatiles analysis of dried powders revealed that the spray dried product at 140°C contained higher number (29) of compounds, compared to lyophilization which had only 26 compounds.

**Table 1: Number of volatile compounds found in various dried powders obtained by spray and freeze drying of cajá-umbu pulp.**

Dehydration type	Temperature	Number of peaks
Spray-drying	100°C	18
Spray-drying	120°C	20
Spray-drying	140°C	29
Spray-drying	160°C	19
Lyophilization	-58°C	26

The most representative class of compounds for the dried powders obtained by atomization were the terpenes, and the compound with the highest concentration was limonene at all the operating temperatures of the Spray-dryer (Table 2). Other terpenes identified were  $\alpha$ -pinene, cis- $\alpha$ -bisabolene, 3-carene,  $\beta$ -pinene, *m*-xylene. Narain et al.<sup>[5]</sup> reported the presence of these compounds in ripe cajá-umbu (*Spondias* sp) fruit pulp when the extraction was performed by the Purge & Trap extraction technique and compounds were separated by using Carbo-WAX column and identified in a GC-MS system.

Tong Chin et al.<sup>[8]</sup> studied the influence of the temperature on the retention capacity of the volatile compounds markers of the atomized durian pulp and monitored the propanethiol and ethyl propanoate compounds at two temperatures of 170°C and 130°C, and reported that at a temperature of 170°C a reduction in the number of volatile compounds occurred. In the present work as seen in Table 1, the temperature at which a higher number of peaks was obtained and also a higher intensity was observed was at 140°C. At this temperature it is also possible to detect the appearance of compounds which at other temperatures were not found, for example, 3-carene, *m*-xylene while there was an increase in the concentration of the esters such as ethyl acetate, ethyl butanoate and ethyl lactate.

The use of high temperatures can also lead to the formation of new compounds in dehydrated products. Gozales-Palomare et al.<sup>[9]</sup> working with dehydrated powder of *Hibiscus sabdariffa* at temperatures of 150, 160, 170, 180, 190, 200 and 210°C reported the formation of furfuraldehyde in the dehydrated product at temperatures of 180-210°C. Similar results were found for dehydrated cajá-umbu powders at temperatures of 140 and 160°C, being higher in 160°C. According to Nunes et al.<sup>[10]</sup>, the presence of furfural in ODG is probably expected as heating increases ascorbic acid degradation. Therefore, furfural analysis could be used to monitor product quality during guava drying processes as it may be considered as a marker of heating.

**Table 2: Volatile compounds present in dried powder of cajá-umbu pulp**

Compound	LRI <sub>Lit</sub>	Dried powder-Spray drying				FDP
		100°C	160°C	140°C	120°C

\* LRI - Linear Retention Index; FDP - Freezed dried powder

An interesting factor to be emphasized is the higher presence of esters in the cajá-umbu pulp powder obtained by freeze-drying than in powder obtained by spray-drying. Compounds such as ethyl lactate (16.96%), which possesses a mild odor and propyl butanoate (8.432%) characterized by a fruity odor, were found in significant concentrations. Tietel et al.<sup>[11]</sup> studying the changes in concentrations of volatile compounds of tangerine reported that a slight increase in temperature caused a decrease in the concentration of esters such as ethyl acetate, ethyl butanoate, ethyl hexanoate. Similar behavior was observed in this study when compared to the lyophilization technique that uses low temperatures, when compared with the spray-drying technique that uses high temperatures.

Another aspect that probably influenced a lower retention of esters in the spray-drying was the retention capacity of the wall material in relation to these compounds. Rosenberg et al.<sup>[12]</sup> studying the factors that affect ester retention in the spray-drying technique observed that these compounds are not readily retained in the carrier material with a concentration of less than 30%. For the dehydrated cajá-umbu pulp, a similar behavior was observed to that reported by Rosenberg et. al.<sup>[12]</sup> since the carrier material (maltodextrin) concentration was 15%, thus not resulting in a better retention of the esters.

#### 4. Conclusions

The pulp dehydration in the spray dryer maintained the nutritional and organoleptic characteristics of the fresh pulp resulting in a promising product for marketing purposes. In the identification of the volatile composition of the dried powders, 29 compounds were identified in the spray-drying process at 140°C and 26 compounds in the dehydrated powder by lyophilization. However, the major compound identified was limonene in both dehydration techniques. At all temperatures (100, 120, 140 and 160°C) of dehydration tested by spray drying, the highest number of volatile compounds were identified in the dried powder at a temperature of 140°C. Thus, it is concluded that the optimum dehydration temperature of the cajá-umbu pulp by the spray-drying process is 140°C.

### **Abstract**

*The objective of this research work was to obtain blackberry pulp powder (BL, without encapsulating agent) and microencapsulated blackberry pulp (ML, with encapsulating agent :mixture of starch arrowroot and gum arabic (1:1)) obtained by freeze drying and spray drying and evaluate their physico-chemical properties. The yield of blackberry freeze drying process was higher than the value found for spray drying process. The presence of encapsulating agent and drying method used for producing the powders influenced the average particle size, diameter, hygroscopicity, solubility, wettability and anthocyanin content of the powders.*

**Keywords:** *process yield; average size; hygroscopicity; solubility; anthocyanin; antioxidant property.*

---

## **1. Introduction**

Blackberry (*Rubus fruticosus*) cv. Tupy is a fruit rich in anthocyanins and phenolic compounds, which has high antioxidant activity.[1] However, its short shelf life, due to their fragility and high postharvest respiration rate, consists of an enormous challenge for agri-food industries. Application of microencapsulation by spray drying and freeze drying is a technique to maintain or increase the stability of blackberry pulp bioactive compounds and to prolong its shelf life.[2] More specifically, spray drying is a technological process in which a fluid product is transformed into powder by atomizing it into a hot gas stream.[3] Freeze drying is based on dehydration by sublimation of a frozen product resulting in a dry material.[4] Both processes can be used as encapsulation method when it incorporates 'active' material within a protective matrix, which is essentially inert to the material being encapsulated.[5] The arrowroot (*Maranta arundinaceae* L.) starch presents good digestibility [6] and gelling ability [7]. Gum arabic is widely used in food industry. It is nontoxic, odorless and tasteless. It interacts with water and has a wide range of applications, such as emulsification, texture control and flavor encapsulation.[8] Until now, no study used arrowroot starch and gum arabic mixture as encapsulating agent during spray drying or freeze drying. The objective of this research work was to obtain pulp blackberry in powder microencapsulated with mixture of starch arrowroot and gum arabic (1:1) by spray drying and freeze drying processes in order to evaluate the influence of different drying methods and presence of encapsulating agent on the physico-chemical properties of blackberry powders.

## **2. Materials and Methods**

### **2.1. Materials**

Frozen fruits of blackberry (*Rubus fruticosus*), cv Tupy, were acquired from "Agro Monte Verde Eirelli", Cambuí – MG, Brazil, and used in this research work. Pulp was obtained by grinding of blackberry fruit in a blender, previously thawed in the refrigerator (8 °C) for 24 h. Then, pulp was sieved to remove the seeds, homogenized and packed in polypropylene bottles and coated with aluminium foil to protect against photodegradation. The samples were stored in freezer at  $-40 \pm 3$  °C until drying process. Blackberry soluble solids content was 9 °Brix, determined with a benchtop refractometer (Reichert, Model AR200, USA). The pulp presented total solids content of 10.3 g/100g of pulp.

The following encapsulating agents were used: arrowroot starch containing  $15.24 \pm 0.19\%$  of water,  $0.40 \pm 0.03\%$  of protein,  $0.12 \pm 0.01$  % of fat,  $0.33 \pm 0.01\%$  of ash and  $83.91 \pm 0.00\%$  of carbohydrates [9]; and gum arabic (Instantgum®, Colloides Naturels, São Paulo, Brazil) containing  $14.00 \pm 0.10\%$  of water,  $1.38 \pm 0.16\%$  of proteins,  $0.37 \pm 0.02\%$  of

lipids,  $3.70 \pm 0.10\%$  of ash and  $80.46 \pm 0.00\%$  of carbohydrates.[9] All other reagents used for the analyses presented analytical grade.

## **2.2 Preparation of blackberry pulp microparticles**

Blackberry microparticles were produced from homogenization of blackberry pulp with encapsulating agent, consisting of arrowroot starch and gum arabic mixture (1: 1 mass / mass) in ratio of 1:1.78 (mass / mass, blackberry pulp solids and encapsulating agent). Solution of encapsulating agent and blackberry pulp was performed in a mixer type homogenizer at room temperature for 5 minutes. Spray drying and freeze drying techniques were used to prepare blackberry pulp microparticles.

### *2.2.1 Spray drying*

The freshly prepared solution of blackberry pulp and encapsulating agent (item 2.2) was diluted in water in proportion of 1:2 (w / w) to enable its spraying. A benchtop spray dryer (Model B191, Büchi, Flawil, Switzerland) with feed mass flow rate of 0.2 kg / h was used in the process. Atomization was accomplished using a 0.5 mm double-flow atomizer nozzle. Compressed air was used as atomizing media and the inlet and outlet air temperatures were 143 °C and  $105.43 \pm 3.13$  °C, respectively. Compressed air flow rate was 0.6 m<sup>3</sup> / h and its pressure was maintained at 8 bar. Powders were collected at cyclone and finally transferred for polyethylene packages. These spray dried blackberry microparticles were stored in desiccator containing dried allochroic silica gel at 25 °C.

### *2.2.2 Vacuum freeze drying*

A portion of frozen blackberry pulp with and without encapsulating agent (item 2.2) was freeze dried (Mod. 501, Edwards Pirani, Crawley, West Sussex, UK), with initial temperature of -40 °C, pressure of 0.1 mmHg and final temperature of 25 °C per 2 h, with total cycle time of 48 h. The product obtained was ground in hammer mill (MR Manesco and Ranieri LTDA, model MR020, Piracicaba- Brazil) and sieved. Freeze dried blackberry microparticles were stored in the same conditions of spray dried samples.

## **2.3 Powder characterization**

*2.3.1 Drying process yield, moisture content, water activity, hygroscopicity, solubility, wettability, particle size distribution of the blackberry powders*

Drying process yield was determined by ratio between powder solids mass and feeding solids mass of blackberry pulp. The powder moisture content was gravimetrically obtained by vacuum oven at 60 °C until constant weight. [9] Water capacity was determined by direct reading at 25 °C, using AquaLab Lite apparatus (Decagon Devices Inc., Pullman, USA).

Hygroscopicity was determined according to methodology proposed by Cai and Corke [10], with some modifications. About 1 g of each powder sample was placed in desiccators containing saturated sodium chloride (NaCl) solution, equivalent to 75.7% relative humidity at 25 °C. After one week, the samples were weighed in triplicate and hygroscopicity was expressed in grams of water absorbed per 100 g of solids dry mass of the sample (g / 100g).

Solubility was determined according to the method of Eastman and Moore (1984), cited by Cano-Chauca et al. [11]. The method consisted of adding 1 g of sample to a vessel containing 100 mL of distilled water, operating with high-speed magnetic stirring - level 4 of magnetic stirrer for 5 minutes, followed by centrifugation at 3000 G for 5 minutes. Aliquot of 25 mL of supernatant was removed and brought to the oven at 105 °C until constant weight. The solubility was calculated by weight difference.

Wettability time was evaluated according to the method described by Hla and Hoge Kamp [12]. The method consisted in dropping of 1 g of powder over 400 g of distilled water at 25 °C in 600 mL beaker and visual measurement using a stopwatch to determine the time required for presence of powdered material on the water surface.

The particle size distribution was determined by a particle size analyzer based on laser diffraction (Mastersizer 2000, Malvern Instruments, UK). The mean diameter was determined based on the diameter of a sphere with equivalent volume (De Brouckere Mean Diameter, D[4.3]). Samples were analyzed in triplicate with dispersion in 99.5% ethanol.

### *2.3.2 Anthocyanins content*

Anthocyanins in powders were determined according to the method employed by Sims and Gamon [13] with adaptations. Samples were weighed in triplicate and homogenized with 3 mL of cold solution of acetone/Tris-HCl (80:20, volume/volume, pH 7.8 0.2M) for 1 minute. The samples remained at repose for 1 hour, protected from light. Then, they were centrifuged for 15 minutes at 3500 rpm and the supernatants were immediately taken to be read in spectrophotometer (B422 model, Micronal) in visible region at 537 nanometers (anthocyanins). The acetone/tris-HCl solution was used as blank sample. The absorbance values were converted to mg/100g of blackberry pulp solids.

### 2.3.3 Statistical analysis

Significant differences between average results were evaluated by analysis of variance (ANOVA) and Tukey test at 5% of level of significance, using SAS software (Cary, NC, USA).

## 3. Results and discussion

Microencapsulated blackberry pulp were successfully obtained by spray drying and freeze drying techniques, using a mixture of arrowroot starch and gum arabic as encapsulating agents. However, spray drying of blackberry pulp without encapsulating agent was not possible. There is great difficulty in drying fruit pulps by spray drying method without addition of encapsulating agent, since fruits are rich in low molecular weight sugars, which have low glass transition temperatures and influence transition temperature of dried particles, hindering drying process by this method. With addition of encapsulating agent, the end glass transition temperature of the pulp and agents mixture tends to increase, reducing stickiness of pulp by microencapsulation and, consequently, decreasing its adhesion in drying chamber, making possible to collect the powder. [14]

The powders presented blackberry characteristic sweet aroma and reddish color. The results of characterization of freeze dried blackberry pulp (BL), microencapsulated freeze dried blackberry pulp (ML) and microencapsulated spray dried blackberry pulp (MS) powders are shown in **Table 1**. The yield of freeze drying process was significantly ( $p < 0.05$ ) higher than value found by spray drying. In spray drying method, losses are due to the material adhered to drying chamber and cyclone, which is generally not suitable for use. Blackberry powders with encapsulating agent (ML and MS) presented significant water contents ( $p < 0.05$ ), lower than the non-encapsulating blackberry (BL) powder. The water activity values for all powders was below 0.3, indicating their microbiological stability ( $A_w < 0.3$ ). Particles of ML and ML powders were significantly ( $p < 0.05$ ) higher than MS powder particles and, although BL and ML powders were produced by the same method, ML powder particles were significantly ( $p < 0, 05$ ) smaller than BL powder particles, without encapsulant. The presence of encapsulating agent and the type of method used to produce the powders influenced the average particle diameter of powders. The size of spray particles is directly influenced by the size of spray droplets. Size of these droplets is dependent on type of atomizer and physical properties such as atomizer rotation, atomizer pressure and solution solids concentration.[15] The size of particles produced by freeze drying is a consequence of type of milling and its operating conditions.

**Table 1. Characterization of freeze dried blackberry pulp (BL), microencapsulated freeze dried blackberry pulp (ML) and spray dried microencapsulated blackberry pulp (MS) powders.**

<b>Analysis</b>	<b>Powder of freeze dried blackberry pulp (BL)</b>	<b>Freeze dried microencapsulated blackberry pulp (ML)</b>	<b>Spray dried microencapsulated blackberry pulp (MS)</b>
Process yield (%)	89.24 ± 2.81A*	95.86 ± 0.89A	57.69 ± 8.97B
Moisture content (%)	10.72 ± 2.81A	4.50 ± 0.31B	1.30 ± 0.10B
Aw (decimal)	0.13 ± 0.01B	0.11 ± 0.01B	0.16 ± 0.02A
Mean diameter D [4.3] (µm)	149.50 ± 2.92A	95.96 ± 5.87B	9.82 ± 0.12C
Hygroscopicity (g of adsorbed water / 100g solids)	21.28 ± 0.45A	12.86 ± 0.14C	17.04 ± 0.30B

Total Anthocyanins (mg / 100 g of blackberry solids)	125.27 ± 9.77A	125.99 ± 5.25A	86.35 ± 3.37B

\*Same letters in the same line show no statistical difference ( $p > 0.05$ ).

BL powder was shown to be more hygroscopic and more water soluble than powders produced with encapsulating agent. Arrowroot starch and gum arabic used as encapsulants have low hygroscopicity. Accordingly, microencapsulation of blackberry pulp tends to reduce the hygroscopicity of resulting powder. Moreover, although gum arabic is highly soluble in water [16], arrowroot starch in its native form has low solubility in water at room temperature, which probably contributed to decrease the solubility of the blackberry powders. This behavior indicates that the blackberry pulp was actually microencapsulated by the arrowroot starch and gum arabic mixture and by both methods.

The wettability of freeze drying powders (BL and ML) were significantly ( $p < 0.05$ ) lower than the value found for spray dried powder. This occurred because powders obtained by freeze drying presented larger particle size (Table 1). Particles of larger sizes have more spaces between them, being more easily penetrated by water.[2] On the other hand, powder particles obtained by spray drying were much smaller and less porous. This led to a larger formation of lumps when they came into contact with water. The low wettability of very

fine powders is due to their high surface tension and the viscous layer formed on the surface of the liquid that prevents capillary flow between the intergranular pores.[17]

Concerning the anthocyanin content, freeze dried blackberry powders (BL and ML) presented values significantly ( $p < 0.05$ ) higher than spray drying (MS) powder. The bioactive compounds losses in spray drying process are related to the large air exposed surface [18] and high temperatures, whereas the loss during freeze drying is associated with the grinding of the material after lyophilization.[19]

#### 4. Conclusions

Freeze drying and spray drying methods were successfully used for powder microencapsulation of blackberry pulp (ML and MS) and only freeze drying method was able to dry blackberry pulp (BL) without encapsulant. The yield of the freeze dried blackberry drying process powders was significantly ( $p < 0.05$ ) higher than the value found for spray drying process. Blackberry powders was microbiological stability. The presence of encapsulating agent and the type of method used to produce the powders influenced in physical chemical characteristics of the powders.

### **Abstract**

*Capsicum pubescens*, a chili specie present in south Mexico (Veracruz state) registers upon 30% loss due to the constraints of the market. Therefore, the objective of this project was to determine the physical and chemical parameters of *Capsicum pubescens* as well as to evaluate the kinetics of drying of this species. Color tests revealed that the samples were the color was less affected by drying conditions ( $p>0.05$ ) correspond to those dried at 60°C (0.5 cm thickness), and 50°C (0.5 and 1 cm thickness) which coincides with the preference of surveyed population. Thus, *Capsicum pubescens* may be dried under these conditions.

**Keywords:** *Capsicum pubescens*; drying; sensorial analysis; food loss.

---

## 1. Introduction

Most chile belongs to the species *Capsicum annuum* while four other lesser known species have also been domesticated. One of this species, the pepper tree (*C. pubescens*), also known as rocoto and locoto in South America, manzano or peron in Mexico, originated in the Andean highlands with extensions in Central America and Mexico [1] [2]. The varieties of this species of chile vary in shape, and the color changes from green (in its immature state) to yellow, orange or red (mature state) [3]. This species is of recent introduction to Mexico where it is cultivated in states with high elevations (1200 to 3000 m) including the High Mountain regions in the state of Veracruz [4]. *C. pubescens* is mainly cultivated in the months from August to December [5]. Despite this fact, it is highly appreciated in several Mexican states and European markets [5][6] because it is more resistant than other common chile species (*C. annuum*) to aphids and its particular flavor. Even though there is scarce information on its sensory qualities, it has been reported that it contains a relatively greater number of individual capsaicinoids and show more diversity in capsaicinoid profiles than other *Capsicum* species [2]. Moreover, its capsaicin:dihydrocapsaicin ratio is different from *C. annuum* which supports and sustain its particular flavor.

Even though *C. pubescens* seems to possess particular properties and its appreciated in international markets, there is scarce information regarding its conservation. Moreover, local producers from the High Mountains region in the state of Veracruz register up to 30% loss of manzano chile due to the constraints of the market. Convective drying is an excellent option to diminish *C. pubescens* loss as well as to provide national and international markets with product throughout the year. Therefore, the objective of this project was to evaluate the kinetics of drying of this species and to determine the physical and chemical parameters of *Capsicum pubescens* during drying. Also, a sensorial analysis of manzano chili powder obtained after drying of fresh fruit was performed.

## 2. Materials and methods

### 2.1 Selection and characterization of the raw material

Samples of *Capsicum pubescens* were collected in their mature state (established by the presence of intense yellow color) in a rural area called Ateopa in the municipality of Alpatlahuac, Veracruz (Mexico, 1860 m altitude) between August 2017 and January 2018. After collecting the samples they were transported to Orizaba, Veracruz to be dried. The samples were cut into slices of 0.5 and 1 cm thickness.

### 2.2 Drying process

Tests were conducted in a pilot plant scale vertical tray dryer (MOD-SEM-2 Polinox, MX). Drying tests were carried out at temperatures of 50, 60 and 70°C and the air velocity was imposed at 1.2 m/s. In each test, the drying kinetics were evaluated by recording the

moisture content change as function of time. During the drying process, samples were taken to analyze the main physical-chemical parameters ( $a_w$ , moisture content and color) every 15 minutes during the first hour, 30 minutes in the following hour, and finally every 60 min until the water activity of the samples reached 0.6.

### 2.2.1 Effective diffusion

The effective diffusivity of food products can be estimated by Fick's second law of diffusion. Considering the geometry of the pepper tree samples, diffusion is better estimated through the solution of Fick's equation for slab geometry. For long drying periods, this solution can be simplified to only the first term of the series as:

$$\ln M_R = \ln \frac{8}{\pi^2} - \left( \frac{\pi^2 D_{eff} t}{4L^2} \right) \quad (1)$$

Where the moisture content was expressed as the moisture ratio ( $M_R$ ),  $D_{eff}$  corresponds to water diffusivity in  $m^2/s$ ,  $t$  is the time in s and  $L$  is the thickness in m. Moisture content ratio was calculated by means of eq. (2):

$$M_R = \frac{X}{X_0} \quad (2)$$

Where  $X$  corresponds to the moisture content at any time in g water/g of dry solid and  $X_0$  is the initial moisture content in g water/g of dry solid. Tests were conducted in duplicate.

Drying kinetic data was adjusted to a single exponential as shown in equation 3:

$$M_R = \frac{X}{X_0} = e^{-kt} \quad (3)$$

where  $k$  is a model parameter. The goodness of fit of the data to the model was evaluated by means of the  $R^2$  parameter.

### 2.3 Sensorial analysis test

Manzano chili samples were subjected to a sensorial analysis by means of an hedonic verbal test of 7 points with untrained panelists (N= 150). The samples were presented simultaneously and later, each panelist evaluated each sample only once accompanied by Mexican yam bean (jicama) (*Pachyrizus erosus*). Each participant was asked to indicate how much they liked each sample, assigning an attribute according to the category reported on a scale which ranged from "I disliked it a lot" to "I really liked it a lot". The samples were coded to identify the condition in which it was dried. After concluding each test, panelists were asked to drink water as a neutralizer to avoid interference with the next treatment.

## 2.4 Statistical analysis

Differences between drying kinetics and physicochemical parameters of *C. pubescens* samples regarding the drying parameters as well as the significance in the preference of samples were analyzed through an ANOVA test (MiniTab, 2016).

## 3. Results and discussion

### 3.1 Air drying kinetics

Fig. 1 and 2 shows the drying kinetics of *C. pubescens* dried at two thickness (0.5 and 1 cm) and three temperatures (50, 60 and 70°C) and Table 1 shows the values of the rate constants for the first order kinetic parameter as well as the diffusion coefficient for each drying condition proposed.

Fig. 1 Drying kinetics of *C. pubescens* samples of 1 cm thickness ( $\blacktriangle=70^{\circ}\text{C}$ ,  $\bullet=60^{\circ}\text{C}$ ,  $\blacksquare=50^{\circ}\text{C}$ )

Table 1 reveals that the diffusion coefficient is in the range of  $10^{-9}$ - $10^{-10}$   $\text{m}^2/\text{s}$  which is similar to the diffusion value reported by Lucio-Juárez et al (2012) for habanero chili (*C. chinense*) ( $5.9470 \times 10^{-10}$   $\text{m}^2/\text{s}$ ) which has similar structure to *C. pubescens*. In accordance with the findings of Nguyen and Price [7], the diffusion coefficients for the thicker slices (1 cm) are greater than those for thinner slices (0.5 cm) which are not observed in all foodstuffs. As exposed in this last study, the rate constant from a first order kinetic drying model encompasses several mass transfer mechanisms including the diffusion of water in the falling drying rate.

Fig. 2 Drying kinetics of *C. pubescens* samples of 0.5 cm thickness (▲=70°C, ●=60°C, ◆=50°C)

Table 1. Rate constant and diffusion coefficient for the drying kinetics of *C. pubescens*

Drying condition	Rate constant (min <sup>-1</sup> )	Diffusion coefficient (m <sup>2</sup> /s)
50°C, 0.5 cm	0.0152	6.4516x10 <sup>-10</sup>
50°C, 1 cm	0.0075	1.2706x10 <sup>-9</sup>
60°C, 0.5 cm	0.0168	7.1135 x10 <sup>-10</sup>
60°C, 1 cm	0.0129	2.1909 x10 <sup>-9</sup>
70°C, 0.5 cm	0.0177	7.4706x10 <sup>-10</sup>
70°C, 1 cm	0.0149	2.5267 x10 <sup>-9</sup>

In the present case, the rate constant parameter for the single exponential equation (which is generally related with the diffusion coefficient) effectively represents the drying rates for the samples of 1 cm thickness but is less accurate for samples of 0.5 cm thickness (Fig. 2). Moreover, statistical analysis revealed that the water content difference between samples of chili of 0.5 and 1 cm thickness dried at the same temperature was not significant ( $p > 0.05$ ). This may be explained by the internal structure of *C. pubescens* which may play a role in the similarity of loss water at both sample thickness.

### 3.2 Physicochemical parameters of samples of manzano chili (*C. pubescens*) during the drying process

The color change of the different samples of manzano chili was recorded during the drying process. Table 2 shows the average value of  $\Delta E$  after 300 min at each drying condition tested for *C. pubescens*. Results showed that color changed significantly depending on the drying conditions at which samples were subjected ( $p < 0.05$ ). After 300 min the lesser color change was observed in samples dried at 60°C and 0.5 cm, and 50°C for both sample

thickness (1 cm, and 0.5 cm). Color of *C. pubescens* (and of chili species in general) is given by carotenoids which may be affected by heat (Hernández-Ortega et al., 2015). Thus, the difference in color may also reflect the loss of carotenoids due to drying.

Regarding the water activity, after 300 min of drying all samples of manzano chili were below 0.6. Analysis test revealed that the decrease of the water activity was not significantly different among the drying conditions studied ( $p>0.05$ ). The lack of difference between the samples suggests that the loss of water is similar regardless the thickness. This supports the idea that there is a concentration of the water content in thinner samples due to natural causes, such as the internal structure.

**Table 2.  $\Delta E$  and  $a_w$  of slices of *C. pubescens* (after 300 min) at different drying conditions**

Drying condition	$\Delta E$	$a_w$
50°C, 0.5 cm	12.26±0.12	0.391±0.55
50°C, 1 cm	9.6±0.22	0.524±0.71
60°C, 0.5 cm	7.79±0.03	0.378±0.07
60°C, 1 cm	15.41±0.57	0.367±0.21
70°C, 0.5 cm	14.24±0.09	0.301±0.02
70°C, 1 cm	15.34±0.12	0.405±0.10

### 3.3 Sensorial analysis test

Statistical analysis revealed that 145 out of 150 people manzano chili powder was highly desirable ( $p<0.05$ ). We counted the type of samples that were highly accepted (I strongly prefer) by panelists, and we found that nearly 70% preferred the samples dried at 60°C and 0.5 cm thickness and 60% preferred the samples dried at 50°C and 1 cm thickness. Interestingly, this drying conditions coincide with those in which the samples showed lesser color change (Table 2). As surveyed population was invited to chose the sample as a function of its flavor, this last result suggests that population relates a good flavor with reddish color.

## 4. Conclusions

*Capsicum pubescens* slices dried at different drying conditions showed values of water activity lesser than 0.6 after 300 min process. The diffusion coefficient of thicker samples (0.5 cm) was higher than the values observed in thicker samples (1 cm) similarly with what was observed in bananas. This behavior suggests that there is a concentration of the water content in thinner samples due to natural causes, such as the internal structure. A sensorial analysis test revealed that panelists preferred the samples with lesser color change. As this conditions coincide with those in which the carotenoid content is less damaged *C. pubescens* may be dried in slices at 60°C and 0.5 cm or 50°C and 1 cm.

### **Abstract**

*Tarragon is a small shrubby perennial herb in the Asteraceae family. It is cultivated for the use of its aromatic leaves in seasoning, salads, sauces, vinegars, mustard and spices. In this study, tarragon was dried in two different drying equipment (infrared (ID) and microwave dryers (MD)) to compare the drying and final product properties (moisture content, water activity and colour change). Three different output power levels of 125, 250 and 500 W were used for MD, whereas the ID treatment involved three drying temperature levels that were 60, 70 and 80°C. A comparison of the drying kinetics, MD was more effective in shortening drying time when compared with ID.*

**Keywords:** *Tarragon, microwave drying, infrared drying, color change*

---

## 1. Introduction

Herbs and spices are used to season foods throughout the world. These are the aromatic substances that enhance savoury character as flavouring agents and as appetite stimulants. The use of spices has increased significantly over the past years, partly due to renewed interest in dishes that use a wide variety of spices. Tarragon (*Artemisia dracunculus* L.) is a medicinal and aromatic plant that extends all over Eurasia. Tarragon is an herbaceous plant of the Asteraceae family. It is a strong aromatic plant and is also considered as a medicinal plant [1]. Two varieties of tarragon can be distinguished [2; 3]: French Tarragon and Russian Tarragon. French Tarragon of the South European origin is mainly used as a culinary herb in oils, sauces, vinegars, mustard and spices [4; 5]. Tarragon can be consumed as fresh, dried and frozen product. Drying is the main step in the preparation of tarragon for marketing. Not enough data is available in the literature about drying and storage of tarragon.

Correct drying of aromatic plants is necessary for high quality and stable products. The final moisture content (MC) must reach 5-10%. Colour is an important component of quality throughout agriculture and food industry, because colour is closely associated with factors such as freshness, ripeness, desirability and food safety. It is often the primary consideration of consumers when making purchasing decisions. A limited amount of information was found about the stability of dried tarragon and the colour change after drying. Some of tarragon's aspects are lost when it is dehydrated, though, and its colour deteriorates. There has been much research into microwave drying techniques, examining a broad spectrum of fruits and vegetables [6] and others, however, more data are still needed on the effect of microwave drying on the potential role of medicinal plants.

Mathematical modelling of drying processes and kinetics is a tool for process control and can be used to choose suitable method of drying a specific product. The developed models can be used to design new drying systems, determine optimum drying conditions and to accurately predict simultaneous heat and mass transfer phenomena during the drying process. Taking into account the above-mentioned considerations, this study was designed with the objectives to (1) determine the drying characteristics and quality degradation in terms of colour, moisture content and water activity of tarragon subjected to the two drying methods; and (2) examine and compare the applicability of eleven different thin-layer models to the simulation of moisture loss in tarragon during drying.

## 2. Materials and Methods

### 2.1. Material

Fresh tarragon leaves of uniform maturity were purchased from the local market at Gaziantep. They were handpicked and cleaned, washed in sufficient tap water twice to remove mud and

other foreign matter and drained completely. The roots and mature stems were removed prior to washing.

## 2.2. Drying

Drying trials were carried out at three microwave generation power levels: 125, 275, and 625W by using a microwave dryer (Arçelik ARMD580, Turkey). The tarragon leaves (25 g) selected from uniform and healthy plants. Three drying trials were conducted at each power level. The values obtained from these trials were averaged and the drying parameters determined. The rotating glass plate was removed from the oven every 30 s during the drying period and moisture loss determined by weighing the plate using a digital balance (Mettler Toledo PM30, Germany) with 0.01 g precision.

A laboratory scale infrared dryer was used for infrared dehydration of the samples (OHAUS MB200, USA). Approximately 5 g of tarragon leaves were uniformly spread on a dish (12 cm diameter 3 cm height) The drying experiments were conducted at infrared temperatures levels of 60, 70 and 80°C. This drier is equipped with a temperature controller and an electronic balance with an accuracy of  $\pm 1^\circ\text{C}$  and  $\pm 0.001$  g, respectively.

Three drying trials were conducted at each drying temperatures and power levels. Drying process continued until they reached equilibrium state, i.e. constant weight.

## 2.3. Colour measurement

The colour of fresh and dried leaves was determined by using colorimeter (Hunterlab Colorflex, USA). The results were expressed in accordance with the CIE Lab system. The total colour change ( $\Delta E$ ) of dried tarragon leaves with respect to fresh tarragon was calculated by Eq. (1).

$$\Delta E = \sqrt{\Delta L^2 + \Delta a^2 + \Delta b^2} \quad (1)$$

## 2.4. Moisture content

Moisture content was determined by drying a sample in an air oven at 105°C until constant mass was obtained.

## 2.5. Water activity

Water activity was measured with a water activity measurement device (Rotronic, HP23-AW-A, New York) with a 0.0001 sensitivity.

## 2.6. Mathematical modelling of drying curves

A few theoretical, semi-theoretical and empirical drying models have been reported in the literature. The most frequently used type of model for thin layer drying is the lumped

parameter type, such as the Newton equation [9-11]. The moisture ratio during drying is determined using equation (2):

$$MR = \frac{M_t - M_e}{M_0 - M_e} \quad (2)$$

where,  $M_t$  is the moisture content of the product at any time,  $M_e$  is the equilibrium moisture content,  $M_0$  is the initial moisture content all in kg water/kg dry matter.

In this analysis, it was assumed that the moisture gradient driving force during drying is a liquid concentration gradient; meanwhile the effect of heat transfer was neglected as a simplifying assumption. For all experimental conditions, the value of  $(M_t - M_e) / (M_0 - M_e)$ , a dimensionless moisture content was obtained. Because samples were not exposed to uniform relative humidity and temperature continuously during drying, the moisture ratio was simplified as recommended by [7] expressed as follow:

$$MR = \frac{M_t}{M_0} \quad (3)$$

For mathematical modelling, the equations in Table 1 were tested to select the best model for describing the drying curve equation of the tarragon. The moisture ratio of the tarragon leaves during drying was calculated using equation (3). The goodness of fit of the tested mathematical models on the experimental data was evaluated using coefficient of determination ( $R^2$ ), mean relative percentage deviation (P) value and the percentage root mean squares error (RMSE) value with higher  $R^2$  values and lower RMSE and P values indicating a better fit [8] as follow:

$$P = \frac{100}{N} \sum_{i=1}^N \frac{|M_{exp} - M_{cal}|}{M_{exp}} \quad (15)$$

$$RMSE = \sqrt{100 \frac{\sum (M_{exp} - M_{cal})^2 / M_{exp}}{N}} \quad (16)$$

where  $M_{exp}$  and  $M_{cal}$  are experimental and predicted moisture content values, respectively, and N is the number of experimental data. A model was considered acceptable if the P values and RMSE values were below 10% and  $R^2$  values were higher than 0.90.

### 3. Result and Discussion

Microwave drying trials were conducted at output power levels of 125, 275 and 625 W and the influence of each microwave power level on moisture ratio over drying time presented in Fig. 1a. The drying time decreased as microwave power level was increased. The times required for the moisture content of tarragon leaves to decrease from 7.897 to 0.097 % (d.b) were 188, 60 and 40 min at microwave output power levels of 125, 275 and 625W, respectively. The effect of microwave power level of decreasing drying time was observed by [23, 24]. The results indicate that mass transfer is more rapid at higher microwave power

levels because more heat is generated within the sample, creating a larger vapor pressure differential between the interior and the surface of the product [25].

**Table 1. Mathematically models used for modelling of drying curves**

Model Name	Model Equation	Reference
Lewis-Newton	$MR = \exp(-k*t)$	(4) [9]
Page	$MR = \exp(-k*t^n)$	(5) [10]
Modified Page	$MR = \exp(-(k*t)^n)$	(6) [11]
Henderson and Pabis	$MR = a*\exp(-k*t)$	(7) [12]
Logarithmic	$MR = a*\exp(-k*t) + c$	(8) [13]
Two-Term	$MR = a*\exp(-k_0*t) + b*\exp(-k_1*t)$	(9) [14]
Two-Term Exponential	$MR = a*\exp(-k*t) + (1-a)*\exp(-k*a*t)$	(10) [15]
Diffusion Approach	$MR = a*\exp(-k*t) + (1-a)*\exp(-k*b*t)$	(11) [16]
Modified Henderson and Pabis	$MR = a*\exp(-k*t) + b*\exp(-g*t) + c*\exp(-h*t)$	(12) [17]
Verma	$MR = a*\exp(-k*t) + (1-a)*\exp(-g*t)$	(13) [18]
Midilli and Küçük	$MR = a*\exp(-k*t^n) + b*t$	(14) [19]

*MR* moisture ratio; *a, b, c, g, h* coefficients; *n* drying exponent specific to each equation; *k* specific to each coefficients equation; *t* time

Infrared drying trials were conducted at radiation temperature levels of 60, 70 and 80°C. A graph of moisture ratio versus drying time during the infrared drying of tarragon leaves at different temperature levels is presented in Fig. 1b. From the data, moisture ratio decreased over drying time. Furthermore, infrared radiation temperature level influenced the change in moisture ratio of tarragon leaves. The results also showed that when infrared radiation temperature level increases, the time taken to dry tarragon leaves greatly decreased. Accordingly, the drying times required to reduce the moisture content of tarragon leaves to approximately 0.115 % (w.b) were 126, 88 and 66 min when infrared temperature levels of 60, 70 and 80°C, respectively, were applied. A decrease in drying time with increased infrared temperature level has also been reported by other researcher [20].

From these findings it could be stated that drying time for tarragon leaves at 80°C was 2 times shorter than that of 60°C. The experiments data showed that drying time for tarragon leaves at 625 W was 4 times shorter than that of 125W.

The eleven different MR models used to predict the moisture content as a function of drying time are presented in Table 1. The coefficient of determination ( $R^2$ ), the RMSE and P value were used to assess how well the models characterized the drying curves. The statistical analysis of the models for a given set of drying conditions are shown in Table 2. An analysis of variance indicated that the microwave power and infrared temperature levels significantly affected the drying parameters. Higher microwave power and infrared temperature levels are associated with significant decrease in drying time and moisture ratio which was much more noticeable in microwave than infrared drying. This has been demonstrated in the studies of Azzouz et al. [21]. On the other hand, among the eleven models, the Midilli and Küçük,

model provided the best fit to the microwave and infrared radiation drying data as indicated by a higher  $R^2$  and lower RMSE and P value than those of the other models.

Fig. 1 Variations of moisture ratio as a function of time for different a) infrared drying temperatures, b) microwave drying power

Water activity of the dried tarragon leaves at different infrared temperatures and microwave power are given in Table 3. Water activity decreased as temperature increased in the infrared dryers. In addition, water activity decreased as microwave power increased in the microwave dryers.

The impact of various drying techniques upon the colour parameters of the dried tarragon leaves was exhibited in Table 3. The *L* value of all the dried tarragon declined considerably

when compared with the fresh tarragon. Additionally, temperature and/or microwave power rise significantly prompted the decline of *L* values and surge of *a* values which may be by reason of non-enzymatic browning reaction. Among the used microwave drying, the highest *a* value was obtained by the microwave drying at 125 W, while the lowest *a* value loss was obtained by the microwave drying at 625 W.  $\Delta E$  is a function of *a*, *b* and *L* values, and it was reliant on drying techniques. Microwave drying technique at 275 W resulted in the highest  $\Delta E$  while lowest  $\Delta E$  value was attained from the infrared drying technique at 80°C.

**Table 3-Comparison between infrared temperatures and microwave power for colour parameters and  $a_w$  values**

#### 4. Conclusions

This study characterized the influence of drying conditions on the drying behaviour of tarragon leaves using infrared radiation and microwave drying. It was found that the drying rate increases substantially with the microwave power level or infrared temperature level used. The Midilli model was found to be more suitable for predicting the drying behaviour of tarragon leaves, with the values for  $R^2$  above 0.99 and with the lowest values of RMSE and P values for both drying methods. A comparison of microwave and infrared drying times indicate that irrespective of the power or radiation temperature applied, microwaving is an effective method of shortening the time required for drying to the desired moisture content without charring the samples. Moreover, microwave drying had less influence on the colour and rehydration ratio of the finished product than infrared drying.

### **Abstract**

*Technical performance of two solar drying technologies was evaluated: Solar Greenhouse Drying (SGD) with auxiliary heating system, and Direct Solar Drying (DSD) in order to evaluate its effect on antioxidant activity (AA) and total flavonoids of blackberry (*rubus spp*) waste destined. The SDG and DSD results were compared with those of the dehydrated samples in an electric stove (ES). The fresh and dried fruits were evaluated; the blackberry seedless pulp was used. The AA and flavonoids showed degradation of 70% and 20% compared to the fresh sample. For both compounds, SGD is the one that offers the greatest conservation.*

**Keywords:** *solar drying; antioxidant capacity; flavonoids; blackberry pulp (*rubus spp*); solar energy*

## **1. Introduction**

México was the leader in the production of blackberry in recent years, with 248 thousand 500 tons per year and 13 thousand hectares had been planted for the year 2016 and 96% of the total production corresponds to the state of Michoacán [1,2]. Generally, the largest consumption of blackberries is fresh, but they can be processed and sold in different presentations such as: frozen in bulk or in individual containers, with or without seeds, lyophilized or in juices, in dietary supplements, jelly and jams [3].

The consumption of blackberry has received considerable commercial attention due to its content of phenolic compounds that contribute to its high antioxidant capacity whose health benefits have been well described [3]. Flavonoids have a wide range of biological effects, including antioxidant, anti-inflammatory, antiallergic, anti-ulcer, antibiotic and anticancer properties [3,4]. However, the blackberry is one of the most sensitive and perishable fruit products that exist. It is estimated that 50% of blackberry production is wasted from production to the end of the value chain (both cold and fresh), due to causes associated with the sensitivity of fruits and lack of conservation methods [5].

Solar dehydration technology offers an alternative for food preservation that is economical, needs low maintenance, environmentally friendly and preserves nutrients [6]. The objective of this study was to perform the solar dehydration of the blackberry pulp without seed and in form of a film with a thickness of 0.5 mm, determining the characteristics of the drying using a greenhouse solar dryer and a direct solar dryer. The direct solar dryer was with natural convection and the greenhouse solar dryer with forced convection at 0.5 ms<sup>-1</sup> (equipped with three solar air heaters). Additionally, the antioxidant capacity and the flavonoid content were determined as a measure of the quality deterioration of the product.

## **2. Materials and Methods**

### **2.1. Samples and pretreatment**

The samples of fresh blackberry were supplied by a local farmers from Los Reyes Michoacán Valley, the samples were considered "production process", that is, they did not meet export standards. They were frozen and transported to the Renewable Energy Institute, in Temixco Morelos where the tests were carried out. Before carrying out the drying tests, the blackberries were disinfected, pureed in a blender and the seeds were separated from the pulp with a strainer. They were placed in plastic trays of 33x47x1 cm, the pulp formed a homogeneous film with thickness 0.5±0.1 cm and then dehydrated by each of the following methods.

### **2.2. Drying methods**

The experimental study was carried out in Temixco, Morelos with a latitude of 18° 50'N and a length of 99° 14'W situated at elevation 1299 meters above sea level. The tests were carried out on July 16-17 (first drying), June 21-22 (second drying) and July 5-6 (third drying), of 2017. The samples were dehydrated between 9:30 am and 5:00 pm (solar time) continuously. The DSD and SGD prototypes are described in López, V. et al, [7] and Tamayo [8] and developed in the Renewable Energy Institute, (IER-UNAM).

### 2.2.1. Direct Solar Drying (DSD).

Two trays with blackberry pulp were placed in the direct dryer prototype (Fig. 1a), with an area of 0.48 m<sup>2</sup> and exposed to direct sunlight until reaching a water loss equilibrium measured with a balance with an accuracy of 0.1 g. The monitoring of the moisture loss of the product during drying was carried out by successive records every 20 minutes (first two hours of drying) and then every 30 minutes (up to constant weight).

### 2.2.2. Solar Greenhouse Drying (SGD).

Twenty six trays with blackberry pulp (thirteen in each table) extended all along the table (Fig. 1b), inside the drying chamber of the greenhouse which operated with auxiliary solar heating up to constant weight. The recording and monitoring of weight loss was performed in the same way as that described for DSD.

### 2.2.3. Electric Stove (ES).

Two trays with blackberry pulp were placed inside the electric stove drying chamber at 60±1 °C with forced convection at 1 ms<sup>-1</sup> for seven hours (time required to reach a constant weight loss). The recording and monitoring of weight loss was performed in the same way as that described for DSD and SGD.

Fig. 1a. Direct Solar Drying (DSD) scheme; 1b. Solar Greenhouse Drying (SGD).

## 2.3. Extraction of organic compounds

It was weighed 0.5 g of fresh and dried sample of blackberry pulp. Two sequential extractions of organic compounds was carry out usin 5 ml of methanol at 80%, sonicated in an ultrasound bath for 30 min, centrifuged at 1820 rpm for 10 min. The supernatant was recovered. The total organic extract was filtered with a Pasteur pipette packed and stored in an amber vial at 4°C until analysis.

#### **2.4. Antioxidant activity (AA)**

It was used the method developed by Blois, 1958 [9] and described by Brand-Williams et al. in 1995 [10] to determine antioxidant activity by the use of a stable free radical 1,1-diphenyl-2-picrylhydrazyl (DPPH). In total darkness is added 100 µL of the organic extract to a spectrophotometric cell followed by 2.9 ml of DPPH reagent. After reaction for 30 min at 25 °C the absorbance versus prepared blank was read at 517 nm. The results of antioxidant activity of the blackberry pulp (fresh and dried) were expressed as mg of equivalent ascorbic acid per gram of dry matter (mg AAE/g d.m) through the calibration curve with ascorbic acid (all samples were performed in triplicates). The calibration curve range was 0, 5, 9, 12.5, 17, 21 and 25 mg/100ml ( $R^2 = 0.98$ ).

#### **2.5. Total Flavonoid**

The total flavonoid content was determined by the aluminum chloride colorimetric assay [11, 12]. An aliquot (1 ml) of extracts or standard solution of quercetine was added to 10 ml amber vial containing 4 ml distilled water and vortexed for 30 seconds. Was added 300 µl NaNO<sub>2</sub> at 5%, vortexed for 30 seconds, and incubate at room temperature for 6 minutes. After the time, 300 µl of AlCl<sub>3</sub> at 10% was added and keep it for 5 minutes at room temperature. Subsequently, 2 ml of NaOH (1M) was added, and finally the volume of each dilution was completed with 2.4 ml of distilled water. The absorbance versus prepared blank was read at 510 nm after 30 min of reaction at 25 °C . The results of total flavonoid content of the blackberry pulp (three replicates per treatment) are expressed as mg of equivalent quercetin per gram of dry matter (mg QE/g d.m). The calibration curve range was 20, 40, 60, 80 and 100 mg/l ( $R^2 = 0.99$ ).

### **3. Results and discussion**

#### **3.1. Comparison of drying kinetics**

Fig. 2 shows the relationship of the average drying time (n=3) and the final moisture content (less than 32% dry matter) by the different drying methods of the blackberry pulp. The reference of the kinetics is given by drying in electric stove (ES) were the drying time was 480 min at 60°C and 1ms<sup>-1</sup>, the final moisture content was 0.31 kg of water per kilogram of dry matter. The DSD tests are carried out by natural convection and the SGD with forced convection at 0.5 ms<sup>-1</sup>. The average drying times for SGD and DSD

corresponded to 960 min respectively, with a moisture content of 0.33 and 0.35 kg<sub>w</sub>/kg<sub>dm</sub>. The drying times for solar technologies do not show significant differences.

Fig. 2 Comparison of drying kinetics (n=3) by different methods: Solar Greenhouse Drying (SGD), Direct Solar Drying (DSD) and reference in electric stove (ES).

### 3.2. Antioxidant Activity in blackberry pulp

In Fig.3 the antioxidant activity in the blackberry pulp of the fresh and dehydrated samples by the different technologies are presented. The fresh sample contains  $20.22 \pm 2.94$  mg AAE/g d.m, and on average dehydrated samples loss 70% of their antioxidant capacity compared to fresh samples. The antioxidant activity in the blackberry dehydrated by SGD and DSD ( $5.86 \pm 0.51$  and  $5.80 \pm 0.39$  mg AAE/g d.m) is barely greater than the method of drying in the electric stove SE ( $5.28 \pm 0.32$  mg AAE/g d.m).

Fig. 3 Antioxidant activity of the blackberry pulp, fresh and dehydrated by different technologies

The concentration of the antioxidant activity is shown in Fig.4a for each of the three tests and for each drying technologies. The influence of the average irradiance of the day on the total antioxidant capacity of the samples is shown. For SGD and DSD samples 1 and 3 are

affected by the influence of irradiance, with an inversely proportional correlation, a higher irradiance lower antioxidant activity, a lower irradiance greater antioxidant activity. However, sample 2 of SGD and DSD, seems not to follow this trend.

The Fig. 4b shows the influence of temperature on antioxidant activity, for each of the tests dried by different technologies. The effect is shown by the influence of temperature giving an inversely proportional correlation. That is, the samples subjected to a higher average drying temperature correspond to the lower concentrations of the antioxidant activity. The samples dehydrated in the electric stove at 60 °C, are those that have a lower antioxidant activity.

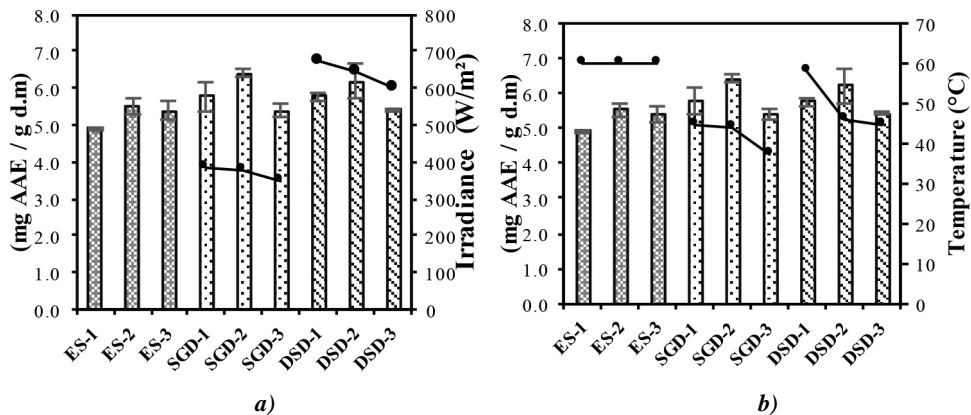

Fig. 4a Antioxidant activity in blackberry pulp and its effect by irradiance; 4b antioxidant activity in blackberry pulp and its effect by temperature.

### 3.3. Total flavonoid content in blackberry pulp

Fig.5 shows the content of total flavonoids in the blackberry pulp of the fresh and dehydrated sample. The fresh sample contains  $12.17 \pm 0.79$  mg of QE/g d.m. The samples dehydrated by SGD, DSD and ES technologies contain  $10.53 \pm 0.46$ ,  $9.94 \pm 0.21$  and  $8.89 \pm 0.24$  mg of QE/g d.m. On average the total flavonoids in dehydrated samples are degraded 20% compared to fresh samples.

Fig.6a shows the influence of average irradiance on the total flavonoid content. A correlation of the concentrations was observed for the samples that subjected it to a higher average irradiance, resulting in lower concentration of total flavonoids. In the same way, Fig. 6b shows the influence of the average temperature of the day on the concentration of total flavonoids present. A greater effect due to the temperature is observed, since the samples dehydrated in the electric stove at 60°C, are those that have a lower concentration, even when they are in darkness inside the drying chamber. Inside the drying chambers of SGD and DSD the samples that were subjected to a higher average temperature are those that show lower concentration of flavonoids, and vice versa.

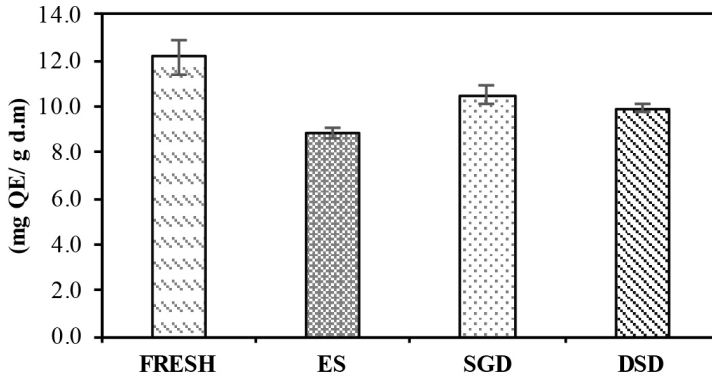

Fig. 5 Total flavonoids in the blackberry pulp, fresh and dehydrated by different technologies

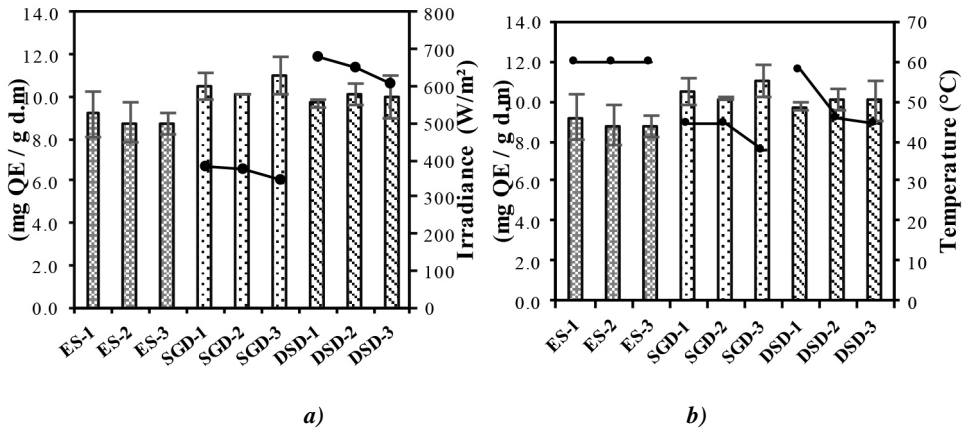

Fig. 6a Total flavonoids in blackberry pulp and its effect by irradiance; 6b total flavonoids in blackberry pulp and its effect by temperature.

#### 4. Conclusions

The samples dehydrated by ES showed an average drying time of 480 min with a final moisture content 0.26 kgw/kgdm. The samples dehydrated by solar technologies do not present significant differences between them, for SGD and DSD the average drying time was 960 min, with final moisture content 0.33 and 0.35 kgw/kgdm.. The antioxidant activity of dehydrated blackberry pulp by different technologies (SGD  $5.86 \pm 0.51$ , DSD  $5.80 \pm 0.39$  and  $5.28 \pm 0.32$  mg AAE / gdm) show a decrease of 70% compared to fresh samples ( $20.22 \pm 2.94$  mg AAE / gdm). The concentrations of total flavonides in fresh samples corresponding to  $12.17 \pm 0.79$  mg of QE / gdm, and the concentrations measured in the dehydrated samples (SGD  $10.53 \pm 0.46$ , DSD  $9.94 \pm 0.21$ ,  $8.89 \pm 0.24$  mg of QE /

gdm) represent a 20% decrease. In the comparison of solar technologies and electric stove, both solar technologies present a better conservation of flavonoid and antioxidant capacity. In the individual analysis of the tests a relation of temperature and irradiance in the final concentrations was observed, at higher temperature and irradiance, lower concentration of total flavonoides and lower antioxidant capacity, having a greater effect on the drying temperature, since the dehydrated samples in the stove at 60°C shows the lowest concentrations.

### Abstract

*Dried and sterile acellular esophageal matrix was obtained within a new drying process based on the use of supercritical carbon dioxide (SC-CO<sub>2</sub>). Experiments were performed coupling a conventional detergent enzymatic treatment with two different drying methods: (i) SC-CO<sub>2</sub> drying alone; (ii) dehydration in ethanol and a subsequent SC-CO<sub>2</sub> drying. Long term preservation was achieved for several months after drying, demonstrating the maintenance of extracellular matrix (ECM) structure, mechanical properties and biocompatibility within cell repopulation studies in vitro. Overall, the results highlighted the potential of this novel technology to obtain a dry and sterile acellular matrix that can be easily stored for oesophageal regeneration in patients with emergency need.*

**Keywords:** *decellularized tissue; supercritical drying; carbon dioxide; tissue engineering; long term storage*

## 1. Introduction

Congenital and acquired diseases may involve surgical esophagus substitution. In adult population, esophageal cancer is the eighth most common cancer in the world [1] while esophageal atresia is a congenital anomaly in children that occurs in 1/2500 to 1/4000 live births [2,3]. Esophageal tissue engineering is an emergent alternative for the development of esophageal substitute as repairing technology [4]. Several esophageal engineered substitutes have been explored using synthetic and natural derived scaffolds and materials [5], however, at present, tissue engineering applications to esophageal replacement are limited to enlargement plasties with absorbable non-cellular matrices [6]. Therefore the development and reinforcement of alternative approach are needed to improve the current state of the art. The use of natural matrices in tissue engineering has become extremely promising as tissue substitute for organ reconstruction. Natural acellular matrices are derived from animal or human organs/tissues within a decellularization process which is able to remove cells and immunogenic material [7]. The result is a natural derives scaffold that retains the architecture of the original tissue and also the molecular components of the native extracellular matrix (ECM). Organ decellularization for tissue engineering has become more and more promising for the organ/tissue replacement with preliminary promising clinical experience [8]. Organ decellularization can be successfully applied to esophagus, resulting in a scaffold that maintains ultrastructure and composition of the native extracellular matrix (ECM) [9]. In a clinical scenario, long term preservation and banking of sterile decellularized organs ready for transplantation would be desirable for patients with emergency needs. However, once produced, decellularized scaffolds can't be stored for long time because sterilization and preservation technologies are still lacking. Improvement of the current state of art could be obtained within supercritical carbon dioxide (SC-CO<sub>2</sub>) drying. SC-CO<sub>2</sub> drying has been already used in for the production of biomaterials such as 3D porous scaffolds [10] and hydrogel [11]. Within SC-CO<sub>2</sub> drying the vapor-liquid interface can be avoided with a minor capillary stress for the product that maintains the original structure. SC-CO<sub>2</sub> has a low critical temperature that doesn't degrade thermo sensitive components. SC-CO<sub>2</sub> has also bactericidal properties and it has been deeply investigated as alternative pasteurization and sterilization methods [12,13].

In this scenario the aim of this work is the development of a novel method for the sterilization and long maintenance of decellularized tissue using SC-CO<sub>2</sub> drying.

## 2. Materials and Methods

Porcine esophagus was chosen as test sample. Esophagi were collected from white domestic piglets (*Sus scrofa domesticus*) from 25 to 40 kg in weight. All surgical procedures and animal handling were carried out in accordance with UK Home Office guidelines under the Animals (Scientific Procedures) Act 1986 and the local ethics

committee. Esophageal decellularization was achieved by using a detergent enzymatic treatment (DET) as previously reported [9]. Two different experimental procedures have been explored for the drying: a single step SC-CO<sub>2</sub> drying at 35°C and 10 MPa up to 360 min, and a combined double step with ethanol (EtOH) for 80 min followed by SC-CO<sub>2</sub> drying (EtOH+SC-CO<sub>2</sub>) at 35°C and 10 MPa up to 90 min. A high pressure sapphire window cell (Separex S.A.S.) was used to carry out the experiments. The internal temperature and pressure were set with a thermostatic bath and an HPLC pump (Gilson 25SC). CO<sub>2</sub> (purity 99.990%, Messer) was flowed into the reactor at a constant flow rate of 23 ml/min until 10 MPa; then the pressure was maintained constant by tuning on a micrometric valve. The vessel was depressurized opening the valve at the end of the drying. Samples were packaged for long-term storage in sterile plastic bag at 4°C up to 6 months. Samples were weighted after the treatment assuming that all weight loss was due to the moisture removal from the ECM. Weight reduction was expressed as the ratio of %  $W_{end}/W_{start}$ , with  $W_{end}$  and  $W_{start}$  expressing respectively the weight of the sample after and before the treatment. Microbiological analysis were performed by means of the standard plate count techniques as previously reported [14] for mesophilic bacterial, mesophilic bacterial spores and yeasts and molds. The enumeration was referred to the weight of initial product and expressed in colony forming units CFU/g. The degree of inactivation was calculated considering the  $\log(N/N_0)$ , where  $N_0$  (CFU/g) and  $N$  (CFU/g) is the number of CFU per gram in the untreated and treated sample, respectively. Mechanical characterization was performed with tensile tests with a Midi 10 electromechanical testing machine (Messphysik Materials Testing) at a speed of 0.1 mm/s on regular rectangular peaces fixed at the loading frame. Before testing, the dried samples were rehydrated for 24 h in Phosphate Buffer Saline (PBS-Sigma). Histological analysis were performed on tissue's slice for Haematoxylin and Eosin (H&E), Masson's trichrome (MT) and Alcian blue (all from Bio-Optica). Cytochemistry analyses on tissue's slices were performed using Alexa Fluor 488 Phalloidin (Thermo Fisher) 1:200 and Hoechst (Sigma Aldrich) 10  $\mu$ M diluted in PBS with 0.1% Triton X-100 (Sigma Aldrich). Color and fluorescence images were obtained using a color camera mounted on fluorescence inverted microscope (Leica DMI4000). Human bone marrow mesenchymal stem cells (hBMMSCs) were provided by the Cell factory of Policlinico Hospital (Milan, IT) and they were used for scaffold repopulation *in vitro*. Cell repopulation experiments were performed up to 8 days of culture in customized microwell evaluating the cell adhesion and viability. Cultured samples were analyzed with Live/Dead viability/cytotoxicity kit for mammalian cells (Thermo Fisher) according to manufacturer's instructions

### 3. Results and Discussion

Two methods were investigated for the obtainment of a dried acellular esophagus. A successful dried matrix was reached in a shorter time using the combined ethanol and SC-

CO<sub>2</sub> treatment. The addition of EtOH as co-solvent during the process positively influenced the solubility of polar solvent in SC-CO<sub>2</sub> [15] and therefore reduced the time of drying. In Fig 1 is represented a cylindrical portion of decellularized esophagus before and after the supercritical drying, and after the rehydration in PBS.

**Fig. 1. Picture of cylindrical section of esophagus before (not dried) and after the supercritical drying and the subsequent rehydration in PBS.**

Certain shrinkage was observed after the rehydration; mechanical tests didn't show significant differences between the two processes (data not shown) and also a good maintenance of mechanical properties during time (data not shown). The preservation of the esophageal architecture was demonstrated with the presence of the three layers with histological analyses: mucosa, submucosa and muscular layers in all the analyzed samples for H&E (data not shown). MT staining pointed out the maintenance of the collagen in the *lamina propria*, *submucosa* and *intermuscular septa* of the *muscularis externa*. AB staining did not show a further decrease of glycosaminoglycan (GAG) after the drying (data not shown). The preservation of the architecture were obtained till 6 months for the H&E (Fig 2 Top) and confirmed with MT and AB (data not shown). Live and Dead analysis demonstrated good biocompatibility *in vitro* up to 8 days of culture for the samples dried with the combined process, meaning that SC-CO<sub>2</sub> alone was not able to remove some toxic component from decellularization (data not shown). Repopulation tests demonstrated the presence of live cells on the surface; the repopulation was possible also after 3 and 6 months of storage. Fig 2 (centre and bottom) shows the live and dead analysis at the surface for the total nuclei (Hoechst) in blue and for the dead cells in red (Ethidium). Cells shown high viability *in vitro* and therefore good biocompatibility even after 8 days of culture in the samples stored for 6 months. The initial load of natural flora population is shown in Table 1. A complete inactivation of the microorganisms was obtained after the EtOH-SC-CO<sub>2</sub> process, while SC-CO<sub>2</sub> drying alone was not able to inactivate completely mesophilic bacterial and spores (data not shown).

Fig. 2. H&E staining (Top), live and dead analysis for nuclei with Hoechst (centre) and with Ethidium (bottom) at different storage time.

Table 1. Initial microbiological load of the decellularized esophagus before the treatment

Microorganism	Log N <sub>0</sub> [CFU/g]
Mesophilic bacteria	8.22±0.89
Mesophilic spores.	0.57±0.12
Yeast and molds	8.27±0.66

#### 4. Conclusions

Overall the results highlighted the potential of this novel method to obtain a dry acellular matrix that can be stored for long term without substantial change of properties from the native tissue. SC-CO<sub>2</sub> drying represents a promising alternative for the long term maintenance of decellularized tissue.

#### 5. Acknowledgements

### Abstract

*Harnessing the benefits of rosemary polyphenols is limited by variability in their physicochemical properties. These limitations may be overcome by encapsulation in systems possessing hydro-lipophilic centers thereby accommodating molecules of different polarities. Proliposomes offer a viable option in this regard, being particles which form liposomal suspension in water. Lyophilized extracts of rosemary were encapsulated in hydrogenatedsoyphosphatidylcholine/cholesterol by solvent replacement method. Spray dried proliposomes were obtained with lactose as carrier. Using Central Composite Design, the effects of lipid, extract and carrier concentrations on response variables including bioactive content and retention, moisture content characteristics, recuperation and redispersibility were evaluated by statistical analysis.*

**Keywords:** Polyphenols; antioxidant; proliposomes; spray drying.

---

## 1. Introduction

Plant polyphenols have indeed proven to be very worthy antioxidants with evidence of protection of cell constituents against oxidative damage, therefore, limiting the risk of various degenerative diseases associated to oxidative stress.<sup>[1]</sup> This efficacy together with their safety profile, biocompatibility, multifunctionality, relative affordability and ready availability may have favoured their choice as additives in foods and nutraceuticals.<sup>[2]</sup> Research into polyphenol has garnered much momentum over the years.<sup>[3]</sup> One important vegetable source of these polyphenol compounds is *Rosmarinus officinalis* L. (Lamiaceae) commonly called rosemary. Extracts of rosemary have been evaluated for antioxidant and various other effects, and its efficacy correlated to high amounts of phenolic acids e.g. rosmarinic acid and caffeic acid; phenolic diterpenes being chiefly carnosic acid and carnosol; and flavonoids.<sup>[4]</sup> The performance of obtained extract is influenced by processing and environmental conditions to which it is exposed as well as its physicochemical properties.<sup>[5]</sup> Thus, employment of strategies that ensure incorporation of the multiple bioactive polyphenol components of these extracts for synergistic activity while desirable physicochemical properties are kept intact is evidently desirable. The aim of this study, therefore, is to use Design of Experiments (DoE) in evaluating the effects of composition factors critical to desirable response attributes and system performance during spray drying of proliposomes of rosemary polyphenols.

## 2. Materials and Methods

### 2.1 Preparation of rosemary extract

Polyphenol-rich powder extracts of rosemary was obtained by freeze drying. Concentrated liquid extract was congealed at -20 and -80 °C then lyophilized using VLP 195 FD-115, Thermo Fischer Scientific Lyophilizer at -40 °C. Dry rosemary powder particles obtained was collected in airtight amber bottles and stored at -20 °C.

### 2.2 Quantification of marker compounds in lyophilized extract by HPLC

Polyphenol markers, namely caffeic acid (CA), rosmarinic acid (RA), carnosol (CAR), and carnosic acid (CNA) in the powdered extract were quantified by HPLC. The chromatographic method used was previously developed and validated by our group.<sup>[6]</sup>

### 2.3 DoE for evaluation of effect of composition variables in proliposome formulations

Control parameters critical to physicochemical characteristics of proliposome powders were selected using Quality by Design (QbD) approach, with a focus on composition variables. Critical independent variables evaluated were concentration of lipid, extract and drying carrier (relative to liposomal solid content). The effects of these factors on quality attributes of proliposomes such as biomarker retention, biomarker content, water activity and moisture content were investigated. The individual and combined effects of these factors were evaluated at three levels using a completely randomized 2<sup>3</sup> Box-Wilson Central

Composite Design (CCD),<sup>[7]</sup> with three replicates in the central point. Tables 1 and 2 show the uncoded and coded variables studied, respectively.

**Table 1: Uncoded variables and their respective values**

Coded variable	Uncoded variables	-1	0	1
A	Lipid concentration (%)	4	7	10
B	Extract concentration (%)	1.5	3	4.5
C	Carrier concentration (%)	1	1.2	1.4
i.e. Carrier:(Lipid+extract)				

**Table 2: CCD for proliposomes of rosemary (coded variables)**

Formulation	Coded variables		
	A	B	C
F2	1.000	-1.000	-1.000
F9	-1.682	0.000	0.000
F4	1.000	1.000	-1.000
F3	-1.000	1.000	-1.000
F11	0.000	-1.682	0.000
F13	0.000	0.000	-1.682
F10	1.682	0.000	0.000
F16	0.000	0.000	0.000
F1	-1.000	-1.000	-1.000
F12	0.000	1.682	0.000
F15	0.000	0.000	0.000
F7	-1.000	1.000	1.000
F17	0.000	0.000	0.000
F5	-1.000	-1.000	1.000
F6	1.000	-1.000	1.000
F8	1.000	1.000	1.000
F14	0.000	0.000	1.682

The process model has the following form (Eq. 1):

$$Y_i = a_0 + a_1 \cdot X_1 + a_2 \cdot X_2 + a_3 \cdot X_3 + a_{11} \cdot X_1^2 + a_{22} \cdot X_2^2 + a_{33} \cdot X_3^2 + a_{12} \cdot X_1 \cdot X_2 + a_{13} \cdot X_1 \cdot X_3 + a_{23} \cdot X_2 \cdot X_3 + \varepsilon \quad (1)$$

where:  $a_0$  to  $a_{33}$  are the regression coefficients,  $X_1$  to  $X_3$  denotes the factors,  $Y_i$  is the relative average or expected response associated with the combination factors and  $\varepsilon$  represents the experimental error. Statistical significance of linear, quadratic and interaction effects of the investigated variables on evaluated proliposomes properties was assessed through variance analysis (ANOVA) and regression analysis using Statistica<sup>®</sup> 10 (StatSoft Inc, USA).

## **2.4 Preparing proliposomes of polyphenol-rich rosemary extract**

### *2.4.1 Incorporation of rosemary polyphenols*

Liposomal preparations incorporating polyphenols of rosemary were prepared by solvent replacement method.<sup>[8,9]</sup> The lipid phase comprised predetermined quantities (by DoE) of hydrogenated soy phosphatidyl choline (Phospolipon 90H - LIPOID GMBH, Ludwigshafen, Germany) and cholesterol (Sigma-Aldrich, St Louis, USA). The aqueous phase consists of a dispersion of lyophilized rosemary extract in purified water. The two phases were brought to the same temperature before the lipid phase was injected into the aqueous phase under agitation. Residual solvent was removed by rotary evaporation at 48 °C/600 mmHg. Liposomal formulation obtained was dried with lactose (Natural Pharma, SP, Brasil) as the drying carrier (quantity determined by CCD).

### *2.4.2 Spray drying*

Spray dried proliposomes (SDP) were generated from the liquid liposomal formulation (LLF) in a laboratory scale bench top SD-05 spray dryer (Lab-Plant UK Ltd, Huddersfield, UK) with a concurrent flow regime. Spray drying conditions were maintained as follows: atomizer, 1 mm; inlet drying gas temperature, 100 °C; feed flow rate of liquid formulation, 4 g/min; atomizing air pressure, 1.5 KgF/cm<sup>2</sup>; feed flow rate of atomizing air, 17 Lpm; and feed flow rate of spray drying air, 60 m<sup>3</sup>/h.

## **2.5 Proliposome characterization**

Proliposome powders were characterized as follows:

### *2.5.1 Water activity (Aw) and moisture content (Xp)*

Moisture content of the spray dried product was determined in a moisture analyzer Sartorius MA35 (Goettingen, Germany). Water activity was measured in an AquaLab 4TEV (Decagon Devices Inc., Pullman, WA) at 25 °C, using dew point sensor.

### *2.5.2 Retention and content of biomarker compounds in proliposomes*

Total retention and concentration of bioactive markers in proliposomes was evaluated by the HPLC quantification method described.<sup>[6]</sup> Retention was determined as % biomarker compound quantified in a sample of proliposome powder relative to amount in lyophilized extract contained in the proliposome sample. Total content of biomarker in bulk quantity was determined relative to proliposome powder (w/w). Concentrations were determined by comparison to those of standards.

## **3. Results and Discussion**

### **3.1 Proliposome characterization**

Experimental data of proliposome properties evaluated were subjected to regression analysis to detect the statistically significant effects of composition variables on proliposomes properties. In this way, the linear, quadratic and interaction regression

coefficients and their statistical significance were derived (Table 3). ANOVA and effect estimates assume normal and independent residuals distribution, with mean zero and constant variance.

### 3.1.1 Water activity ( $A_w$ ) and Moisture content ( $X_p$ )

Water activity ( $A_w$ ), a measure of the energy state of water present in a system, is a qualitative property independent of sample quantity. It is usually considered as indicative of microbiological stability with values less than 0.5 recommended as enough to guarantee product stability. Results showed that besides the interaction effects between lipid/extract concentration and extract/carrier concentration, only the quadratic effect of carrier concentration also had significant effect on water activity (Table 3). The negative value attributed to the effect may be that water activity is related to the form in which the lactose exists, among other factors. Lactose has been previously used in drying of lipid systems encapsulating polyphenols.<sup>[10]</sup> Lactose monohydrate has been shown to lose its water of hydration at 100 °C, the drying temperature in this study.<sup>[11]</sup> Thus, increasing the carrier concentration leads to a higher percentage bound-water loss and lower  $A_w$ . While  $X_p$  and  $A_w$  are mainly related to the drying conditions, formulation composition also plays an important role as drying could promote changes in water binding and dissociation, with effect product properties. On the other hand, carrier concentration showed no level of significance on  $X_p$  of SDP while lipid and extract concentrations became significant only at  $p \leq 0.1$ . Values of  $A_w$  and  $X_p$  were  $< 0.5$  and 5%, respectively, for SDP (data not shown). This suggests that proliposomes obtained are potentially stable to microbial proliferation.

### 3.1.2 Retention of selected biomarkers

Retention of RA and CAR in SDP showed significant dependence on similar factors. Linear effects of % extract was observed as highly significant ( $p \leq 0.01$ ) for retention of both compounds. However, while the effect on RA was positive, it was negative for CAR, implying that as the quantity of extract incorporated increases, retention of the former increases while that of the latter decreases. The degradation pattern of CAR in this system appears to be concentration dependent thus giving rise to decreased % retention on increasing concentration,<sup>[12]</sup> typical of first order degradation. Its higher lipophilicity also suggests favored partitioning into lipidic wall of the proliposomes rather than aqueous core.

Hence, higher extract/lipid ratio favourably retained hydrophilic compounds protected in the aqueous vesicle core against lipophilic components which are no longer efficiently encapsulated and therefore exposed to degradation at the vesicle periphery.<sup>[13]</sup> The linear effect of % lipid incorporated further demonstrates this relationship, although quasi significant ( $p \leq 0.10$ ) to both RA and CAR retention with respective negative and positive effects. It may be that the negative effect of % lipid on RA retention is related to solubility of the compound. Increasing lipid concentration is suggested to favor retention of lipophilic material such as CAR (positive value for same factor) as against less lipophilic ones such as RA. Evaluated lone factors ranged from being significant ( $p \leq 0.05$ ) to highly significant ( $p \leq 0.01$ ) for CNA retention. Lipid and carrier concentrations showed positive effects on

CAN, similar to CAR and in line with their lipophilicity. Increasing % extract, however, significantly ( $p < 0.05$ ) reduces relative retention of CAN. Since the degradation of CAR is concentration dependent, the reaction is skewed away from buildup of its concentration hence, further degradation of CNA. The significant ( $p < 0.05$ ) positive effect of carrier concentration on CNA retention may be due to protective effect offered by lactose molecules to prevent or slow down its degradation.<sup>[10,14]</sup> Evaluated factors showed no interactive effect on retention properties of bioactive compounds in SDP. In any case, the integrity of the bioactive compounds was largely preserved with proliposome products exhibiting 60.0% – 104.6 % retention. It is noted that these retention extremes is in accordance with the lipophilicity of each compound i.e. more lipophilic compounds such as CAR and CNA have the highest retention values at F11 with the highest lipid ratio whereas the less hydrophobic compound, RA is more concentrated at F9 with least lipid ratio, and vice versa (Table 4). Response surface plots (not shown) for visual effects of relationship between studied variables and biomarker retention response revealed that retention pattern of marker compounds at 0.0 (mean) level of Carrier/C<sub>Solid</sub> is similar to that at -1.682 (low), and 1.682 (high) levels. While RA retention is facilitated at high level of % extract, both CAR and CNA are favourably retained at high levels of % lipid.

**Table 3: Linear, quadratic and interaction regression coefficients and statistical significance for SDP**

### 3.1.3 Biomarker composition of proliposomes

Linear effects of lipid and extract concentrations were most significant ( $p \leq 0.001$ ) of factors evaluated. This being that the overall content of polyphenols components of proliposome product is directly proportional to the amount of extract incorporated and inversely to the lipid concentration and is consistent with results obtained for other extracts incorporated in lipid systems. Regression coefficients presented (Table 3) showed that whereas % extract has positive values for all compounds, those of % lipid are negative. R<sup>2</sup> values indicate the adequacy of adjustment of results obtained by the statistical model proposed. Carrier concentration was also highly significant ( $p \leq 0.01$ ) to concentrating all marker compounds in the proliposome. Lone effects of all factors evaluated showed

different levels of significance. Whereas interactions between % lipid and % extract, and % extract and carrier concentration showed quasi significance ( $p \leq 0.1$ ) on the total content of RA and CNA, the same level of significance was observed on CNA content following interaction between % lipid and carrier concentration. These results reveal that polyphenols accumulation is highly dependent on the % extract present and independent of the levels of concentration of carrier. Surface plots (not shown) show effects of the most significant variables (% extract and % lipid) remained visibly constant at all Carrier/ $C_{Solid}$  levels.

#### 4. Conclusions

Proliposome is a viable system for the retention of polyphenols of rosemary. Careful choice of carriers and their appropriate concentration may, however, be necessary towards obtaining these desirable properties. These many factors and possibilities underscore the importance of Design of Experiments, a systematic approach to determine the relationship between factors involved in a process and the effects of those factors on the output of that process. The Central Composite Design is demonstrated as an efficient approach in which the effects of several factors can be assessed within a workable number of experiments.

### **Abstract**

*Chayote (Sechium edule) is a fruit that is said to be a nutritional and have healing properties. 90% of its weight is made up of water which makes this fruit highly perishable. Convective drying is an excellent option to reduce the loss of this product as well as prolong its shelf life. Thus, the main objective of this work was to assess the physicochemical characteristics of different chayote samples (slices, cubes and strips) during its drying and rehydration process. Results suggest that cubes represent an alternative for commercial use as an additive in foodstuffs due to their size.*

**Keywords:** *chayote; convective drying; rehydration process; physiochemical properties.*

---

## 1. Introduction

The chayote (*Sechium edule*) is native to Mesoamerica where the greatest genetic diversity is found, however, it can also be found in other parts of the world. Mexico is one of the leading producers of this fruit which losses up to 25% of the harvest due to bad practices during the postharvest, particularly during the storage and refrigeration of the product as estimated by local producers. These bad practices lead to physical damages that generate darkening in the pericarp, formation of depressions, incomplete maturation, susceptibility to microbial attack, formation of shoots and weight loss [1].

Resarchers have studied methods for the preservation of the fruit due to its good nutritional and healing properties as well as for its accessibility to low-income groups [2] [3] [4] [5]. Chayote has a low content of lipids, proteins and calories, and is an important source of minerals, aminoacids and vitamins. At the same time, this fruit is highly perishable because about 95% of its fresh weight is water [6]. The reported properties of chayote include diuretic (leaves and seeds), as well as cardiovascular and anti-inflammatory properties (leaves and flesh). Also, the consumption of chayote was associated with the reduction of the retention of urine and burning when urinating when kidney stones are dissolved [7].

The drying process allows prolonging the shelf life of foods with high moisture content. Convective drying may particularly constitute a good option for the conservation of chayote due to the ease of the operation of convective driers as well as the relative simplicity in the handling of the samples to be treated. On the other hand, the analysis of the rehydration of dried food is necessary since it allows to evaluate indirectly the damage that occurred in the food due to the drying process. Moreover, it is fundamental to evaluate the physicochemical properties of rehydrated foods to ensure the conservation of their flavor and sensorial properties. To date, there are few studies where the physicochemical characteristics of the chayote during its drying and rehydration process are evaluated. On that basis, the aim of this work was to, determine the drying characteristics of samples of chayote cut in three different geometric shapes (cubes, slices and strips) dried in a convective dryer at temperature of 60°C; to study the drying process parameters on the physical and chemical properties of this fruit (water, moisture and color activity); and to study the rehydration process of the samples obtained in the drying process.

## 2. Materials and Methods

### 2.1 Selection and characterization of the raw material

Export-quality chayote samples (*Sechium edule* v. *virens levis*) from the city of Campo Grande located in the municipality of Ixtacxocuitlan, Veracruz were used in the present study. Chayote samples fruits were completely smooth and without spines. They weighted

between 200-300 g, had an average moisture content of 92.8% and water activity ( $a_w$ ) of 0.994, in average.

After the selection of the samples, they were washed and cut with a manual cutter in three different geometric shapes: slices (5 cm diameter and 0.5 cm thickness), cubes (1 cm length); and strips (7cm height, 1cm length and 0.5cm thickness).

## 2.2 Drying process

Tests were conducted in a pilot plant scale vertical tray dryer (MOD-SEM-2 Polinox, MX). Drying tests were carried out at a temperature of 60°C and the air velocity was imposed at 1.2 m/s. In each test, the drying kinetics were evaluated by recording the moisture content change as function of time. During the drying process, samples were taken to analyze the main physical-chemical parameters ( $a_w$ , moisture content and color) every 15 minutes during the first hour, 30 minutes in the following hour, and finally every 60 min until the water activity of samples reached 0.6. Tests were conducted in duplicate.

Drying kinetic data was adjusted to three common models employed in the drying process to model data: Page model, Newton model and Henderson-Pabis model (Table 1) where  $M_R$  corresponds to the adimensional moisture content and  $k$ ,  $k_1$ ,  $k_2$ ,  $k_3$ ,  $a$  and  $n$  are model paramters. For this purpose, the moisture moisture content ( $M_R$ ) was expressed as the moisture ratio ( $M_R$ ) by means of eq. (1):

$$M_R = \frac{X}{X_0} \quad (1)$$

Where  $X$  corresponds to the moisture content at any time in g water/g of dry solid and  $X_0$  is the initial moisture content in g water/g of dry solid. The goodness-of-fit of the data to the proposed models was evaluated by means of the  $R^2$  parameter.

### 2.2.1 Physicochemical characterization of the chayote

Water activity was determined using the AquaLab equipment (AquaLab Series 3 TE model, USA) in conditions of  $25 \pm 1^\circ\text{C}$ . Moisture content ( $X$ ) was determined by means of an Infrared moisture analyzer (Sartorius MA35, USA). In order to obtain more realistic moisture content values, the moisture analyzer was warmed up for 30 minutes prior the determination of the moisture content. After this, the samples used for the determination of  $X$  (1 g) were returned to the dryer chamber where they were previously taken.. The color was determined by using a MiniScan XE plus colorimeter (HunterLab, USA). The color measurement was carried out by placing the sample inside the equipment, thus, acquiring the color parameters corresponding to the luminosity:  $L^*$ , and chromaticity:  $a^*$  and  $b^*$ . The color data was captured in a computer integrated to the colorimeter and processed by a software application (Universal software 4.10, USA) to obtain the total difference of color ( $\Delta E$ ). Tests were conducted in duplicate.

### 2.3 Rehydration of convective dried chayote samples

The adsorption capacity of the samples was determined by weighing 0.5 g of the dried chayote samples on an electronic analytical balance (Santorius TE14S, USA). Then, the samples were submerged in 150 mL of water at 3 different temperatures: 20, 50 and 85 ° C, respectively. The samples were removed at different times (2, 4, 6, 10, 15, 20, 25, 30, 35, 40, 50 and 60 min). The final weight of the samples was recorded after removing the excess of water from the surface with absorbent paper. The rehydration ratio was calculated as the maximum amount of water absorbed (g) per g of dehydrated material for each experiment at the different times as proposed by Domaz [8]. Tests were conducted in duplicate.

## 3. Results and discussion

### 3.1 Air drying kinetics

During the drying process the moisture content of the samples was monitored at different times. The coefficients of drying models and the goodness of fit for chayote samples are given in Table 1. In general, the Page model sufficiently described the drying kinetics for strips and cubes (Fig. 1 and Table 1). All samples showed a slight loss of water at the beginning of the process but in the case of slices this slight loss was also observed at the gap of time between 120 and 180 min (Fig. 1). The best model fit for slices was observed with a polynomial model (Fig. 1).

*Table 1. Coefficients of convective drying models and goodness of fit for chayote samples*

Model	Equation	Sample	Parameter	R <sup>2</sup>
Newton	$M_R = \exp(-kt)$	Strips	k=0.0155	0.9476
		Cubes	k=0.0129	0.8257
		Slices	k=0.0083	0.6167
Henderson-Pabis	$M_R = a \cdot \exp(-k_2t)$	Strips	k <sub>2</sub> =0.0153; a=1.1810	0.9315
		Cubes	k <sub>2</sub> =0.0129; a=1.4783	0.8237
		Slices	k <sub>2</sub> =0.0097; a=1.4264	0.6128
Page	$M_R = (-k_3t^n)$	Strips	k <sub>3</sub> =0.0051; n=1.2	0.9521
		Cubes	k <sub>3</sub> =4.2868x10 <sup>-7</sup> ; n=2.9	0.9866
		Slices	k <sub>3</sub> =4.2868x10 <sup>-7</sup> ; n=2.9	0.9167

The drying kinetics for sliced samples of chayote previously reported showed a typical first-order kinetic shape. The structure of the seed of chayote is shown in Fig. 2. In general, the seed is composed by three structures: the endocarp, the endosperm, and the cotyledons and it differentiates from other seeds in that its moisture content remains high during maturity. Moreover, the seed remains intact within the fleshy fruit [9]. In the light of the structure of the seed, it seems that the shape of the drying kinetics of the chayote slices

determined in the present work corresponds to a first period into which water loss of flesh occurs and a second period corresponding to the subsequent drying of the seed. Akonor and Tortoe [10] worked with the drying of slices of chayote of thickness of  $4\pm 1$  mm. Eventhough they did not report neither the exact variety nor the state of maturity of the samples used in the tests a photograph included in their study suggests that the internal structure of the seed of the variety used in their study differs from the structure of the seed used in the present study. As for Huerta-Mora et al. [11], they worked with the drying of slices of chayote of thickness of 2 cm. This fact may diminish the wáter diffusivity of the wáter in the flesh of the fruit, thus, led to a drying kinetic of first order.

Fig. 1 Drying kinetics of chayote samples ( $T = 60^{\circ} C$ ). Circles correspond to sliced samples, squares to cubes and the diamonds to strips.

Fig. 2 Chayote slices.

There are few reports in the literature regarding the drying kinetics of cubes and strips of chayote. The calculated values for the coefficients of the Newton model (Table 1) for cubes and strips samples are three times greater in average than those calculated by Ruíz-López [5] for slices. These may indicate that the water loss is facilitated by the shape and the smaller volume of the samples submitted to a drying process which may also be reflected in the rehydration of the samples as it will be discussed below.

### *3.1.1 Color change of samples of chayote during the drying process*

The color change of the different samples of chayote was followed during the drying process. In general, results showed that in general samples after 240 min of drying are slightly darker, less greener and yellower than samples before drying.  $\Delta E$  determination revealed that the samples that registered less color change correspond to the ones cut into slices followed by cubes.

## **3.2 Rehydration process of different shapes of dried chayote samples**

The rehydration process of the samples of chayote is shown in Fig. 3. In general, the degree of rehydration increased in the first minutes and diminished with time in accordance with the reported previously [11]. The time in which the degree of rehydration began to stabilize corresponds to 20 min for strips, 30 min for slices and 25 min for cubes. The samples that showed a higher capacity of rehydration were the ones cut into cubes in contrast with the chayote slices which showed the lesser rehydration ratio among all samples. Also, higher rehydration ratios were observed when higher water temperatures were employed as reported by Kumar et al [12] for chayote samples (Fig. 3). In order to better explain the higher water gain in cubes, we performed an image analysis with the software ImageJ© to assess the differences of the samples' sizes before and after rehydration. We also calculated the surface area of the dehydrated samples. Tests revealed that the samples that showed the higher ratio surface area and volume corresponds to the cubes followed by the strips and slices. In fact, both, chayote strips and cubes showed a moderate deformation on its length and thickness and length after drying, respectively. However, the samples in cubes recovered its original shape more easily than strips possible due to less mechanical stress present in cubes compared to strips. Despite this fact, all samples presented good rehydration ratios (Fig. 3). Interestingly, Kumar et al [12] reported lesser rehydration ratios for chayote cubes with the same size of our samples ( $L = 1$  cm) compared with the ones found in the present work. According to Lewicki [13], pre-drying and drying may limit the water absorption of plant tissue and at the same time both procedures may intensify the leakage of solubles. Thus, the difference on the rehydration ratios of the samples observed by Kumar et al [12] and us may be due to the pre-drying treatment used by Kumar et al [12] which could led to the leakage of solubles of the samples.

Fig. 3. Rehydration ratios at 20, 50 and 85°C of chayote samples.

#### 4. Conclusions

The moisture content of chayote samples was reduced by more than 85% through convective drying at 60°C showing a slight color change at this temperature. Samples in slices showed a second water loss period unlike the other shapes studied which could be attributed to the presence of the seed in these tests. As for the rehydration process, after 60 minutes at three different temperatures (20, 50 and 85°C), the samples showed a rehydration capacity between 53-98% which confirmed that the internal structure of the samples did not suffer significant structural damage due to convective drying. Also, the rehydration capacity tend to increase as the temperature of the fluid increases as previously reported [12]. According to the results obtained, dried chayote may represent an alternative as complement of food products and, particularly, samples in cubes represent an alternative for commercial use as an additive in instant soups due to their size.

### Abstract

*The aim of this work is to study the effects of drying conditions on the quality of extracted prickly pear seed oil, specifically  $\alpha$ -tocopherol content. Drying experiments were carried on following a full  $2^3$  factorial design using a vertical drying tunnel. The temperature range was 45 to 70°C, relative humidity range was 15 - 30% and air velocity was 1 and 2 m/s. The Midilli-Kucuk model was found with satisfaction describing the seed air drying curves with a correlation coefficient of 0.999 and a standard error of 0.01. For each drying condition, the extraction of fixed oil seeds was performed at cold using mechanical pressing method. The oil quality was evaluated on the basis of the  $\alpha$ -tocopherol content. The  $\alpha$ -tocopherol was identified and quantified by high-performance liquid chromatography (HPLC-UV). According to the experimental results, it was found that convective drying of thin layer of seeds at soft air conditions, drying temperature of 45°C, relative humidity of 15% and air velocity of 1m/s give the optimal quality of extracted oil in terms of  $\alpha$ -tocopherol content.*

**Keywords:** prickly pear seeds; convective drying; semi-empirical modeling;  $\alpha$ -tocopherol seed oil; optimization.

## 1. Introduction

The constantly research of new essential oil sources should be performed in order to meet the new needs of industry. Prickly pear cactus (*Opuntia ficus-indica*) is extensively cultivated in Tunisia. The current production is estimated at more than 1 200 000 tons of fruits per year.

Seeds constitute about 10-15% of the edible pulp and are usually discarded as waste after extraction of the pulp. According to Stintzing et al.<sup>[1]</sup>, oil processed from the seeds constitutes 7-15% of whole seed weight and is characterized by a high degree of instauration wherein linoleic acid is the major fatty acid (56.1-77%). According to Hasani et al.<sup>[2]</sup>, the most active form of vitamin E in the oils seed is  $\alpha$ -tocopherol which is believed to protect the body against degenerative malfunction, particularly cancer and cardiovascular disease.

Fresh prickly pear seeds, by-products from prickly pear fruit processing, are highly perishable and their drying at equilibrium moisture content is recommended for the storage, standardization and the biochemical stability of the product before extraction<sup>[3]</sup>. According to the literature, convective drying affected the quantity and the quality of the extracted essential oil and volatile compounds from various medicinal and aromatic plants.

Therefore, this work aims (i) to investigate the effect of the hot-air convective drying conditions on the drying kinetics of a thin layer of prickly pear seeds, (ii) to select the best mathematical model predicting the drying curves (iii) to study, according to full 2<sup>3</sup> factorial design approach, the effect of convective drying air conditions on the quality of fixed oil extracted from seeds, on the basis of the  $\alpha$  tocopherol content, at temperature ranging from 45 to 70°C, relative humidity between 15 and 30% and air velocity of 1 and 2 m/s.

## 2. Materials and Methods

Fruit samples of the 'Ameclayae' variety in the ripe stage (Fig.1) were harvested in August from Knais, region of Sousse (Tunisia). They were taken to the laboratory the same day, where they were carefully selected and washed with tap water to remove glochids and impurities. Then the fruits were air-dried during few minutes and manually peeled. Seeds were separated by pressing the whole edible pulp and rinsing the residue, several times abundantly with distilled water.

A laboratory scale convective dryer (designed and constructed in the LETTM laboratory) was used for realising drying tests of thin-layer of seeds. For each experiment, a mass of 500  $\pm$  (1) g of fresh prickly pear seeds was distributed on a stainless perforated tray as a thin layer of about 0.5 cm thickness. The tray was suspended to a digital balance, the balance being placed outside the drying chamber. The dryer worked in closed loop and was equipped with an industrial programmable controller to adjust air temperature, air relative humidity and air velocity to a given set point. The mass of the product was continuously measured and recorded by a microcomputer until constant weight. At the end of each

drying test, the essential oil of the seeds was extracted and submitted to qualitative analyses. The dry mass of the product was determined by vacuum oven drying method at  $105 \pm 1^\circ\text{C}$  for 4 hours. The change in moisture of prickly pear seeds during drying was expressed as a moisture ratio MR defined by the expression of Eq. (1).

$$\text{MR} = \frac{X - X_{\text{eq}}}{X_o - X_{\text{eq}}} \quad (1)$$

where X,  $X_o$ , and  $X_{\text{eq}}$  are moisture content at any drying time, initial and equilibrium moisture content (kg water/kg dry matter), respectively. This last parameter  $X_{\text{eq}}$  was experimentally determined at different climatic conditions (desorption isotherms)<sup>[4]</sup>.

*Fig. 1 Prickly pear fruit of the 'Ameclayae' variety.*

The extraction of oil from dried seeds was performed at cold temperature using liquid/solid separation method. Before the extraction process, the dried seeds were reduced into a fine powder using electronic grinder, at a temperature around  $23^\circ\text{C}$ . This mechanical separation processing is the most recommended in agricultural industry for its low cost and it preserves nutrients. There are four tocopherols and four tocotrienols in the seeds oil.  $\alpha$ -tocopherol was chosen because it is the most active molecule and represents a good reagent against oxidation parameters. Besides, the  $\alpha$ -tocopherol plays a vital role in the human body as antioxidant to neutralize free radicals and protect the cell tissues. The  $\alpha$ -tocopherol was identified and quantified by using an analytical HPLC system Agilent Series 1100, equipped with a quaternary pump and a UV-visible detector (diode array detector). Identification of compound was achieved by comparing their retention time values with those of standard curve (concentration versus peak area).

### 3. Results and discussion

#### 3.1. Chromatograms of $\alpha$ -tocopherol in prickly pear oil

Typical chromatograms of  $\alpha$ -tocopherol in seeds oil corresponding to two different drying conditions are presented on Fig. 2.

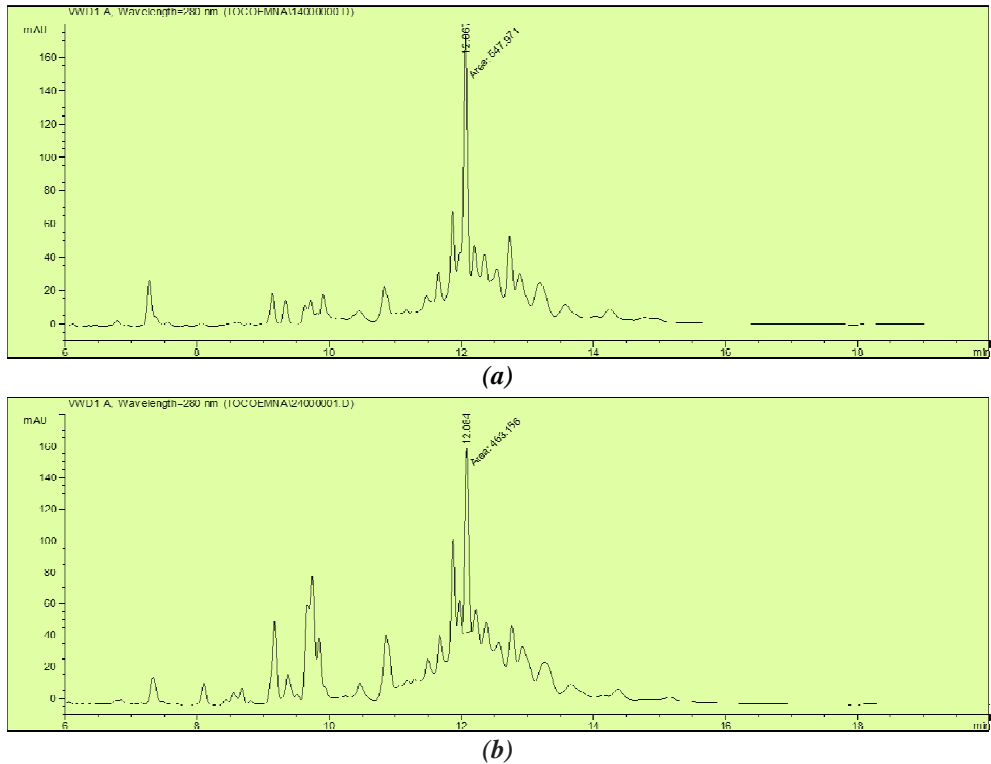

Fig. 2 Chromatograms of  $\alpha$ -tocopherol in prickly pear oil (a) at ( $T_a = 70^\circ\text{C}$ ,  $HR = 15\%$ ,  $u_a = 2\text{m/s}$ ) and (b) at ( $T_a = 45^\circ\text{C}$ ,  $HR = 15\%$ ,  $u_a = 2\text{m/s}$ )

### 3.2. Experimental drying curves

The drying kinetics curves of thin layer prickly pear seeds at different drying conditions are given on Figs. 3 and 4. As it can be observed, the constant rate-drying period do not appear clearly in drying curves which is similar with those reported in literature: orange seeds by Rosa et al.<sup>[5]</sup> and grapefruit seeds by Cantu-Lozano et al.<sup>[6]</sup>. The absence of a clearly constant rate period is due to the difficulty of the capillary migration of water from the wet heart to the rigid surfaces of prickly pear seeds. The heating up period is attributed to the warming of the seeds from the ambient temperature to the over temperature of 45 or 70°C, and shorter by 45°C drying temperature. Otherwise, the air temperature is the operating parameter which affect significantly the drying kinetics of thin layer of seeds as reported by several investigators, e.g. Tang and Sokhansang<sup>[7]</sup> for lentils and Desmorieux and Decaen<sup>[8]</sup> for *Spirulina*. Although, the drying process is controlled by the water internal diffusion inside the seeds, the less important effect of air velocity on the drying kinetics can be explained by the dependence of the convective exchange coefficients with the air velocity. This suggests that the moisture content depends on the effective diffusion and can be simply modelled by the Fick's second law and the semi-empirical models derived from it.

Fig. 3 Experimental prickly pear seeds moisture ratio versus drying time at different drying conditions

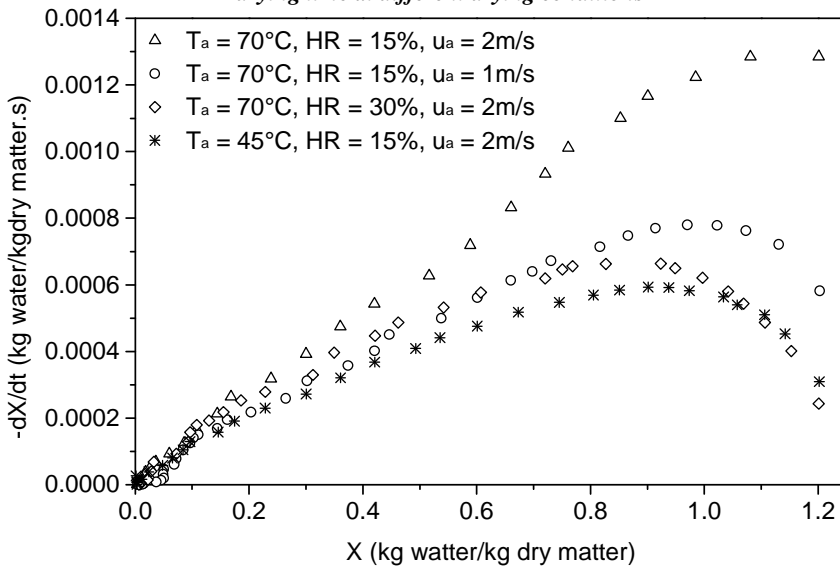

Fig. 4 Experimental drying rate versus moisture content at different drying conditions

### 3.3. Smoothing of the experimental drying curves

The experimental data obtained were fitted by eight semi-empirical models proposed in the literature (Newton, Modified Page, Henderson and Babis, Modified Henderson and Pabis, Two-Term, Logarithmic and Midilli-Kucuk). All the models gave high coefficient of determination ( $r$ ) values in the range 0.9697-0.9998 at 45 °C, 0.9615-0.9998 at 50 °C and

0.9474-0.998 at 70 °C. This indicates that all the models could satisfactorily describe the convective drying of the prickly pear seeds from 45 to 70°C. According to our results, the Midilli-Kucuk model obtained the highest *r* value of 0.9992, and the lowest (*s*) value of 0.0143, averaged over the range of the drying conditions. This selected Midilli-Kucuk model is expressed as:

$$MR = n_1 \exp(kt^{n_2}) + n_3 t \quad (2)$$

### 3.4. Effect of drying conditions on the extracted oil quality

According to our results, reported in Table 1,  $\alpha$ -tocopherol was found in variable concentrations (0.249-0.970 mg/kg). These values are arithmetic mean of at least three separate determinations. They are lower than those reported by Ramadan and Morsel<sup>[9]</sup> for prickly pear seed oils (56 mg/kg) obtained by solvent extraction and analyzed by HPLC technique. This difference in the  $\alpha$ -tocopherol concentration can be explained essentially by the fruit variety, the stage of fruit ripeness, the drying mode prior extraction and also the extraction process. Indeed, according to Tuberoso et al.<sup>[10]</sup>, tocopherol contents were significantly higher (*p* < 0.05) in oils obtained by solvent extraction than by pressing. Furthermore, the amount of  $\alpha$ -tocopherol in grape seeds oil was 124,5 mg/kg<sup>[11]</sup> and in Chia seed oil ranging from 0.4 to 9.9 mg/kg<sup>[12]</sup>.

**Table 1.**  $\alpha$ -tocopherol concentrations corresponding to 2<sup>3</sup> factorial design

Test number	T <sub>a</sub> (°C)	HR(%)	u <sub>a</sub> (m/s)	Y (mg/kg)
1	45	15	1	0.970
2	70	15	1	0.830
3	45	30	1	0.482
4	70	30	1	0.491
5	45	15	2	0.249
6	70	15	2	0.463
7	45	30	2	0.725
8	70	30	2	0.311

The effect of increasing the air velocity from 1 to 2 m/s, averaged over all levels of air temperature and air humidity, decreases the  $\alpha$ -tocopherol concentration from 0.693 to 0.437 mg/kg. Also, the effect of increasing the air humidity from 15 to 30% decreases the  $\alpha$ -tocopherol concentration from 0.628 to 0.502 mg/kg. Temperature is a factor of lesser

importance. Indeed, the effect of increasing air temperature from 45 to 70°C decreases the  $\alpha$ -tocopherol concentration from 0.606 to 0.523 mg/kg. That mean that  $\alpha$ -tocopherol molecule is more stable at heat treatments. Stability of  $\alpha$ -tocopherol is explained by the role of phenolic compounds that protect the  $\alpha$ -tocopherol from oxidation during the heating. Indeed, Ramadan and Morsel<sup>[9]</sup> reported that, the amount of phenolic compounds in prickly pear seeds was found to be 403 mg/kg of seeds. According to Rocha et al.<sup>[13]</sup>, drying temperatures is the most important parameter to preserve the active ingredients of volatile oil in gland cells, which are very sensitive to temperature increase. Likewise, Miranda et al.<sup>[14]</sup> observed an increase in tocopherol content with drying air temperature in quinoa seeds within temperature range of 40-80°C. Our results show that  $\alpha$ -tocopherol is more sensitive to increase velocity, which can be linked to oxygen, than to the temperature. These results are consistent with those found by Park et al.<sup>[15]</sup> who reported that more than 20%  $\alpha$ -tocopherol degradation were observed in conditions of 21% oxygen.

#### 4. Conclusions

- The experimental drying kinetics of a thin layer of prickly pear seeds exhibits a heating-up, constant rate and falling rate periods. The drying air temperature was the main factor influencing the drying kinetics.
- The Midilli-Kucuk model was the best for fitting the drying kinetics of prickly pear seeds.
- The relative humidity and the velocity of air were the factors that influence the prickly pear seed oil quality, qualified by  $\alpha$ -tocopherol contents after extraction. The convective drying of thin layer fresh seeds at air drying temperature of 45°C, air relative humidity of 15% and air velocity of 1m/s involves the highest quality of extracted oil in terms of  $\alpha$ -tocopherol compound concentration. This optimum scenario for best oil quality can be used in photochemical industries.

#### 5. Nomenclature

HR	Air relative humidity	(%)
MR	Moisture ratio	
T <sub>a</sub>	Air temperature	(°C)
u <sub>a</sub>	Air velocity (m/s)	(m.s <sup>-1</sup> )
X	Moisture content on dry basis	(kg.kg <sup>-1</sup> )
Y	$\alpha$ -tocopherol concentration	(mg.kg <sup>-1</sup> )

### **Abstract**

*Amorphous solid dispersions (ASDs) refers to drug - carrier systems, where the drug is dispersed in the carrier at a molecular level. In this work, ASDs were formulated by spray drying. The aim was to achieve high drug loads of an amorphous hydrophobic drug (Efavirenz - EFV) in the carrier Soluplus®. Solid state characterizations (mDSC, XRPD, DVS, Raman, SEM, stability and solubility studies) were done. EFV amorphisation in ASDs (20 to 85% EFV loads) resulted in improved drug solubility compared to unprocessed EFV crystals and tendency of properties evolution over time for ASDs with EFV loads higher than 70 wt%.*

**Keywords:** *amorphous solid dispersion, spray drying, high drug loading, soluplus, efavirenz.*

---

## 1. Introduction

Poorly water-soluble drugs have steadily grown on the global pharmaceutical industry. The technological approach focused on rendering the drug amorphous to improve apparent solubility remains a challenge since amorphous state is metastable in nature with a potential to undergo recrystallization [1]. In order to prevent this conversion, amorphous materials have been stabilized as solid dispersions using generally hydrophilic carriers for stabilization [2].

An amorphous solid dispersion (ASD) refers to drug-carrier systems in which the mechanism of drug dispersion is the key to understand its behavior. Such formulations impart an antiplasticizing effect on the amorphous compound yielding an increase in the glass transition temperature thereby reducing molecular mobility [3]. However, in order to achieve adequate stabilization, solid dispersions are often produced with a relatively low drug load (<30 wt%) dispersed in the carrier at molecular level. The problem is that a low drug-loaded ASD requires a large dose to ensure therapeutic efficacy.

The insertion of high drug load formulations on the market is expected to meet patients demand for fixed, unique and smaller dosage combinations products. Furthermore, the supersaturated combinations may reduce dosage amounts as well as decrease the production in the pharmaceutical industries to supply cost savings. The aim of the current work was to generate, by spray drying, ASDs comprising a hydrophobic drug class II BCS (low solubility, good permeability for oral administration) in a hydrophilic carrier (Soluplus®-SOL) expecting to achieve drug loads higher than 40% w/w in the binary mixtures. The physical stability will be the critical control point. The drug of choice is Efavirenz (EFV). EFV is a non-nucleoside reverse transcriptase inhibitor used in the first-line treatment of HIV with low solubility (3-9 µg/mL) and high permeability [4].

## 2. Materials and Methods

EFV was kindly supplied by Cristalia Ltd (Itapira, Brazil), SOL (polyvinyl caprolactam-polyvinyl acetate-polyethylene glycol) was obtained from BASF corporation (Ludwigshafen, Germany) and Ethanol (Carlo Erba, Italy) was used as organic solvent.

The feeding solution was prepared by dissolving EFV in a 10 wt% solution of Soluplus in ethanol. Binary mixtures EFV-SOL containing from 20 to 85 wt% of EFV were formulated as spray-dried powders. The individual constituents (drug and polymer) were also spray-dried from ethanol solutions and used for comparison purposes.

A Buchi B-290 minispray dryer (Buchi Labortechnik AG, Flawil, Switzerland) equipped with Inert Loop B-295 and an integrated two-fluid 0.7 mm nozzle was used to produce the ASD samples. Compressed nitrogen was used as the drying/carrying gas with a flow rate of 600 L/h. The solution feed rate was typically 3 g/min, the inlet temperature was set to 80±2 °C and the outlet temperature was maintained at 59±2 °C.

X-ray diffraction (XRD), modulated differential scanning calorimetry (mDSC), Raman spectroscopy, Scanning electron microscopy (SEM) and Infrared Spectroscopy (IR) were used to characterize the solid state of the spray-dried samples.

Water sorption isotherms were determined gravimetrically using an automated dynamic water sorption analyzer (DVS). Samples were subjected to 0–95 % relative humidity (RH) sorption-desorption cycle, over 10 % RH increments. For stability studies, samples were analyzed using DVS and exposed to stress conditions at 40 °C and 75 % RH during 15 days. Every 3 days, the samples were quickly analyzed by DSC to monitor changes in the physical state.

Solubility studies of unprocessed EFV crystals and ASDs were carried out in duplicate. For that purpose, an excess amount of samples was added into 30 mL of a dissolution medium containing purified water plus 0.25 wt% of sodium lauryl sulfate (SLS) under agitation at  $37 \pm 0.5$  °C in a water bath. The withdraws were collected from 5 min until 48 h.

### 3. Results and discussion

#### 3.1. X-ray diffraction (XRD)

The absence of Bragg peaks in X-ray diffractograms (Fig. 1) of all spray-dried solids indicates the complete loss of the crystalline structure of EFV, which becomes amorphous during the spray-drying process.

#### 3.2. Thermal analysis (mDSC)

Thermal analysis was performed to investigate the apparent EFV-Soluplus® miscibility. Fig. 2 shows the single experimental glass transition temperature ( $T^g$ ) identified for pure constituents and for each binary mixture EFV- SOL loaded with 40, 60 and 85 wt% EFV. The  $T^g$  of mixtures ( $T^g_{mix}$ ) are placed as an intermediary between the pure drug and polymer values and are close to the theoretical values of  $T^g$  calculated by Gordon-Taylor (GT) equation (Equation 1). This equation relates the individual contributions of each component in an ideal mixture (with no interactions between the components).

$$T^g_{mix} = \frac{W_{PA} \cdot T^g_{PA} + K \cdot (1 - W_{PA}) \cdot T^g_{PO}}{W_{PA} + K \cdot (1 - W_{PA})} \quad (1)$$

$T^g_{PA}$  and  $T^g_{PO}$  are the drug and polymer glass transition temperatures (K), respectively.  $W_{PA}$  is the drug mass fraction in the mixture. K is defined as fitting parameter characterizing the curvature of the evolution and is defined by equation 2 [5].

$$K = \frac{T^g_{PA} \cdot \rho_{PA}}{T^g_{PO} \cdot \rho_{PO}} \quad (2)$$

Densities ( $\text{g/cm}^3$ ), determined by helium picnometry,  $\rho_{PA}$  and  $\rho_{PO}$ , are 1.39 and 1.18, respectively.

According to XRD and DSC results, an amorphous solid dispersions of EFV- SOL seems to be formed during the spray-drying process.

Fig. 1 XRD diffractograms of: (1) pure EFV; (2) pure SOL; (3) 40 % EFV; (4) 60 % EFV and (5) 85 % EFV.

Fig. 2 Glass transition temperature ( $T_{mix}^g$ ): measured (blue circles) and theoretical values by GT equation (dotted red line).

### 3.3. Raman microscopy

Raman microscopy was also performed for three EFV-SOL ASD (Fig. 3). They were evaluated by observing the characteristic peaks of pure drug (peak at  $2250\text{ cm}^{-1}$ ) and pure polymer (peak at  $2900\text{ cm}^{-1}$ ). As expected, the increase of the drug load in the mixture corresponded to a more

intense characteristic EFV peak. The presence of characteristic peaks of pure components in all ASD Raman spectra shows the absence of specific interactions between the two components and confirms the ideal mixing suggested by the evolution of the mixtures  $T^g$  and SOL for all studied drug loads.

Fig. 3 Raman spectra for the EFV-SOL ASD with different drug loads: 40%; 60%; 85% EFV.

### 3.4. Scanning electron microscopy (SEM)

SEM images of the spray-dried powders are shown in Fig. 4. ASD EFV-SOL particles are predominantly spherical and different in shape from both original constituents that are the unprocessed EFV crystals (Fig. 4B - long rods with regular and organized multi-face geometry) and the spray-dried polymer (Fig. 4A - wrinkled particles). A good mixing between both compounds could lead to these apparently homogeneous solid particles.

### 3.5. Stability studies

Fig. 5 displays the DVS isotherm plots for the studied samples, showing the change in mass percentage as a function of changing relative humidity. The reversibility of the water uptake was clearly seen in all cases. Taking as example the curves at 75 % RH (Fig. 5B), the tendency of increasing the hydrophobic character of EFV-SOL ASD by increasing the EFV load is demonstrated. The decreased affinity to water with increased drug load could be an interesting attribute for the physical stability of the amorphous drug phase in high drug load ASDs.

Fig. 4 SEM images of spray-dried ASD constituted by a EFV-SOL binary mixture.

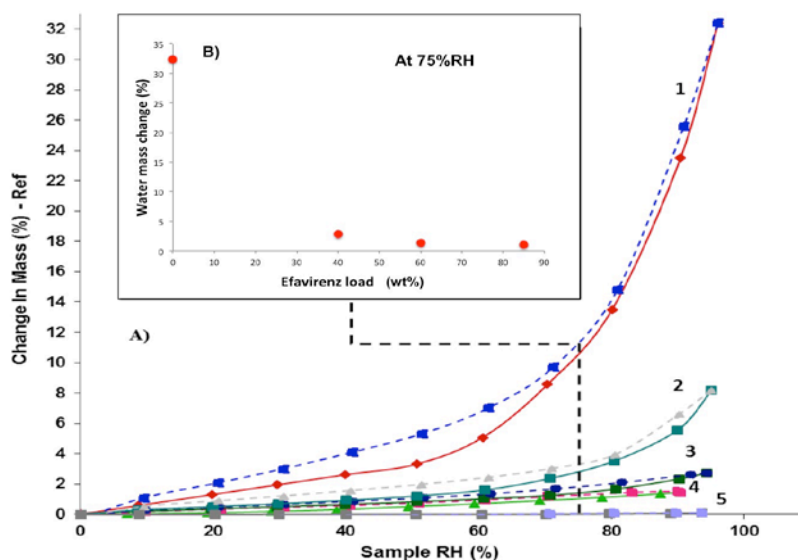

Fig. 5 A) DVS isotherms for 1- pure SOL; 2- 40% EFV; 3- 60% EFV; 4- 85% EFV; 5- pure EFV.  
B) Water mass change (%) at 75%RH for the ASD.

The stability results under stress conditions are presented in Table 1. It is noticeable that the samples have evolved over time since  $T_{mix}^g$  increases in both cases, suggesting a variation in the amorphous mixture composition. However, we did not observe any particular signs of

amorphous phase separation or drug recrystallisation for the sample loaded with 40 % EFV. Contrarily, 70 % EFV-SOL ASD revealed an evolution of crystallization enthalpy ( $\Delta H$ ) over time, corresponding to a partial EFV recrystallization. This tendency for recrystallization can be attributed to the high drug load of the ASD, probably corresponding to a supersaturated (and instable) amorphous state of the drug. Considering  $\Delta H=52.83$  J/g for the unprocessed EFV crystals, it was possible to estimate the percentage of drug recrystallizing in this ASD during storage. Table 1 also shows that, after 15 days of storage, approximately 6.6 % of the amorphous EFV dispersed in Soluplus recrystallized.

### 3.6. Solubility studies

In Figure 6, the results showed that spray-dried EFV- SOL ASDs produced with 20, 40 and 60 wt% EFV presented a good solubility enhancement in comparison with the unprocessed EFV crystals. EFV- SOL ASDs solubility decreases gradually with drug load increasing in the spray-dried powders. Indeed, EFV- SOL ASD with 20wt% EFV exhibited the maximum apparent EFV solubility over approximately 36h in simulated intestinal fluid.

*Table 1. Stability results under stress conditions (40 °C/75 % RH) for EFV-SOL ASD with drug loads of 40 % and 70 %*

t (days)	40 % EFV-SOL		70 % EFV-SOL	
	$T_{mix}^g$ (°C)	$T_{mix}^g$ (°C)	Crystallization enthalpy $\Delta H$ (J/g)	Crystallization (%)
3	59.8	51.4	1.3	2.4
6	64.9	53.4	2.6	4.9
9	64.1	55.9	2.8	5.3
15	67.2	57.7	3.5	6.6

## 4. Conclusions

A robust formulation with optimal drug load and excipients is one of the key factors of successfully developing an ASD system. In this work, amorphous solid dispersions of the poorly water soluble compound Efavirenz were prepared with drug loads in the range 20 to 85 wt% EFV, using Soluplus® as hydrophilic carrier and spray drying as the production process. Solubility tests revealed a good solubility enhancement for all ASD compared with crystalline drug solubility. To the best of our knowledge, it is the first study reporting such high levels of drug loading (up to 85 wt%) in supersaturated amorphous solid dispersions of

EFV. However, our results also showed that the physical stability should be a monitoring critical point for EFV-SOL ASDs with EFV loads higher than 70 wt% EFV.

*Fig. 6 Kinetic solubility of spray-dried EFV-SOL ASD.*

### **Abstract**

*Producing dried powders from blueberry pomace allows to reduce its environmental impact and gives value to this waste material. This work aims to evaluate the effect of particle size (fine or coarse) of blueberry pomace dried at 70 °C on its fibre content and main physicochemical properties, including antiradical capacity, total phenols and anthocyanins content, hydration and emulsifying properties. The effect of storage on antioxidant properties was also evaluated. Results showed a significant effect of particle size on fibre content and consequently, on water retention, holding and emulsifying capacity of the powder. Neither phenols nor anthocyanins were affected by particle size or storage time.*

**Keywords:** *blueberry pomace, powders, fibre, antioxidant properties.*

## 1. Introduction

Fruit and vegetables industrialization produces a huge amount of waste with negative impact on the environment and expensive management [1]. Most of this waste is used as animal feed or as fertilizers, both having low economic value. In an environmentally friendly way, it would be very interesting to use agro-food industry waste and by-products as a source of edible ingredients, thus increasing added value of the waste materials. Fruit powders have become an emerging way of consuming fruit and vegetables and it has attracted a growing interest in recent years [2], according to their broad applications in food formulation as colorant, flavoring ingredient or as natural preservatives. Fruit by-products also contain high amount of health-promoting compounds such as, fibre, proteins, vitamins and minerals [1]. Blueberries has anti-inflammatory properties and has been reported to prevent several diseases. This health benefits have been attributed to their content in various phenolic compounds such as anthocyanins and other flavonoids [3]. Due to the fruit seasonal availability and a recent increase in the production, industrialization of the blueberries into juice, dried fruit and powders has increased in the last years. Fiber and phenolic constituents have higher concentration in blueberry pomace, a by-product of juice processing, than in the fruit itself [1]; in addition, beneficial effects of these by-products on metabolomic alterations have been reported [4]. Fiber content of blueberry pomace may offer functional properties associated with water retention and emulsifying capacity. Among the processing methods that could be applied to established blueberry pomace, drying and further powdering could be a good way to increase the shelf life of the product [5]. The aim of this research was to evaluate physicochemical properties, including antioxidant properties and other technological properties, of a blueberry pomace powder obtained by air drying at 70 °C and grinding at two different intensities. Changes on antioxidant properties after 20 weeks of storage were also determined.

## 2. Materials and Methods

### 2.1. Blueberry pomace

Frozen blueberries (*V. corymbosum* var. *duke*) were supplied by Samanes S.L (Navarra, Spain) and processed as [7]. Separated blueberry pomace (P) was air dried at 70 °C (POL-EKO, Controltecnica, S.L., Madrid) until reaching a water activity below 0.3. Dried pomace (DP) was grinded at 10,000 rpm (Thermomix®, Vorwerk, Spain) for 10 s to obtain a coarse powder (CP) and for 2 min at 30 s intervals to obtain a fine powder (FP). Powders were stored in opaque glass jars under controlled relative humidity of 24% at 25±1 °C until analysis. Antioxidants stability of powders during 20 weeks of storage were evaluated.

### 2.2. Physicochemical properties

**Water activity** was measured with a dewpoint hygrometer (Aqualab 4TE; Decagon devices Inc., Pullman WA, USA). **Moisture** was obtained by method described by [7]. **Total soluble solids** content of samples ( $x_{ss}$ ) were determined by refractometry, measuring Brix degrees of a solution 1:10 (w/v), and transformed into  $x_{ss}$  as appropriate. **Specific volume** of powders was obtained by measuring the volume of a sample in a 10 mL test tube. All determinations were performed in triplicate.

**Particle size distribution** of the powders was determined by diffraction laser (Mastersizer 2000, Malvern Instruments, UK) with air as dispersant at 2.5 bar (dry method) or water (wet method); refraction indexes were 1.52 for the sample and 1.33 for the dispersed phase. Characterization was made in terms of D [4,3], D [3,2], and d<sub>10</sub>, d<sub>50</sub> and d<sub>90</sub>. Provided results are the average of five replicates. **CIEL\*a\*b\* coordinates, hue and chrome** were measured with a spectroradiometer (MINOLTA model CM-1000R). Values provided are the average of triplicates. **Fibre content**, Neutral Detergent Fibre (NDF), Acid Detergent Fibre (ADF), and Lignin Detergent Fibre (LDF) were obtained as [8]; these allowed obtaining the amount of hemicellulose (soluble fibre), cellulose, lignin (non-soluble fibre) and total fibre. Fiber determinations were performed in duplicate and results were given in percentage of dry basis (db).

An 80% methanol:water solution was used to extract the **antioxidant compounds** of the fresh pomace (1:20 w/v solution) and the dried powders (1:100 w/v solution). After 1 h of stirring, the mixture was centrifuged at 10,000 rpm for 5 min. Total phenol content of samples was obtained following the Folin-Ciocalteu method slightly modified [9]. Results were given in mg of Gallic Acid Equivalents (GAE) per 100 g of sample (db). Monomeric anthocyanin content was obtained by the pH differential spectrophotometric method as in [10]. Absorbance (Helios Zeta UV/Vis, Thermo scientific, UK) was measured at 510 nm and 700 nm at pH 1.0 and 4.5. In order to obtain the monomeric anthocyanin content equations (1) and (2) were applied, where: Abs<sub>510</sub> is the absorbance at 510 nm Abs<sub>700</sub> is the absorbance at 700 nm, Mw: molecular weight of glucosid-3-cyanidin (449.2 g/mol), f: dilution factor, ε: molar extinction coefficient (26,9 L/mol·cm). Results were given as mg of cyanidin-3-O-glucoside equivalents per 100 g of sample (db). The **antioxidant activity** (AA) was measured with DPPH and ABTS methods described in [9]. Presented results were expressed in mg of Equivalent Trolox (ET) per g of sample sample (db). All antioxidant determinations were performed in triplicate.

$$ABS = (Abs_{510} - Abs_{700})_{pH\ 1.0} - (Abs_{510} - Abs_{700})_{pH\ 4.5} \quad (1)$$

$$\text{Total monomeric anthocyanin} = \frac{ABS \cdot Mw \cdot f \cdot 1000}{\epsilon \cdot l} \quad (2)$$

**Hygroscopicity** was measured according as the water gained by the powders in a hermetic container with a saturated solution of Na<sub>2</sub>SO<sub>4</sub> (81% RH) during one week (g/100 g dry solids). Solubility was determined as the ratio of soluble solids:total solids. **Wettability** was determined as a result of the time in which 2 g of samples takes to get completely wet in water. The **swelling capacity** (SC) was obtained from the ratio between the volume of the sample after 18 h at 25 °C and the initial weight. Results are given in mL/g as the average and standard deviation of the replicates.

**Water holding capacity** (WHC) was obtained as the water contained in the hydrated residue per unit of dry matter. It was obtained by means of equation 3, where HR is the weight of the hydrated powder (~1 g of powder hydrated during 18 hours at 25 °C), and DR the weight of the freeze dried sample (DR). **Water retention capacity** (WRC) was obtained as follows: sample was weighed in a conical tube and hydrated with water during 18 h at 25 °C. Then,

the tube was centrifuged at 514 x g during 30 min and sample weighed (R+W). After, the residue was freeze dried and weighed (R). WRC was calculated as the ratio between the W and the R. Results correspond to the average of three replicates.

$$\text{WRC} = \frac{\text{HR-DR}}{\text{DR}} \quad (3)$$

**Oil holding capacity** (OHC, in g of oil per g of powder) was obtained following the method described by [11]. Powdered samples were mixed with sunflower oil and kept overnight at room temperature. Samples were then centrifuged at 1,500 x g during 5 min, the supernatant was discarded and weight of pellet obtained. Results are the average of three replicates.

**Emulsifying activity** (EA) was obtained as described by [12]. Samples were diluted in water (2% w/v) and mixed with sunflower oil in a vortex at 2,400 rpm for 5 min. Then, the mixture was centrifuged at 12,857 x g for 5 min and the emulsion volume was obtained according to equation 6, in which VEL refers to the volume of the emulsified layer (mL) and V to the total volume of fluid (mL). **Emulsion stability** (ES) was evaluated using the method described by [12]. The emulsion prepared to obtain EA, was heated up to 80 °C during 30 min. When tempered again at room temperature, it was centrifuged at 514 x g during 5 min. ES was obtained as equation 7, where V<sub>REL</sub> is the volume of the emulsion layer (mL) and V is the total volume of fluid (mL).

$$\% \text{EA} = \frac{\text{VEL}}{\text{V}} \cdot 100 \quad (6)$$

$$\% \text{ES} = \frac{\text{V}_{\text{REL}}}{\text{V}} \cdot 100 \quad (7)$$

### 3. Results and discussion

Water activity (*a<sub>w</sub>*), moisture content (*x<sub>w</sub>*) and total soluble solids (*x<sub>ss</sub>*) of fresh pomace (P), dried pomace (DP) and grinded dried pomace to a coarse powder (CP) or to a fine powder (FP) are shown in table 1.

**Table 1. Water activity, moisture (g<sub>w</sub>/g) and *x<sub>ss</sub>* (g<sub>soluble solids</sub>/g) of fresh and dried blueberry pomace. Mean ± standard deviation of three replicates.**

	<i>a<sub>w</sub></i>	<i>x<sub>w</sub></i>	<i>x<sub>ss</sub></i>
P	0.989±0.003 <sup>c</sup>	0.722±0.003 <sup>b</sup>	0.079±0.002 <sup>a</sup>
DP	0.189±0.004 <sup>a</sup>	0.0173±0.0015 <sup>a</sup>	0.28±0.011 <sup>b</sup>
CP	0.236±0.004 <sup>b</sup>	0.0170±0.0019 <sup>a</sup>	0.35±0.011 <sup>b</sup>
FP	0.20±0.06 <sup>a,b</sup>	0.019±0.0006 <sup>a</sup>	0.46±0.012 <sup>c</sup>

Values with different superscript letters in the same column are significantly different (p < 0.05).

As expected, dried pomace resulted in a much more stable and rich in soluble solids product than wet pomace. After grinding, both the water activity and the soluble solids content increased significantly, thus indicating that the reduction in the particle size promotes the water ability to conduct deterioration reactions and the solutes ability to dissolve. Indeed, the

finer the powder, the greater the breakdown of long polysaccharides chains and the release of shorter and more soluble ones. As a result, not only the soluble solids content of FP was higher than that of CP, but also the fiber content of FP was significantly lower than that of CP (table 2). It is worth noting that the fiber content of any of the powders is over 30% and that insoluble fiber represents around 68% of total fiber, since other properties such as the hydration and emulsifying properties of the powders will depend on them [13].

**Table 2. Content (%) of cellulose, hemicellulose, lignin, insoluble fibre and total fibre of coarse (CP) and fine (FP) powders. Mean  $\pm$  standard deviation of two replicates.**

	Cellulose	Hemicellulose	Lignin	Insoluble fiber	Total fiber

Values with different superscript letters in the same column are significantly different ( $p < 0.05$ ).

Grinding intensity of the powders, for the powder and for the powder in solution, the average size of particles in FP was significantly lower than that in CP (table 3). This will affect hydration related properties of the powders.

**Table 3. Results of D [4,3], D [3,2], and d<sub>10</sub>, d<sub>50</sub> and d<sub>90</sub> of particle size distribution of coarse (CP) and fine powder (FP). Mean  $\pm$  standard deviation of six replicates.**

Values with different superscript letters in the same row are significantly different ( $p < 0.05$ ).

Regardless of the particle size, solubility of blueberry pomace powders was quite low, but similar to that reported for asparagus fiber [14]. The high fiber content, especially of the insoluble type, would be the main cause of this. In the same way, hygroscopicity was of the order of that obtained by [15]. Among the properties here analyzed, only the specific volume, the wettability, the SC, the WHC and the ES were significantly affected by the particle size of the powder, with higher values in CP samples than in FP ones. This could be due to the higher porosity of the powders of bigger size particles and, consequently, to the higher amount of air retained in their structure [16]. As for wettability, the lower density of CP involved that this sample remained more time on the water surface, thus increasing the time to get completely wet. Although emulsifying properties are reported to be affected by the type, the size, the shape the superficial area and the chemical composition of different fiber particles [17], these took very similar values in the two powders analyzed. OHC, EA and ES of blueberry pomace powders were similar to that of peach, and apple fibers [18]. Color of powders (table 5) were affected by both the drying and the grinding steps. Drying significantly increased all the color coordinates, including chrome and hue. Grinding effect on color was only evident for FP, that resulted slightly less red and yellow than the CP. In any case, differences in the color of the samples were imperceptible to the human eye.

**Table 5. CIEL\*a\*b\* coordinate, chroma and hue of fresh pomace (P), dried pomace (DP), coarse (CP) and fine (FP) powder. Mean  $\pm$  standard deviation of two replicates.**

Values with different superscript letters in the same column are significantly different ( $p < 0.05$ ).

Antioxidant properties of different samples are shown in table 6. As it can be observed, total phenols content (TP) reached higher values in P and DP than in grinded samples. Within the powders, the higher values obtained for FP could be due to a greater extractability of such compounds as the particle size decreased [13]. As regards the monomeric anthocyanidins content (MA), their content decreased significantly after the drying step because they are sensitive to both temperature and oxidation [19]. Grinding only affected MA content of FP due to its higher surface/volume ratio and its subsequent higher exposure to oxygen. In agreement with these results, the antioxidant activity (AA) of blueberry pomace measured by both DPPH and ABTS methods was significantly reduced due to drying and further grinding.

**Table 6. TP content (mg GAE/100 g db), MA (mg glucosid-3-cyanidin/100 g db), AA with DPPH and ABTS methods (mg TE/g db). Mean  $\pm$  standard deviation of three replicates.**

	<b>TP</b>	<b>MA</b>	<b>AA- DPPH</b>	<b>AA- ABTS</b>
P	4.4 $\pm$ 0.2 <sup>c</sup>	74.5 $\pm$ 0.4 <sup>c</sup>	145.7 $\pm$ 0.6 <sup>c</sup>	87.3 $\pm$ 0.4 <sup>c</sup>

FP	3.36 $\pm$ 0.10 <sup>b</sup>	31 $\pm$ 4 <sup>a</sup>	83.8 $\pm$ 1.5 <sup>a</sup>	57 $\pm$ 2 <sup>a,b</sup>

Values with different superscript letters in the same column are significantly different ( $p < 0.05$ ).

Antioxidant properties of the powders were measured again after 20 weeks of storage under controlled conditions. Differences between initial and final values of all compounds are shown in table 7. In general terms, the antioxidant properties of the powders remained quite stable during storage, regardless of the powder particle size. Only the antioxidant activity of the coarse powder measured by DPPH was significantly lower after storage.

**Table 7. TP (mg GAE/100 g db), MA (mg glucosid-3-cyanidin/100 g db) content and AA with DPPH and ABTS methods (mg TE/g db) reduction after 20 weeks of storage. Mean  $\pm$  standard deviation of three replicates.**

	TP	MA	AA- DPPH	AA- ABTS

FP	0.35 $\pm$ 0.18 <sup>a</sup>	-4 $\pm$ 2 <sup>a</sup>	8.2 $\pm$ 1.1 <sup>a</sup>	0.1 $\pm$ 1.1 <sup>a</sup>

Values with different superscript letters in the same column are significantly different ( $p < 0.05$ ).

#### 4. Conclusions

Thermal treatment associated with drying reduces antiradical capability of blueberry pomace, mainly by reducing total phenol and anthocyanin content. Mechanical damage induced by grinding operation of dried pomace reduces total fiber content determining water and oil interaction properties. This effect results in a lower wettability, swelling capacity, water holding and water retention capacity of fine powder. Although emulsifying activity is not affected by particle size, the emulsion stability is significantly higher in coarse powder.

### **Abstract**

*This research developed an apple snack with potential probiotic effect ( $> 10^7$  CFU/g) by combining vacuum impregnation with *Lactobacillus salivarius* spp. *salivarius* (CECT 4063) and freeze-drying. Throughout storage (30 days), both the lactobacillus viability and the total flavonoids content decreased. Trehalose addition (10% by weight) to the impregnation liquid and/or its homogenization at 100 MPa accelerated the loss of cell viability but delayed flavonoids degradation and promoted an increase in the amount of phenols and total antioxidants.*

**Keywords:** *L. salivarius* spp. *salivarius*; homogenization; trehalose; freeze-drying; antioxidants.

## 1. Introduction

*Helicobacter pylori* is a pathogenic bacterium that causes severe gastric problems to a large part of the world's population, especially in less developed countries [1]. Traditional treatments based on antibiotics have side effects and are not 100% effective [2]. Recent studies show that some strains of the *Lactobacillus* genus are effective in the treatment against *Helicobacter pylori*, reducing the colonization of this pathogen, what has promoted the incorporation of *Lactobacillus* in the formulation of certain foods [3]. However, the survival of these microorganisms in food is rather limited, especially in not dairy products. Some food engineering techniques, such as the formulation with certain ingredients (e.g. probiotics) or the modification of the structures conferring protection to the microorganism (e.g. encapsulation) can be applied in order to alter probiotics functionality and/or increase their survival against adverse conditions. Specifically, in this study the effect of trehalose addition (10%, w/w) to the impregnation liquid and/or its homogenization at 100 MPa on *Lactobacillus salivarius* spp. *salivarius* (CECT 4063) survival during the manufacture and storage of a freeze-dried apple snack was evaluated. Given the high content in antioxidant compounds of the raw materials, also changes in this bioactive substances were analyzed.

## 2. Materials and Methods

### 2.1. Solid matrix

Apples (var. Granny Smith) cut into 5 mm thick rings (20 and 65 mm of internal and external diameter, respectively) were used as solid matrix for the snack preparation.

### 2.2. Impregnation liquids

The impregnation liquid was prepared from commercial clementine juice (Hacendado brand). Following the procedure described by Betoret et al. [4], yeast extract (5 g/L) and sodium bicarbonate (9,8 g/L) were added for the optimal microbial growth. When required, 100 g/kg of food grade trehalose (TREHA™, Cargill, Barcelona, Sapin) were also added to the juice formulation. Once all the ingredients were dissolved, the liquids were inoculated (10<sup>9</sup> CFU/L) with strain CECT 4063 of *Lactobacillus salivarius* spp. *salivarius* (Colección Española de Cultivos Tipo, Universitat de València, Burjassot, Spain) that had been previously grown on MRS Broth agar. After 24 h of incubation at 37 °C, part of the liquids were homogenized at 100 MPa on a laboratory scale high pressure homogenizer (Panda Plus 2000, GEA-Niro Soavi, Parma, Italy) before their use as impregnation liquids. Four different impregnation liquids were prepared in total (Table 1).

***Table 1. Different impregnation liquids employed in the present study.***

<b>Impregnation liquid</b>	<b>Trehalose (g/kg)</b>	<b>Pressure (MPa)</b>
0%_0MPa	0	0
0%_100MPa	0	100
10%_0MPa	100	0
10%_100MPa	100	100

### 2.3. Experimental procedure

This section describes the unit operations involved in the manufacture of apple snacks enriched with *Lactobacillus salivarius* spp. *salivarius* (CECT 4063).

First, vacuum impregnation was performed in a vacuum chamber (HERAEUS Vacuum Oven, THERMO SCIENTIFIC) connected to a vacuum pump (ILMVAC, Germany). A vacuum pressure of 50 mbar was applied for 10 min to the apple rings immersed in the corresponding liquid. Then, the atmospheric pressure was restored and maintained for another 10 min.

Vacuum impregnated apple rings were deep-frozen and kept at -40 °C for 24 h (Matek model CVN-40/105). Then, they were placed in a pilot scale freeze-drier (TELSTAR LIOALFA 6-80) at -45 °C and a vacuum pressure of 0.1 mbar for 24 h more.

In the end, freeze-dried apple slices were stored in hermetic and opaque bags and kept under controlled conditions of humidity and temperature for 30 days.

### 2.4. Analytical determinations

All the analytical determinations were carried out at least in triplicate on liquid and/or solid samples at different stages throughout the snack manufacture process.

#### 2.4.1. Water content and water activity

The apple samples moisture content was determined by drying a known amount of sample in a vacuum oven at 60 °C and 200 mbar until it reached a constant weight.

The water activity of apple samples was measured at 25 °C in a properly calibrated dew point hygrometer (Decagon Aqualab model CX-2, with an accuracy of  $\pm 0.003$ ).

#### 2.4.2. Antioxidant properties

Extracts from solid samples were obtained by mixing 2 g of fresh and impregnated apple or 0.35 g of freeze-dried apple with 10 mL of a 80:20 (v/v) methanol-water solution.

Total phenols content was measured at 760 nm in a Helios Zeta UV/Vis Thermo Scientific spectrophotometer by the Folin-Ciocalteu reagent method [5]. Results were expressed in milligrams of gallic acid equivalents per gram of sample (mg GAE/g).

Total flavonoids content was measured at 368 nm in a Helios Zeta UV/Vis Thermo Scientific spectrophotometer by the colorimetric method of aluminum chloride [6]. Results were expressed in milligrams of quercetin equivalents per gram of sample (mg QE/g).

Antioxidant activity was determined at 515 nm in a Helios Zeta UV/Vis Thermo Scientific spectrophotometer by the DPPH method [7]. Results were expressed in milligrams of trolox equivalents per gram of sample (mg TE/g).

### 2.4.3. Viable counts

The *Lactobacillus salivarius* spp. *salivarius* (CECT 4063) concentration was analyzed both in the growing medium, the impregnation liquids and the apple samples by the serial dilution and plating method. MRS seeded plates were incubated in anaerobiosis at 37 °C for 3 days. In the case of solid apple samples, the first dilution was carried out in a stomacher bag in which 5 g of sample were crushed with 45 mL of sterile peptone water.

## 2.5. Statistical analysis

The effect that the different variables considered exert on the obtained results was evaluated with the Statgraphics Centurion XVI program by simple analysis (simple ANOVA) with a 95% confidence level.

## 3. Results and discussion

### 3.1. Changes in *Lactobacillus salivarius* spp. *salivarius* (CECT 4063) content

As it is shown in Fig. 1, *Lactobacillus salivarius* spp. *salivarius* (CECT 4063) content in the impregnation liquid (VI liquid) increased significantly by adding 10% of trehalose by weight to its formulation or by its homogenization at 100 MPa. However, the combination of both factors did not notably improve the viable counts.

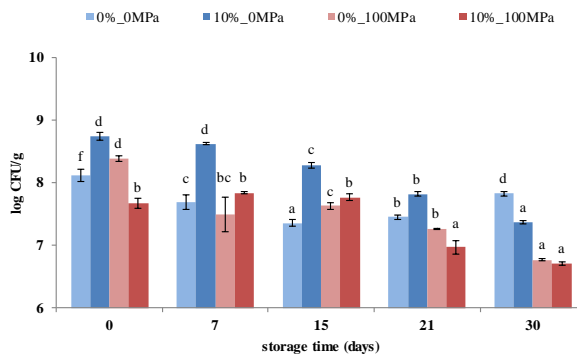

Similar trends were observed in vacuum impregnated apples (VI apple), whose microbial content was significantly lower than that of any of the impregnation liquids. This is logical considering that only 20% of fresh apple volume is filled with the impregnation liquid during the vacuum impregnation step [8].

Finally, freeze-dried apple samples (FD apple) potential probiotic effect was higher than that of vacuum impregnated ones, but not as high as expected from the decrease in their water content (from  $85.3 \pm 1.2\%$  in VI apple to  $4.97 \pm 1.02\%$  in FD apple). Regarding the composition of the impregnation liquid, the addition of trehalose to its composition slightly reduced the adverse effect of freeze-drying on the microbial population. On the contrary, the subsequent homogenization of trehalose enriched juice increased *L. salivarius* spp. *salivarius* vulnerability to the freeze-drying step.

**Fig. 1. Microbial counts in the impregnation liquids and both in vacuum impregnated (VI) and freeze-dried (FD) apple samples. Different letters within a single series indicate statistical significant differences at 95% confidence level.**

Throughout storage (Fig. 2), *L. salivarius* spp. *salivarius* (CECT 4063) content in freeze-dried apple samples suffered a notable decline, in spite of the low water activity reached by the snack ( $0.27 \pm 0.02$ ). This fact was particularly evident when trehalose and/or pressure were applied to the impregnating liquid, thus suggesting that the stress caused by the osmotic and/or the pressure gradient favored the loss of viability and the shortening of the snack self life. Just to mention that for a food to be considered probiotic it must contain at least  $10^7$  CFU/g when consumed [9]. Only snacks impregnated with liquids 0%\_0MPa and 10%\_0MPa met this condition at the end of the storage.

**Fig. 2. Changes in microbial counts throughout storage of freeze-dried apple snacks. Different letters within a single series indicate statistical significant differences at 95% confidence level.**

### 3.2. Changes in antioxidant properties

Despite the notable differences observed in their total phenols and flavonoids content, antioxidant capacity assessed by DPPH method both in the impregnation liquids and the vacuum impregnated apple samples were of the same order (Table 2). As expected, all the antioxidants increased their concentration significantly after the freeze-drying step. As for the composition of the vacuum impregnation liquid, neither the addition of trehalose nor the homogenization resulted in a final snack with improved antioxidant properties.

**Table 2. Antioxidant properties of the impregnation liquids and both the VI and FD apple samples.**

Food matrix	Impregnation liquid	total phenols (mg GAE/g)	total flavonoids (mg QE/g)	DPPH (mg TE/g)
VI liquid	0%_0MPa	0.78(0.07) <sup>a</sup>	1.01(0.07) <sup>c</sup>	0.70(0.04) <sup>a</sup>
	10%_0MPa	0.79(0.08) <sup>a</sup>	0.904(0.004) <sup>c</sup>	0.78(0.06) <sup>a</sup>
	0%_100 MPa	0.7235(0.0007) <sup>a</sup>	0.954(0.014) <sup>c</sup>	0.7(0.2) <sup>a</sup>
	10%_100 MPa	0.82(0.03) <sup>a</sup>	0.93(0.03) <sup>c</sup>	0.73(0.05) <sup>a</sup>
VI apple	0%_0MPa	0.441(0.015) <sup>a</sup>	0.291(0.002) <sup>b</sup>	0.89(0.12) <sup>a</sup>
	10%_0MPa	0.34(0.06) <sup>a</sup>	0.175(0.003) <sup>a</sup>	0.61(0.03) <sup>a</sup>
	0%_100 MPa	0.82(0.11) <sup>a</sup>	0.217(0.002) <sup>ab</sup>	0.92(0.07) <sup>a</sup>
	10%_100 MPa	0.64(0.03) <sup>a</sup>	0.132(0.002) <sup>a</sup>	0.77(0.04) <sup>a</sup>
FD apple	0%_0MPa	11.4(0.6) <sup>e</sup>	8.70(0.07) <sup>f</sup>	7.84(0.07) <sup>d</sup>
	10%_0MPa	3.025(0.012) <sup>b</sup>	1.186(0.012) <sup>d</sup>	5.5(0.2) <sup>c</sup>
	0%_100 MPa	6.0(0.3) <sup>d</sup>	2.01(0.14) <sup>e</sup>	5.0(0.3) <sup>c</sup>
	10%_100 MPa	4.8(0.4) <sup>c</sup>	1.19(0.02) <sup>d</sup>	2.3(0.8) <sup>b</sup>

Mean values and standard deviation in brackets. Different superscripts in the same column indicate statistical significant differences at 95% confidence level.

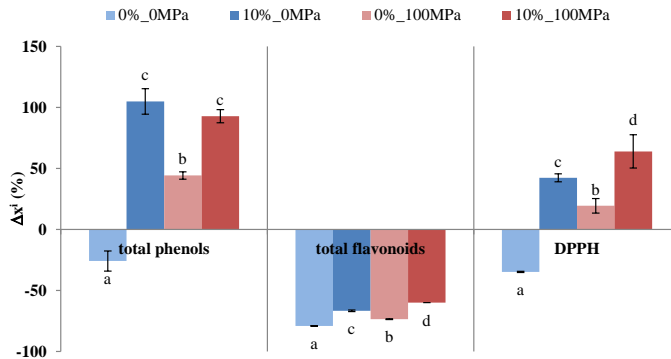

Regarding the stability of the antioxidant compounds throughout the snack storage, it is shown in Fig. 3 the change in each component concentration from the beginning to the end of the storage referred to the initial concentration ( $\Delta x^i$ ):

$$\Delta x^i(\%) = \frac{x_{t=0}^i - x_{t=30}^i}{x_{t=0}^i} \cdot 100 \quad (1)$$

where  $x_{t=0}^i$  and  $x_{t=30}^i$  indicate the component  $i$  concentration in freshly made and 30 days stored FD apples, respectively (g of component  $i$ /total g).

Generally speaking, the total phenols gain was significantly higher and the total flavonoids loss was significantly lower ( $p$ -value < 0.05) in apple snacks that were impregnated with any of the liquids that included trehalose in its composition, but especially in those impregnated with the liquid that was additionally homogenized (10%\_100MPa). As a result, these samples also showed a significantly higher increase in the total antioxidant content measured by the DPPH method.

**Fig. 3. Changes in antioxidant properties after 30 days of storage of freeze-dried apple snacks. Different letters within a single compound indicate statistical significant differences at 95% confidence level.**

Given the ability of trehalose to protect biological structures [10], apple tissue would have been less damaged during the freeze-drying step. As a result, antioxidant compounds would have been less accessible to adverse conditions that promote their degradation. Trehalose protective effect could be promoted by the reduction in the particle size that implies the application of a homogenization step [11], thus favouring the inflow of a greater amount of liquid (and trehalose) into the apple porous structure during the vacuum impregnation.

#### 4. Conclusions

Vacuum impregnation allows to incorporate lactobacillus into the apple porous structure to a greater or lesser extent, depending on the viable counts in the impregnation liquid. The subsequent freeze-drying increases apples stability without negatively affecting the microbial content or the antioxidants content. *Lactobacillus salivarius* spp. *salivarius* survival during the further storage was negatively affected by the addition of trehalose to the impregnation liquid and/or its homogenization. On the contrary, the addition of trehalose to the impregnation liquid and/or its homogenization delayed flavonoids degradation and promoted an increase in the amount of both phenols and total antioxidants.

### **Abstract**

*A spray dryer was modified and tested with superheated steam as the drying medium. The effect of the inlet temperature on the recovery and morphology of the dried powder was then investigated. The results were compared with those obtained from hot-air spray drying. The results showed that the use of superheated steam and an increase in the inlet temperature led to an increase in the product recovery. The morphological results correlated with those of the product recovery in that superheated steam powder exhibited more inflated skin, leading to less adhesion of the sprayed droplets to the dryer wall.*

**Keywords:** *morphology; product recovery; spray drying; superheated steam drying.*

---

## **1. Introduction**

Superheated steam drying is considered to be well established, with many ongoing studies showing that this drying process generally results in products with higher quality, either in terms of physical, chemical or organoleptic properties.<sup>[1,2]</sup> However, most superheated steam drying studies involved the use of solid samples although in reality many liquid materials also need to be dried. Only a few works are so far available on the use of superheated steam as the medium for drying liquid products, which require the use of, for example, a spray dryer.

The idea of superheated-steam spray drying has been verified mainly only via theoretical analysis or numerical modeling. Frydman et al.<sup>[3]</sup> and Ducept et al.<sup>[4]</sup> employed commercial software to simulate the most important features of both superheated steam and hot air spray dryers, including the fields of gas temperature and velocity inside the chamber, droplet trajectories and deposits on the chamber wall. The simulations were experimentally validated by comparing the experimental and simulated residence time distribution of water and KCl solution droplets in the study of Frydman et al.<sup>[3]</sup> and Ducept et al.<sup>[4]</sup>, respectively. However, these investigators did not make any attempt to investigate the characteristics of the resulting powder.

Among the limited attempts to study superheated steam spray drying, the works of Islam et al.<sup>[5,6,7]</sup> exist on the use of vacuum superheated steam spray drying to dry orange juice and orange juice with pulp with maltodextrin as the drying aid. Selected characteristics and properties of powder, i.e., moisture content, hygroscopicity, water activity, particle size, particle morphology, color, rehydration behavior and ascorbic acid retention, produced from the solutions of four different combinations of juice:maltodextrin were studied. Nevertheless, no attempt was made to compare the results with those obtained from a hot air spray dryer at equivalent conditions.

More recently, Lum et al.<sup>[8]</sup> studied the effect of superheated steam drying on the component migration during the formation of multicomponent droplets. The study was conducted by drying fresh milk droplets in the so-called single droplet drying apparatus; the results were then compared with those belonging to hot-air drying conducted in the same apparatus. The results revealed the possibility of controlling component relocation in a multicomponent droplet based on the improved hydrophilicity of the droplet surface as a result of the use of superheated steam, which is hydrophilic in nature, as the drying medium. By appreciating the potential of superheated steam as the medium for spray drying, engineered multicomponent particles with specific features can be produced.

Despite its potential benefits, no attempt has so far been made to experimentally investigate the effect of superheated steam as the drying medium in a typical (multiple-droplet) atmospheric-pressure spray dryer. No comparison also exists with the results belonging to

hot-air spray drying at equivalent conditions in terms of the dryer performance and the characteristics of the dried powder.

In the present study, modification was made to an atmospheric-pressure hot-air spray dryer, so it can be used for superheated steam spray drying. Preliminary study was then conducted to investigate the effect of inlet drying temperature on the product recovery; for simplicity, maltodextrin was used as the test material. Morphology of the powder was also observed to support and explain the measured product recovery. The results were compared with those obtained in the case of hot-air spray drying in the same dryer set-up at the same inlet temperatures.

## **2. Materials and Methods**

### **2.1. Materials**

An aqueous solution (30% w/v) of maltodextrin (DE 10), which was supplied by Chemipan Corporation Co., Ltd. (Thailand), was prepared by dissolving maltodextrin in distilled water and stirring using a magnetic stirrer at 300 rpm for 30 min.

### **2.2. Spray-dryer set-up**

A schematic diagram of the atmospheric-pressure superheated steam spray dryer setup is shown in Fig. 1. A water-tube boiler (Takuma, model TWA-500, Tokyo, Japan), which is able to generate a maximum saturated steam mass flow rate of 500 kg/h at a steam pressure of 7 bar (gauge), was used to supply steam to the system. To remove excess moisture from the steam, a steam pocket (1 inch in diameter), steam header (4 inches in diameter) and steam separator were used. Thermodynamic steam traps were used to drain excess water from the above three components. The steam pressure was adjusted via the use of a pressure reducing valve (Yoshitake, model GD-30, Tokyo, Japan), which was used to control the steam pressure at near-atmospheric pressure of 20 kPa (gauge). An electric heater rated at 9 kW, which was controlled by a proportional-integral-differential (PID) controller (Omron, model E5CN-RMTC-500, Tokyo, Japan) with an accuracy of  $\pm 1^\circ\text{C}$ , was used to convert saturated steam into superheated steam. A blower was used to deliver the saturated steam to the heater. The steam velocity was adjusted to 14-15 m/s by the use of two globe valves; the steam velocity was measured using a pitot tube (Testo, model 445, Lenzkirch, Germany) at point A with an accuracy of  $\pm 0.2$  m/s. The inlet steam temperature was varied at 160, 170 and 180° C. The inlet steam temperature as well as the outlet steam temperature were measured at points B and C, respectively, and were continuously recorded by type T thermocouples connected to a data logger (Yokogawa, model  $\mu\text{R}100$ , Tokyo, Japan).

The drying chamber consists of a stainless steel cylindrical chamber, which is 25 cm in diameter and 50 cm in height, connected to a bottom conical section of 30 cm in height.

**Fig. 1 Schematic diagram of atmospheric-pressure superheated steam spray dryer and associated units: (1) water-tube boiler; (2) globe valves; (3) steam pocket; (4) steam traps; (5) steam header; (6) pressure gauges; (7) steam separator; (8) pressure reducing valve; (9) ball valves; (10) blower; (11) air compressor; (12) liquid feed pump; (13) electrical heater; (14) spray drying chamber; (15) atomizer; (16) cyclone; (17) PID controllers; (18) thermocouples; (19) temperature data logger; (20) powder collector; (21) auxillary heater; (22) steam outlet; (23) cylindrical filter**

A two-fluid nozzle with an orifice internal diameter of 1.0 mm was installed at the top of the drying chamber. The nozzle pressure was maintained at around 2 bar (gauge) during all the spray drying experiments. A glass cyclone, which is 10 cm in diameter and 20 cm in height and has the bottom conical section of 30 cm in height, was used to separate dried powder from the exhaust steam. The dryer can also be operated as a hot-air spray dryer with the use of hot air, which can be supplied to the drying chamber via the use of the blower, as the drying medium.

Maltodextrin solution was fed into the drying chamber via a peristaltic pump (Watson-Marlow, Model 505S, Cornwall, UK) at a feed flow rate of 5 mL/min. The obtained powder sample was collected and sealed in an aluminum bag until further analysis.

Since the superheated steam spray drying experiments were conducted at atmospheric pressure, there was inevitable steam condensation in the powder collector. To prevent the condensation of steam within the powder collector, an auxillary heater was used to maintain the temperature within the powder collector at around 105°C; this value is higher than the saturation temperature of the exhaust steam. Moreover, a steam outlet was provided to drain out the exhaust steam. A cylindrical filter made of stainless steel screen of 500 openings per square inch was used to trap dried powder (see an inset in Fig. 1).

## 2.3. Analytical methods

### 2.3.1. Product recovery

The percentage product recovery was calculated by the following equation:

$$\frac{W_p}{W_f} \times 100\% \quad (1)$$

where  $W_p$  is the amount of solid mass of the collected powder (g) and  $W_F$  is the amount of solid mass of the liquid feed (g).

### 2.3.2. Scanning electron microscopy

The morphology of a spray-dried powder sample was observed via the use of a scanning electron microscope (JEOL, JSM-6400LV, Tokyo, Japan) at an accelerating voltage of 10 kV. Each sample was coated with a gold layer and photographed at 300× magnification level.

### 2.3.3. Statistical analysis

The effects of the type of the drying medium and inlet drying temperature as well as their interactions on the product recovery were determined by the univariate full-factorial analysis of variance (ANOVA). Each experiment was carried out in duplicate. All the experimental data were analyzed using SPSS 16.0 for Windows® (SPSS Inc., Chicago, IL) and are presented as mean values with standard deviations. Differences between mean values were established using Duncan's new multiple range tests at a confidence level of 95%.

## 3. Results and Discussion

### 3.1. Product recovery

The effects of the type of the drying medium and inlet temperature on the product recovery were investigated and are shown in Table 1. The type of the drying medium and inlet drying temperature had a significant effect on the product recovery ( $p < 0.05$ ). However, there were no interactions between the two parameters ( $p > 0.05$ ).

Use of superheated steam as the spray drying medium led to an increase in the product recovery when compared with the use of hot air. This is probably because superheated steam, which has higher heat transfer coefficient and specific heat capacity, could increase the gas-droplet heat transfer rate. The solid surface was more rapidly formed around a droplet during drying, leading subsequently to less adhesion of the sprayed droplets to the drying chamber wall.<sup>[9]</sup>

*Table 1. Effect of drying medium and inlet temperature on product recovery*

Drying medium	Inlet temperature		
	160° C	170° C	180° C
Superheated steam	38.0±2.82 <sup>b</sup>	45.0±1.41 <sup>a</sup>	48.5±2.12 <sup>a</sup>
Hot air	32.5±2.12 <sup>c</sup>	34.5±2.12 <sup>bc</sup>	37.0±2.82 <sup>b</sup>

Values with different superscripts are significantly different ( $p < 0.05$ ).

An increase in the inlet temperature led to an increase in the percentage product recovery. This is because an increase in the drying temperature led to a larger driving force for heat and mass transfer to/from the droplets during drying.<sup>[10]</sup> This in turn resulted in faster drying and more rapid solid surface formation, leading again to less adhesion of the sprayed droplets to the dryer wall.

### **3.2. Particle morphology**

Microstructural characteristics of the powder were investigated, so that the results can be used to support and explain the measured product recovery. Fig. 2 illustrates the effects of the type of the drying medium and inlet drying temperature on the morphology of the maltodextrin powder.

Superheated steam spray-dried maltodextrin powder exhibited overall morphology as larger spherical particles with inflated skin. This indicated that during superheated steam drying, water vaporization took place rapidly and the solid surface was rapidly formed. Besides, it was found that the process conducted at higher temperatures (170° C, 180° C) resulted in a combination of non-broken particles, fractured spheres and broken shells. Broken shells were due to excessive vaporization of water within the particles during superheated steam drying; such vaporization led to significant volume expansion due to rapid pressure build-up in superheated steam drying and as a result the broken structure if the generated vapor could not move out of the particles fast enough.<sup>[2]</sup> On the other hand, hot air spray-dried maltodextrin powder exhibited overall morphology as spherical particles with shrivel skin. This is probably due to the results of the slower water evaporation. The skin of the particles remained moist for a longer period of the time, so the particles deflated when vapor condensed within the vacuole as particles were moved into the cooler region of the dryer.

In both the cases of superheated steam and hot air drying, it was found that an increase in the inlet temperature led to a larger size of the dried particles. This is because an increase in the inlet temperature led to a larger driving force for drying to/form the droplets as mentioned earlier.<sup>[10]</sup> However, it was found that larger particles were obtained in the case of hot air drying than in the case of superheated steam drying at an inlet drying temperature of 160° C. This is probably due to the fact that the drying temperature of 160° C was below the so-called inversion temperature where the drying rate during superheated steam drying was lower than that during hot air drying, leading to the solid surface of particles drying hot air spray drying more rapidly formed than during superheated steam spray drying.

*Fig. 2 Morphology of maltodextrin powder dried by superheated steam at (A) 160°C, (B) 170°C and (C) 180°C; dried by hot air at (D) 160°C, (E) 170°C and (F) 180°C*

#### 4. Conclusions

Modification was made to an atmospheric-pressure hot air spray dryer to allow the use of superheated steam as the drying medium. Preliminary study was then conducted to investigate the effects of the type of the drying medium and inlet drying temperature on the powdery product recovery. Particle morphology was also evaluated. The use of superheated steam as the drying medium as well as an increase in the inlet temperature could improve the product recovery. The morphological results correlated with the results of the measured product recovery in that superheated steam spray-dried powder was noted as larger spherical

particles with inflated skin, leading subsequently to less adhesion of sprayed droplets to the dryer wall.

### Abstract

*The great amount of waste produced by the food industry can be an interesting source of bioactive compounds. To this end, convective drying is one of the most extended method to stabilize the industrial by-products. However, drying conditions can affect not only drying kinetics but also the bioactivity of some compounds. Apple skin constitutes one of the main by-product generated in apple juice or cider production. It contains important amounts of functional compounds such as polyphenols or vitamin C whose extraction can be interesting. The main aim of this work was to determine the influence of drying conditions, temperature and application of ultrasound, in some quality parameters of dried apple skin. For this purpose, apple skin samples were dried at different temperatures (-10, 30, 50 and 70 °C) and with (20.5 kW/m<sup>3</sup>) or without application of ultrasound. Color, total phenolic content, antioxidant activity and vitamin C was measured in fresh and dried samples. The increase of drying temperature and the ultrasound slightly reduced the antioxidant properties of samples while no influence in sample color was observed.*

**Keywords:** *by-product; antioxidant; polyphenol; vitamin C; color.*

---

## **1. Introduction**

The high volume of waste produced in the actual food industries has a great environmental impact. However, in many cases, the waste can be considered as a by-product that constitute a source of interesting bioactive compounds.[1]

Apple is one of the most popular fruits in the world being consumed such as fresh fruit, jam, baby food, juices or snacks. In this sense, apple skin constitutes one of the main by-products generated in the apple industrialization. Apple skin contains great amounts of compounds with high antioxidant capacity, even greater than those present in the flesh.[2, 3, 4] In fact, apple skin can be directly used as a functional ingredient of other food products. [5, 6]. To facilitate the storage and the manage, apple skin must be stabilized and for this purpose convective hot air drying is one of the most applied.[7] However, the temperatures and the long time of processing can damage flavor, nutritional composition or look of dried product.[2, 8]. In fact, the influence about drying process on antioxidant activity of apples and been previously studied not only in apple flesh [9, 10, 11] but also in apple skin.[2] Taking into account the final quality of the product, the drying processes at low temperatures emerges as an excellent alternative. However, the low drying rate at this contidions makes necessary the search of methos to intensify the process [22, 23]. In this sense, ultrasound application constitutes an efficient way to intensify mass transport which can shorten the processing time.[12] Moreover, the effects of ultrasound are mainly mechanical which dn't produce a significant heating of the samples.[13]

The main aim of this work was to assess the influence of the drying temperature and ultrasound application on the color and the antioxidant properties of apple skin.

## **2. Materials and Methods**

### **2.1. Sample preparation**

Apples (Royal Gala var.) of similar ripness state were choosen in a local market (Valencia, Spain). The fruits were washed with tap water and peeled using a household peeler. After that, the samples of apple skin were blanched for 30 s in boiling water in order to inactivate the enzyme polyphenol oxidase.[14] Initial moisture content was determined after maintaining apple samples in a vaccumm oven at 60 °C until constant weight [15].

### **2.2. Drying**

Experiemntal drying processes was carried out at atmospheric freeze-drying and at hot air drying conditions.

### 2.2.1. Atmospheric freeze-drying experiments

Apple skin samples were placed in a holder with regular distribution that assure the homogeneity of air flow and ultrasound treatment during drying process. After, the set was introduced in a blast freezer (HIBER, mod. ABB BF051, Italy) where samples were frozen at  $-35 \pm 1^\circ\text{C}$ . Later, the frozen samples were placed in an ultrasonically-assisted convective drier [22] where drying experiments were carried out at  $-10^\circ\text{C}$  and 2 m/s, without (AIR-10) and with (US-10; 50 W; 21.9 kHz) ultrasound application. Experiments ended when samples lost 85 % of initial weight.

### 2.2.2. Hot air drying experiments

Fresh apple skin samples were placed in a similar holder than the used for atmospheric-freeze drying experiments, and placed in a dryer assisted with ultrasound [16]. Drying experiments (2 m/s) were conducted at 30, 50 and  $70^\circ\text{C}$ , without (AIR30, AIR50 and AIR70) and with (US30, US50, US70; 50 W; 21.7 kHz). All the conditions tested were carried out by triplicate.

## 2.3. Quality parameters

### 2.3.1. Color

Apple skin sample color was assessed by measuring the CIELab parameters  $L^*$  (lightness/darkness),  $a^*$  (redness/greenness) and  $b^*$  (yellowness/blueness) with the help of a colorimeter CM-2500d (Konica Minolta, Japan). All readings were done in triplicate using a D65 illuminant reference system. Chroma was estimated from Eq. 1.

$$C^* = \sqrt{(a^{*2} + b^{*2})} \quad (1)$$

### 2.3.2. Antioxidant properties

An extract of dried apple skin was obtained for measuring antioxidant properties. For this purpose 3 g of sieved powder of apple peel were placed in 25 mL of an ethanol (96 % v/v). (3,5 g of apple's peel powder in 10 mL of ethanol (96 % v/v) in the case of ascorbic acid measurements). The mix was introduced in an ultrasonic cleaner bath (VMR mod. USC-T, USA) for 15 min. After that, the samples were filtered using nonsterile hydrophobic PTFE syringe filters of 4.5  $\mu\text{m}$  (VMR, USA).

### 2.3.3. Antioxidant capacity

Antioxidant Capacity (AC) of the apple skin was determined by the Ferric-Reducing Ability Power (FRAP) method, which was described by Benzie and Strain.[17] The results were expressed as mmol Trolox equivalent per g of dry mass of apple skin.

#### *2.3.4. Total Phenolic Content*

The Total Phenolic Content (TPC) of the apple's peel extracts was determined following the Folin-Ciocalteu method.[18] In this case, the results were expressed as mg of Gallic acid equivalent (GAE) per g of dry mass of apple skin.

#### *2.3.5. Ascorbic Acid content*

The Ascorbic Acid content (AA) was determined adapting the method proposed by Jagota y Dani [19], and expressed as mg of ascorbic acid content per g of dry mass of apple skin. Every measurements were done in triplicate.

The percentage of retention of the different antioxidant parameters was estimated (Eq. 2)

$$Retention = \frac{P_f}{P_0} \cdot 100$$

(Eq. 2)

where  $P_0$  is the value of the parameter obtained (AC, TPC and AA) from fresh apple skin and  $P_f$  from the different dried apple skin samples.

### **3. Results and Discussion**

#### **3.1. Color measurements**

The measurements of apple skin sample color showed that in the AIR experiments, samples dried at the greater drying temperature presented higher luminosity but lower redness and yellowness (Fig. 1). The results obtained at the lower temperature tested were the opposite, being samples less luminous, but with higher values of redness and yellowness attributes being these last characteristics more appreciated for the apple skin of the Royal Gala apple variety.

As for the ultrasound influence on the color, the parameters obtained in US-10 experiments were similar than the obtained at AIR50. The mechanical stress produced by ultrasound over the frozen samples during the long drying period may be the reason for this result. In the case of US30, US50 and US70, the relationship between color parameters and temperature was similar than for AIR experiments.

Regarding the chroma, in the case of AIR experiments, the highest value was obtained at the lowest drying temperature tested, decreasing its value with the increase temperature. (Fig. 1). In the case of US experiments, the US-10 experiments showed significant ( $p < 0.05$ ) lower chroma value than those found at AIR-10. However, at temperatures above freezing point, the application of ultrasound increased the chroma value. In fact, the value obtained in US30 experiments was not significantly different that the obtained in AIR-10, showing

that is possible to achieve the same saturation color in this condition that at atmospheric freeze-drying condition but in a shorter process time.

Figure 1. CIE LAB Color parameters and chroma of apple skin dried at different temperatures without or with (50 W) ultrasound application.

### 3.2. Antioxidant Capacity (AC)

The antioxidant capacity (AC) of the fresh apple peel was  $42 \pm 1$  mg Trolox/g d.m, being this value higher than those obtained for other authors in apple's flesh.[10, 11, 12] On the contrary, the retention of AC after drying was in the range.[10, 11, 12]

No significant difference was found about AC retention among the samples dried at different conditions except for AIR30 ones (Table. 1). In this conditions, samples showed a significant ( $p < 0.05$ ) higher percentage of AC retention. In general, the application of ultrasound didn't significantly affect the AC retention. Therefore, the use of ultrasound can be interesting to reduce drying temperature without significantly affect the AC retention.

### 3.3. Total Phenolic Compounds (TPC)

The TPC content of dried apple skins was  $16.6 \pm 0.9$  mg de GAE/ g d.m, being in the range found for fresh apple skin by Lata [20], and slightly lower than those found by Henriquez et al. [2]. As expected, the drying process reduced significantly the TPC (Table. 1). Above freezing point, the higher the temperature the lower the TPC retention showing the thermosensibility of TPC.[2] Regarding the atmospheric-freeze dried samples, TPC of AIR-10 samples was not significantly different than the TPC of AIR50 ones. The previous freezing of AIR-10 samples could contribute to the rupture of some cells increasing the phenolic compounds degradation. The long time spent in this type of drying process could also increase the TPC degradation.

The ultrasound application generated a slightly decrease of the TPC retention. The mechanical stress induced by ultrasound can be responsible of this slight degradation of phenolic compound being this effect more significant when other adverse effects such as high temperature or freein were less important. Santacatalina et al. [9] also found similar effects of ultrasound application in dried apple flesh.

### **3.4. Ascorbic Acid content**

The ascorbic acid (AA) content obtained of fresh apple peel was  $1.6\pm 0.2$  mg of ascorbic acid/g d.m. As was already expected, the drying produced a partial degradation of this propertie, being the percentage of retention in the range than those found by Moreno et al.[11] In AIR processes above freezing point, the lower the temperature the greater the percentage of AA retention (Table. 1). At  $-10^{\circ}\text{C}$ , the long dying time and the previous freezing of sample can explain the greater AA degradation. Therefore, regarding the antioxidant properties of dried apple skin, the atomospheric-freeze drying is not the more adequate drying method.

As for ultrasound application, no significant ( $p<0.05$ ) effect on AA retention was observed except when drying took place at  $70^{\circ}\text{C}$ . In this case, the retention in US70 experiment was significantly ( $p<0.05$ ) higher than AIR70 process, although these differences were small.

**Table 1. Percentage of retention of total phenolic content, antioxidant capacity and ascorbic acid of apple peel after been dried at different temperature with and without ultrasound application.**

Treatment	% retention		
	AC	TPC	AA
<b>AIR-10</b>	61.8	64.0	59.8
<b>AIR30</b>	78.9	84.9	88.7
<b>AIR50</b>	59.4	73.4	61.3
<b>AIR70</b>	62.0	59.0	55.0
<b>US-10</b>	60.5	61.1	60.8
<b>US30</b>	69.2	62.3	88.9
<b>US50</b>	58.9	66.3	58.9
<b>US70</b>	67.2	50.8	68.5

## **4. Conclusion**

Drying temperature and ultrasound application affected the apple skin quality. The results obtained showed that the atmospheric freeze-drying was not an interesting drying method for both the long processing time and the no-significant influence on quality attributes tested, color and antioxidant properties. General speaking, the influence of ultrasound application during drying on quality attributes was negligible. Then, it constitutes an interesting way to intensify drying process and could permit the reduction of drying

temperature, which can mean an energy needs reduction. However, this last fact must be deeply studied.

### Abstract

*A radio frequency (RF) vacuum technology is proposed for drying kiwifruit slices using a 27.12 MHz, 3 kW RF-vacuum drying system. The results demonstrated that electrode gap, vacuum pressure and sample thickness had major effects on the RF-vacuum drying. The RF-vacuum drying was associated with internal heating and rapid drying, resulting in 65% reduction of hot air (60°C) drying time. Moreover, kiwifruits dehydrated by RF-vacuum drying were associated with better color stability, higher vitamin C retention and higher rehydration capacity ( $P < 0.05$ ). Overall, the RF-vacuum drying process may provide a more effective and practical method for high-quality dehydration of kiwifruits.*

**Keywords:** *radio frequency-vacuum drying; hot air; moisture content distribution; moisture effective diffusivity; quality*

## 1. Introduction

Kiwifruit (*Actinidia deliciosa*) is recognized as “the king of fruits” due to its remarkably high amounts of vitamin C and bioactive compounds with antioxidant activity. The global production of kiwifruit was around 4.27 million metric tons (Mt) in 2016 mainly contributed by China (2.39 Mt), Italy (0.52 Mt), New Zealand (0.43 Mt) and Chile (0.23 Mt).<sup>[1]</sup> However, kiwifruit is a seasonal fruit being harvested during August-October in China. Owing to high moisture content, fresh kiwifruit is highly perishable after harvest, even under refrigerated storage conditions. Thus, developing a proper postharvest drying technique is an important consideration to overcome the problems of seasonality and extend kiwifruit shelf-life to protect farmers’ income and local economy.

The most conventional drying methods for kiwifruits, such as osmotic dehydration and hot air drying, have low technical barriers in developing/undeveloped countries and are preferred in industry, but with intensive labor cost, high energy consumption and long drying time.<sup>[2]</sup> Microwave (MW) and radio frequency (RF) drying methods also known as dielectric heating generate heat within the food material by molecular friction as a result of dipolar rotation and ionic conduction.<sup>[3, 4]</sup> RF heating has received increasing attention over the past decade due to its longer wavelength and deeper wave penetration as compared with MW and is thereby technologically more feasible for industrial applications.<sup>[5]</sup> Furthermore, the use of vacuum in RF heating, resulting in RF-vacuum drying, may further raise drying rate and ensure high quality in the final product because of the reduced drying temperatures as well as oxygen potential and considerably higher vapor pressure gradients between the interior and the surface of materials.

Therefore, the objectives of this study were (1) to determine the effect of RF process variables and sample thickness on the RF-vacuum drying characteristics of kiwifruit slices, (2) to study the drying kinetics and effective moisture diffusivity of hot air and RF-vacuum drying, and (3) to evaluate the quality of dried kiwifruit samples in terms of moisture content uniformity, color, vitamin C content and rehydration capacity.

## 2. Materials and Methods

### 2.1. Materials and RF-vacuum drying system

Freshly harvested kiwifruits (*Actinidia deliciosa* cultivar “Hayward”) observed visually for similar ripeness and size were obtained from Shaanxi, China. The fruits were then hand peeled and cut into slices with diameter  $45.5 \pm 5.4$  mm and three thicknesses:  $6.1 \pm 0.2$ ,  $8.0 \pm 0.2$  and  $10.0 \pm 0.3$  mm.

A 3 kW, 27.12 MHz free-running oscillator RF-vacuum drying system (GJ-3-27-JY, Jiyuan High Frequency Electric, Shijiazhuang, China) was used for RF-vacuum drying experiments (Fig. 1). The RF electrode gaps between the two parallel plates (400 mm × 400 mm) could be adjusted from 20 mm to 300 mm to deliver desired RF energy for specific applications. The system pressure (vacuum) in the RF chamber, and sample temperature and mass were continuously recorded by a pressure sensor (APC500, Sensor Way Technologies Inc., Beijing, China) located in the vacuum cavity, four-channel fiber-optic sensor system (HQ-FTS-D120, Heqi Technologies Inc., Xian, China), an electronic scale (AT8106, Pengheng Electronic Inc., Shanghai, China) with a precision of 0.1 g mounted underneath the bottom electrode, respectively, during the entire drying process.

*Fig. 1 Schematic view of the 3 kW, 27.12 MHz RF-vacuum drying system*

## 2.2 Moisture content determination and drying procedures

The moisture content of kiwifruit slices was determined following the AOAC Official Method 925.40 and expressed as g[water]/g[solid] through the drying process.

RF-vacuum drying: Twenty-four freshly prepared kiwifruit slices ( $523.4 \pm 18.0$  g) were placed uniformly in a single layer inside a container (400 mm  $L \times$  270 mm  $W \times$  20 mm  $H$ ) made of polypropylene (PP) with its side and bottom walls perforated with 10 mm diameter holes. Three electrode gaps (50, 60 and 70 mm) with three vacuum pressure levels (0.01, 0.02 and 0.03 MPa) and three sample thicknesses (6, 8 and 10 mm) were selected as process/product variables for determining RF-vacuum drying characteristics. The sample temperature and mass were continuously recorded by the fiber-optic temperature sensors and the electronic scale without having to turn off RF power or taking out samples. The RF-

vacuum drying process was continued until the moisture content of kiwifruit samples reached 0.18 kg/kg (d.b.)

### 2.3 Mathematical modeling of drying curves

The transient changes in moisture content of kiwifruit samples during drying was expressed as moisture ratio ( $MR$ ) defined as:

$$MR = \frac{M_i - M_e}{M_o - M_e} \quad (1)$$

where  $MR$  is the dimensionless moisture ratio,  $M_i$  or  $M_{i-1}$  (kg/kg, d.b.) is the moisture content at any time  $i$  or  $i-1$ ,  $\Delta t$  is the drying time interval between time  $i$  and  $i-1$  (min),  $M_o$  is the initial moisture content (kg/kg, d.b.) and  $M_e$  is the equilibrium moisture content (kg/kg, d.b.).

### 2.4 Evaluation of product quality

#### 2.4.1 Moisture content uniformity

Moisture content uniformity was moisture distribution among dried kiwifruit slices in the container. The moisture contents of kiwifruit slices located at 10 representative container locations were measured after drying.

#### 2.4.2 Color

The color ( $L^*$ ,  $a^*$ ,  $b^*$ ) of fresh (control) and dried kiwifruit slice samples was measured using a computer vision system. The total value of color difference ( $\Delta E$ ) was calculated as follows:

$$\Delta E = \sqrt{(L^* - L_o^*)^2 + (a^* - a_o^*)^2 + (b^* - b_o^*)^2} \quad (2)$$

#### 2.4.3 Vitamin C (ascorbic acid) content

Ascorbic acid content was determined by the standard 2,6-dichloroindophenol titration method.

#### 2.4.4 Rehydration capacity

Rehydration capacity of dried kiwifruit slices was measured according to the method of Maskan (2001) [6]

$$\text{Rehydration capacity} = \frac{W - W_o}{W_o} \times 100\% \quad (3)$$

where  $W_o$  and  $W$  are the sample weight values (g) before and after rehydration, respectively.

### 3. Results and Discussion

#### 3.1. RF-vacuum drying and heating characteristics

*Fig. 2 RF-vacuum drying characteristics of kiwifruits influenced by electrode gap (a), vacuum pressure (b) and sample thickness (c)*

The electrode gap, vacuum pressure and sample thickness had significant effects on RF-vacuum heating and drying characteristics of kiwifruit slices (Fig. 2). The RF-vacuum drying profile involved three stages regardless of various operating parameters: Stage I in which RF energy was transformed into thermal one within the materials and sample temperature rapidly increased. Once the moisture vapor pressure in the samples exceeded that of environment, the moisture expulsion process got and the drying rate gradually increased. Stage II began when the product temperature reached the highest value (wet bulb temperature), the drying process entered into a rapid drying period (constant drying rate period) and the sample temperature remained at a fairly constant level. As the drying progressed into Stage III, the loss of water in the samples reduced the associated dielectric properties, resulting in reduced

absorption of RF energy, and led to a gradually decreasing rate of drying toward the final stage of drying. Additionally, the thermal energy required for breaking away bound water is higher than that required for free water. Consequently, the RF-vacuum drying rate gradually decreased and the drying process was dominated by the falling drying rate period (Stage III). In general, the RF-vacuum drying process may limit the temperature raise in the samples and reduce severe thermal deterioration of product quality.

Fig. 3 shows a typical drying temperature-time profile at the core and sub-surface of kiwifruit slices subjected to RF-vacuum and hot air drying, indicating that the RF-vacuum dried materials were heated throughout the sample whereas surface higher temperatures were found in hot air drying.

Fig. 3 Typical temperature-time history for sub-surface (2 mm) and core (20 mm) of kiwifruit slices when subjected to hot air and RF-vacuum drying

### 3.2 Drying kinetics and moisture effective diffusivity

The curves for  $MR$  versus drying time with the best drying models under hot air and RF-vacuum drying are shown in Fig. 4. The Page model ( $R^2$  of 0.9998 and  $RMSE$  of 0.0056) was the best fit to describe hot air drying while the logarithmic model ( $R^2$  of 0.9977 and  $RMSE$  of 0.0145) provided the best fit for RF-vacuum drying. Generally, the drying time for kiwifruit slices was reduced by about 65% when using RF-vacuum drying technology as compared to hot air drying, highlighting the advantage associated with RF-vacuum drying technology.

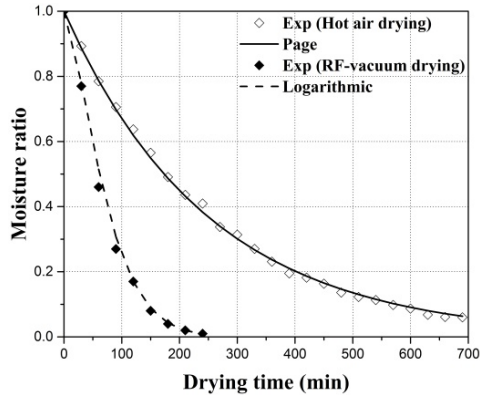

Fig. 4 Drying kinetics of kiwifruit slices when subjected to hot air and RF-vacuum drying

### 3.3 Quality of dried kiwifruit slices

Table 1 quality characteristics of kiwifruits before and after drying

	$L^*$	$a^*$	$b^*$	$\Delta E$	Vc content (mg/100 g)	RC (%)
Fresh	42.2±1.0a#	-8.9±0.1c	24.7±0.4a	-	115.3±6.5a	-
AD	29.7±3.9c	-0.8±0.8a	20.4±0.6c	15.5±1.4a	45.8±5.6c	115.8±4.5b
RF	36.4±2.2b	-5.4±0.4b	22.2±0.4b	7.1±0.8b	62.5±4.7b	148.4±6.8a

Table 1 summarizes the results for kiwifruit product quality after hot air and RF-vacuum drying. The total color change ( $\Delta E$ ) of RF-vacuum dried kiwifruits was significantly smaller ( $P < 0.05$ ) possibly due to the shorter drying time, lower temperatures and reduced oxygen concentration. The retention ratio of vitamin C was less than 60% or lower (54% and 40% for RF-vacuum and hot air dehydrated samples, respectively). Because vitamin C is oxygen and heat sensitive, and can be degraded through oxidation even under low oxygen conditions during drying. The rehydration capacity of RF-vacuum dried kiwifruits was significantly higher ( $P < 0.05$ ) than that in hot air dried samples. The positive vapor pressure pushed from within foods leads to the creation of a porous, loose and fragile texture for the RF dried kiwifruits and therefore results in better water absorption capacity.

Fig. 5 shows the measured moisture distribution in the samples spread over 10 different compartments after the RF-vacuum and hot air drying. For hot air drying, the sample moisture removal was in line with the direction of air flow and resulted in reduced moisture loss as the tray numbers increased from 1 to 10. But the moisture contents of RF-vacuum dehydrated samples were more random and uniform, thereby demonstrating relatively more uniform moisture distribution in kiwifruit slices with RF-vacuum drying.

Fig. 5 Moisture distribution of hot air (a) and RF-vacuum (b) dried kiwifruit samples at 10 compartments in the container with x-axis parallel to the hot air flow

#### 4. Conclusion

The RF-vacuum drying protocol of RF-vacuum of kiwifruits is electrode gap of 60 mm, vacuum pressure of 0.02 MPa and kiwifruit slice thickness of 8 mm, reducing more than 65% drying time as compared to AD. Further, the RF-vacuum drying process ensured better quality retention in the dehydrated kiwifruit slices in terms of color, vitamin C content and rehydration capacity due to fast heating/drying rates and low vacuum pressure. Better uniform moisture distribution was achieved when subjected to the RF-vacuum drying than possible with hot air drying. Overall, RF-vacuum drying technology may provide a more effective and practical dehydration method for kiwifruits with acceptable quality attributes.

### **Abstract**

*In this study, we aimed to investigate chemical and technological characteristics of oven-dried Jerusalem artichoke powder (JAP) to be further incorporated into emulsified chicken meatballs (with/without sodium carbonate) as sodium tripolyphosphate (STPP) replacers. The dietary fiber content of JAP was quite high to improve the health profile of the meat system. JAP samples showed equivalent technological quality to industrial inulin in terms of water-holding, oil-binding, emulsification and gelling abilities. Phosphate-free meatballs formulated with JAP and sodium carbonate had better health impacts compared with phosphate containing meatballs while cooking characteristics were similar. The results showed that oven-dried JAP presented a good health profile and high technological quality to be evaluated as inorganic phosphate replacers in formulation of emulsified poultry products.*

**Keywords:** *Jerusalem artichoke, oven-drying, emulsified chicken meatball, sodium tripolyphosphate, phosphate-free*

---

## **1. Introduction**

Jerusalem artichoke (*Helianthus tuberosus* L.) is a natural raw material which highly contains fiber, minerals and vitamins. The tubers are known to be a health-promoting food source that contains inulin, a soluble dietary fiber, instead of starch as a carbohydrate reserve [1, 2]. Today utilization of natural ingredients in the formulation of meat products as phosphate replacers has come into prominence as a novel topic due to health concerns about chemical additives. Phosphates have a common use to improve quality of various meat products by shifting the pH away from isoelectric point, thereby increasing protein functionality and water-holding capacity and enhancing overall quality attributes, however, due to the emerging and newly identified health risks associated with phosphates, there has been a tendency to decrease the amount of their levels in meat product formulations [3-5]. Therefore, Jerusalem artichoke is a promising ingredient that could be used as an economic source of functional components in phosphate-free meat product formulations. In this study, we aimed to investigate chemical and technological characteristics of oven-dried Jerusalem artichoke powder (JAP) to be further incorporated into emulsified chicken meatballs (with/without sodium carbonate) as a clean-label sodium triphosphate (STPP) replacer.

## **2. Materials and Methods**

### **2.1. Production of Jerusalem artichoke powder (JAP) and emulsified chicken meatballs**

Jerusalem artichoke powder (JAP) was produced from fresh and non-damaged tubers. The tubers were obtained from a local producer in Izmir region, washed with tap water, peeled and immediately immersed in citric acid (1%) solution to avoid enzymatic color changes. The tubers were then sliced into 0.2 mm thickness (Berkel Slicers, Italy). Slices were then air-dried in an industrial drying oven (Defne Spices Co., Izmir) at  $60\pm 5^{\circ}\text{C}$  for 8 h. The dried slices were finally ground through a hammer mill (Brook Crompton, UK) and sieved through 0.5 mm. JAP was stored in glass jars prior to meatball production.

Chicken meatballs were formulated either with STPP (control) or JAP and/or sodium carbonate (SC) as STPP replacers. 70% of the chicken breast muscle was minced through 8 mm plate. The rest of the breast muscles (30%) and chicken skin were minced through 3 mm plate and then emulsified with NaCl, STPP, rosemary extract and ice at 4400 rpm for 5 min (control) in a bowl cutter (K+G Wetter, Germany). Other treatments were prepared using 3.8%, 5.7% or 7.6% JAP, with or without 0.2% SC as STPP replacers. After the emulsification procedure, the emulsions were mixed with 8 mm minced breast muscle and the doughs were cold-set at  $0^{\circ}\text{C}$  for 1 h. After that, the doughs were portioned with molds

and cold-set again at  $-18^{\circ}\text{C}$  for 20 min. Meatballs were then deep-fat fried with canola oil in an electric fryer (Inoksan, Turkey) at  $180\pm 2^{\circ}\text{C}$  for 3 min. The samples were cooled at  $4^{\circ}\text{C}$  prior to analysis.

## 1.2. Methods

### 1.2.1. Characteristics of JAP

Proximate analysis was performed in order to determine total moisture [6], lipid [6], ash [6] and protein [7] content. The water-soluble dietary fiber content of JAP samples was analyzed by Megazyme dietary fiber assay kit (Megazyme International Ireland Ltd., Wicklow, Ireland) according to AOAC [8]. Sucrose, D-glucose and D-fructose concentrations in JAP samples were determined by enzymatic assay (Boehringer Mannheim, R-Biopharm, Germany). In order to evaluate technological quality of JAP samples; water-holding capacity (WHC) [9], oil-binding capacity (OBC) [10], emulsifying capacity (EC) [11] and volumetric gel index (VGI) [12] were analyzed.

### 1.2.2. Characteristics of emulsified chicken meatballs

The dietary fiber content of meatball samples was calculated from the dietary fiber content and incorporation amount of JAP in meatball formulations. The salt content of the samples was determined according to Mohr method [6]. Cook yield (CY) of the samples were calculated from the weight of pre-cooked and cooked samples according to Murphy et al. [13]. Data was statistically analysed by SPSS software with one-way ANOVA and Duncan Post-hoc tests.

## 3. Results and Discussions

### 3.1. Characteristics of JAP

The initial moisture content of fresh Jerusalem artichoke tubers was 82.9%, while the final moisture content of JAP was 5.31%, which indicated that approximately 93% of the water in the raw material could be removed by drying operation. Some images from dried samples could be seen in Fig. 1. Sucrose, D-glucose and D-fructose content of JAP samples were 18.11 g/100 g, 2.6 g/100 g, and 5.8 g/100 g, respectively. Other than that, JAP samples had 11.96% protein, 5.81% ash, and 2.09% lipid. Similar results were previously reported by Praznik et al. [14]. The dietary fiber content of JAP samples was recorded as 58.76%, which is more than half of the chemical composition. This result indicated that dried Jerusalem artichoke tubers represent considerable potential for increasing dietary fiber content and so improving health-promoting effects of meat products as a natural and nutritious ingredient. Our findings were in accordance with Khuenpet et al. [15], who found that inulin content of JAP was 54.86/100 g. The composition of the tubers could differ

depending on varieties, harvesting maturity, storage time, growing conditions and processing technique [14, 15].

*Fig. 1 Some images of dried Jerusalem artichoke tubers and the final product*

Technological characteristics of JAP samples were as follows: WHC, OBC, and EC of the samples were  $3.03\pm 0.60$  ml water/g,  $3.63\pm 0.45$  ml oil/g and  $150.0\pm 7.0$  ml oil/g, respectively. Afoakwah et al. [16] reported that oven-dried JAP had  $4.30\pm 0.10$  g water/g WHC and  $2.06\pm 0.03$  g oil/g OBC, and they stated that OBC of JAP are higher than many other fibers. In their study, freeze-dried JAP samples had higher OBC ( $3.02\pm 0.14$  g oil/g) compared to oven-dried samples, but the values were not as high as our results, probably due to the different origin of the raw materials. Rodríguez-Furlán et al. [9] reported that chicory inulin had  $100\pm 5$  mL oil/g product EC. This result showed that JAP had a better emulsification ability compared to industrial inulin.

VGI values of JAP samples were recorded as  $10.1\pm 1.2\%$ ,  $53.3\pm 4.8\%$  and  $100.0\pm 0.0\%$  in 5%, 10% and 25% (w/v) water solutions, respectively. This result showed that an initial partial gel formation was observed in 5% water solution, whilst JAP samples were able to form a total gel structure in 25% water solution. Gel formation ability of JAP is a considerable quality attribute since the composite gel structure formed after hydrating and swelling of the samples could easily be distributed when used in the meat matrix. Kim et al. [12] reported that 30 and 35% inulin suspensions made 100% gel structure. Thus, JAP

samples could form a gel structure in lower concentrations compared to inulin, in other words gel formation ability was higher in JAP samples than in inulin samples.

### 3.2. Characteristics of emulsified chicken meatballs

The dietary fiber and salt content of emulsified chicken meatballs are presented in Table 1. Since the dietary fiber content of the meatballs was calculated based on the dietary fiber content of JAP samples, expectedly the values were increased with added JAP. According to this, the samples formulated with 3.8% JAP had 2.23% dietary fiber, while the samples formulated with 7.6% JAP had 4.46% dietary fiber. This result showed that in phosphate-free meat product formulations, utilization of JAP would lead to increase dietary fiber content and thus improve the health profile of the product, besides to provide technological advantages. The salt content of the samples was between 0.77-0.97%, which was significantly affected by formulation ( $P<0.05$ ). The highest salt content was recorded in samples containing STPP (P group), while the lowest salt content was recorded in samples containing 7.6% JAP (J3 and JC3 groups) ( $P<0.05$ ). The relatively higher salt contents of P and C samples among treatments could be arisen from the sodium content of these samples. It was noted that increased concentrations of JAP were effective to reduce salt content regardless of sodium carbonate incorporation. This result could be due to the increase in the dietary fiber content with added JAP, which might dilute the sodium chloride used in the formulation.

**Table 1. The dietary fiber and salt content of emulsified chicken meatballs**

Treatments*	Dietary fiber content (%)	Salt content (%)**
P	0.00	0.97 <sup>a</sup> ±0.01
C	0.00	0.95 <sup>b</sup> ±0.02
J1	2.23	0.88 <sup>c</sup> ±0.01
JC1	2.23	0.87 <sup>c</sup> ±0.03
J2	3.35	0.82 <sup>d</sup> ±0.01
JC2	3.35	0.82 <sup>d</sup> ±0.01
J3	4.46	0.78 <sup>e</sup> ±0.01
JC3	4.46	0.77 <sup>e</sup> ±0.01

\* The meatballs were formulated with **P**: 0.5% STPP, **C**: 0.2% Na<sub>2</sub>CO<sub>3</sub>, **J1**: 3.8% JAP, **JC1**: 3.8% JAP+0.2% Na<sub>2</sub>CO<sub>3</sub>, **J2**: 5.7% JAP, **JC2**: 5.7% JAP+0.2% Na<sub>2</sub>CO<sub>3</sub>, **J3**: 7.6% JAP, **JC3**: 7.6% JAP+0.2% Na<sub>2</sub>CO<sub>3</sub>.

\*\* Data are presented as the mean values of replications ± standard deviation of the mean. abcd: Means with the different letter in the same column are significantly different ( $P<0.05$ ).

Cook yield (CY) of the treatments are shown in Fig. 2. The values were between 77.19-90.96% and significant changes among treatments were recorded ( $P<0.05$ ). Samples with JAP and sodium carbonate (JC1, JC2, and JC3) showed similar CY to each other, but JC2 samples had higher CY than samples with STPP (P). This data indicated that JC2 samples

showed a better performance than P samples to reduce fluid losses upon cooking. It was concluded that fiber-sourced ingredients have an important effect to meet the behaviors of phosphates by their water-holding ability in case of appropriate pH values. Our results were in agreement with Prabhu and Husak [17], who reported that utilization of native potato starch and sodium carbonate was effective to increase CY of phosphate-free pork loins.

**Fig. 2** Cook yield of emulsified chicken meatballs. The meatballs were formulated with P: 0.5% STPP, C: 0.2%  $\text{Na}_2\text{CO}_3$ , J1: 3.8% JAP, JC1: 3.8% JAP+0.2%  $\text{Na}_2\text{CO}_3$ , J2: 5.7% JAP, JC2: 5.7% JAP+0.2%  $\text{Na}_2\text{CO}_3$ , J3: 7.6% JAP, JC3: 7.6% JAP+0.2%  $\text{Na}_2\text{CO}_3$ . The standard deviation of the means ranged between 1.93-4.49. a, b, c: different letters indicate significant difference among means ( $P<0.05$ ).

#### 4. Conclusions

The results of the present research showed that oven-dried JAP is a health-promoting ingredient in terms of high dietary fiber content and also it has technological advantages over industrial inulin. Utilization of JAP in combination with sodium carbonate in emulsified chicken meatballs have a good potential to enhance the dietary fiber content and reduce the salt content of the product, simultaneously to increase cook yield. Overall, it was concluded that oven-dried JAP presented a good health profile and high technological quality with the aid of SC to be evaluated as inorganic phosphate replacers in formulation of emulsified poultry products.

## 5. Acknowledgement

The authors would like to extend special thanks to the Republic of Turkey, Ministry of Science, Industry, and Technology for financial support to this study with Project No: 0764.STZ.2014 (SAN-TEZ Program), and many thanks to the co-partner company (Abaloğlu Co., Izmir).

### **Abstract**

*In this study, it was aimed to determine the effects of partial replacement of beef fat with olive oil on quality changes of fermented turkey sausages (sucuk) during processing. Three formulations were prepared by using the lipid phase as 100% beef fat (control), 85% beef fat+15% olive oil and 70% beef fat+30% olive oil. Total moisture, pH, acidity, water activity (aw) and peroxide values were analyzed in sausage dough, at the end of the fermentation and at the end of ripening. The production steps significantly affected moisture decrease in samples, pH and aw values were decreased and acidity was increased in all samples during production. Peroxide value of the samples increased during processing steps and the samples with olive oil had higher peroxide values compared to control. The results showed that during processing steps of fermented turkey sausages, considerable changes could occur depending on lipid type.*

**Keywords:** *sucuk, fermented sausage, dry fermentation, fat replacement, olive oil, turkey meat*

---

## **1. Introduction**

Sucuk, one of the most popular Turkish fermented meat sausages, is typically produced from beef, beef backfat and/or tail fat, salt, sugar, garlic, nitrite/nitrates, various spices and other ingredients [1, 2]. However, poultry meat could also be utilized as the raw material of sucuk especially in industrial production to increase product variability and minimize costs. Fermented meat products are known to contain high contents of fat. Although fat plays a key role in most of the quality attributes like color, texture, flavor and nutritional value of meat products [3, 4], today saturated fat reduction and lipid modification approaches for developing healthier meat products are highly encouraged [5]. Olive oil is a well-known health promoting vegetable oil that contains mostly monounsaturated and polyunsaturated fatty acids, tocopherols and phenolic substances [6, 7]. The objective of the present study was to investigate the quality changes during processing of fermented turkey sausages (sucuk) formulated with olive oil as partial beef fat replacers.

## **2. Materials and Methods**

### **2.1. Production of turkey sucuks**

Fresh post-rigor turkey breast muscles were supplied from a local butcher in Izmir. Other ingredients were purchased from local market. Breast muscles were trimmed of visible fat and connective tissues. Turkey meat and beef fat were then minced through a 3 mm plate grinder. Each treatment was formulated to contain 20% total fat. Control (C) group was formulated with 100% beef fat. Olive oil was added to the formulations by replacing 15% (O15) or 30% (O30) of beef fat. The other ingredients added to treatments were salt, saccharose, ascorbic acid, sodium nitrite, garlic powder and spice mix. After mixing all the ingredients homogenously, the sausage doughs were then stuffed into casings using a filling machine (Alpina, Switzerland). Samples were allowed to stand at 22.5°C and 60% relative humidity (RH) for 3 hours before fermentation in a fermentation chamber (Wisd, South Korea). After that, samples were fermented at 23°C and 88% RH until the pH reached 5.4. After fermentation, sausages were ripened at 21°C and 83% RH for 3 days and at 19°C and 73% RH, respectively to drop the moisture under 40%. During the production, sampling was performed in sucuk dough, at the end of fermentation (pH=5.4) and at the end of ripening (final product).

### **2.2. Methods**

The total moisture content of the samples was determined according to AOAC [8]. pH was measured from three different points by using a pH-meter (WTW pH 330i/SET, Germany) with a penetration probe. Acidity was determined by a titrimetric method and expressed as lactic acid % [8]. Water activity ( $a_w$ ) was measured with a water activity measurement

device (Testo AG 400, Lenzkirch, Germany), with a 0.001 sensitivity. For peroxide analyses, fat was extracted with chloroform and methanol according to the method of Flynn and Bramblett [9] and the peroxide value was analyzed according to AOAC [8]. The data were analyzed by one way ANOVA using the SPSS software version 21. Differences among the means were compared using Duncan's Multiple Range Test. A significance level of 0.05 was used for all evaluations.

### 3. Results and Discussions

The change in total moisture content of the fermented sausages is presented in Fig. 1. The moisture content of sausage doughs was between 61.31-64.33%, while the values were between 40.21-41.40% in final products. The production steps significantly affected moisture decrease in samples due to the removal of free water by drying operation. In final products, O15 samples had lower moisture content compared to other groups ( $P<0.05$ ). While C and O15 had similar moisture contents, moisture increased with higher olive oil levels in the formulation. Formation of an olive oil film between casing and sucuk mixture resulted in an incomplete drying of the product. According to Bloukas et al. [10], the granulated animal fat in sausage mixture helps to loosen up the structure, which aids the continuous release of moisture from the inner layer of the product.

*Fig. 1 Moisture content of fermented turkey sausages during processing. The lipid phase of the samples was formulated with C: 100% beef fat, O15: 85% beef fat+15% olive oil, O30: 70% beef fat+30% olive oil*

pH values, acidity, and water activity ( $a_w$ ) of sucuk samples recorded during processing are given in Table 1. In sucuk dough, pH values were between 5.80-5.85, no significant

differences were recorded among samples. pH values were significantly decreased and acidity was significantly increased in all samples during production ( $P<0.05$ ) with the effect of lactic acid fermentation. In final products pH values were between 5.23-5.31, pH values of O15 and O30 samples were higher than C samples ( $P<0.05$ ). Geçgel et al. [11] reported that utilization of various vegetable oils in fermented beef sausages resulted in an increment in pH values. Despite the increase in pH values of olive oil treatments, the addition of olive oil had an increasing effect on the acidity of the final products ( $P<0.05$ ). That is probably due to free fatty acids naturally present in olive oil. In sucuk doughs, aw values were recorded between 0.939-0.947, all the samples had similar values. aw values of all the samples were significantly decreased during production ( $P<0.05$ ) due to the decrease in free water content by the drying process. Although no significant differences in aw of the samples were recorded after fermentation, in final products, the samples formulated with olive oil had higher aw values compared to control ( $P<0.05$ ). This result could be arisen from different interactions of various lipids with meat protein matrix affecting drying behavior. The aw values recorded during processing were in accordance with Ensoy [12].

\* The lipid phase of the samples were formulated with **C**: 100% beef fat, **O15**: 85% beef fat+15% olive oil, **O30**: 70% beef fat+30% olive oil

Data are presented as the mean values of replications ± standard deviation of the mean. For different analysis; abcd: Means with the different letter in the same column are significantly different ( $P<0.05$ ). ABC: Means with the different letter in the same row are significantly different ( $P<0.05$ ).

Peroxide values of the treatments are shown in Fig. 2. The values of the dough samples showed that autoxidation reactions had already started before stuffing. Processes of mixing

and stuffing were not carried out under vacuum conditions; therefore the presence of high concentration of oxygen in dough could lead the early development of autoxidation reactions. The processing steps were recorded to increase lipid oxidation of all the samples in terms of peroxide value ( $P < 0.05$ ). However, in all cases, peroxide value was lower than 25 meq O<sub>2</sub>/kg of fat which is the limit of acceptability for fatty foods [13, 14]. Peroxide values of the final products formulated with olive oil were higher compared to control ( $P < 0.05$ ), probably due to the high unsaturated fatty acid content of olive oil. Similarly, Geçgel et al. [11] reported that incorporation of different vegetable oils to the formulation of fermented beef sausages caused increments in peroxide values.

*Fig. 2 Peroxide values of fermented turkey sausages during processing. The lipid phase of the samples was formulated with C: 100% beef fat, O15: 85% beef fat+15% olive oil, O30: 70% beef fat+30% olive oil*

### **3. Conclusions**

The results showed that during processing steps of fermented turkey sausages (sucuk), considerable changes could occur depending on lipid type. Since olive oil treatments had different pH, acidity and water activity values from control treatments with beef fat, these features could change sensory characteristics and shelf life of the product. Thus, free water content and thereby water activity should be considered during the production of fermented sausages formulated with vegetable oils. In addition, since olive oil is highly susceptible to lipid oxidation and thereby incorporation of it resulted in an increment in peroxide values, utilization of antioxidants or encapsulation of the added oil could be suggested to improve the oxidative stability of the product.

### **Abstract**

*This research work is about dehydrofreezing assisted by DIC treatment as an innovative conservation process of apple fruits. Samples previously dehydrated and DIC treated were frozen at -30 °C and at two different practical freezing rates. The effects of sample water content (W) and practical freezing rate (PFR) on freezing characteristics and apple texture were examined. Thaw exudate water (TEW) of 200% and 100% db samples was approximately 3 g/100 g water. Whereas, it was lower than 0.5 g/100 g water for samples with 30% db W during thawing at 4 °C. Moreover, the impact of PFR on TEW was significant and very important only for high W samples. For samples whose water content was lower than 100% db, firmness was as higher as the W was lower, without any significant impact of PFR.*

**Keywords:** *Dehydrofreezing; Instant controlled pressure drop; Water content; Practical freezing rate; Texture.*

## 1. Introduction

Freezing is a common fruit and vegetable conservation process that preserves the sensorial quality and nutritional compounds [1]. However, in the case of high-water-content perishable fruits and vegetables, the treatment is usually accompanied by irreversible damage of cell structures and possible deterioration of textural quality of the frozen products after thawing due to large ice crystals formed in the tissue during freezing process [2]. Dehydrofreezing which is a preservation process that involves partial dehydration before freezing can be used in order to diminish tissue damage [3-5].

The reduction in the product water content before freezing improves both freezing performance and product quality in the case of *Golden delicious* apples [6]. Process performance is revealed through an improvement of freezing rate and a decrease of freezing time [7] as well as lower energy consumption, lower cost of packaging, distribution, and storage. Whereas, quality improvement includes better preservation of structural and textural characteristics and decrease of thaw exudate water rich on soluble nutrients.

In the other hand, since the partially dried products are not yet microbiologically stabilized, subsequent treatment is necessary, before freezing, for product decontamination.

Likewise, to remove the impact of possible shrinkage of partially dried products instant controlled pressure drop (DIC) process is also required [8].

However, no work has been reported in the literature about mechanical properties after the combined process ‘air drying + DIC + freezing’. Hence, the main objectives of this study were to (i) establish a new freezing method, namely, DIC-assisted dehydrofreezing, and to (iii) assess and compare the impacts of water content and practical freezing rate on thaw exudate water and textural characteristics of dehydrofrozen products previously DIC treated.

## 2. Materials and Methods

### 2.1. Process treatments

Initial water content (W) of apple fruits (var. *Golden delicious*) was determined according to AOAC official method 934.06 [9]. It was of  $700 \pm 10\%$  dry basis (db). Discs of  $10.0 \pm 0.2$  mm thick were prepared for process treatments and texture analysis.

### 2.2. Partial drying

Partially drying experiments were carried out in a airflow dryer under constant conditions: air temperature, air velocity, and air relative humidity of 45 °C, 2 m/s, and 12%, respectively. Drying experiment was stopped once desired water content (W) levels were attained (200, 100, and 30% db).

### **2.3. DIC treatment**

Partially dried apple samples with different water contents (200, 100, and 30% db) were DIC treated by an adequate equipment (ABCAR-DIC Process, La Rochelle, France).

### **2.4. Freezing**

Partially dried and DIC treated apple samples at different water content levels were frozen in a freezer (Whirlpool Model AFG 363/G, Italy) with air temperature of  $-30\text{ }^{\circ}\text{C}$  at two different practical freezing rates; high practical freezing rate (PFR+) and low practical freezing rate (PFR-) depending on the thermal resistance established between the freezing airflow and the sample surface [7].

### **2.5. Thawing process**

Completely frozen apple samples previously DIC treated were thawed in a refrigerator (FAR Model RT 140, Romania) at  $4\text{ }^{\circ}\text{C}$  overnight just before starting the textural measurements [6].

### **2.6. Quality assessments**

#### *2.6.1. Determination of thaw exudate water*

Dehydrofrozen DIC treated-apple samples were used to measure thaw exudate water (TEW) expressed in g/100 g water, during the thawing phase [7,10].

#### *2.6.2. Texture measurement*

Textural firmness of DIC treated-dehydrofrozen/thawed apple slices was evaluated by measuring the maximum puncture force through a puncture test with a cylindrical puncture probe of 2 mm in diameter at a constant speed of 5 mm/s using Instron Universal Testing machine (Model 5543, USA) [6].

### **2.7. Statistical analysis**

Bifactorial analysis of variance and SNK test were carried out using the Statistical Package for the Social Sciences (SPSS) version 20.

## **3. Results and discussions**

### **3.1. Thaw exudate water**

The impacts of water content (W) of apple samples and practical freezing rate (PFR) on thaw exudate water (TEW) during thawing of DIC treated-dehydrofrozen apple samples were investigated and experimental results are illustrated in Figure 1.

*Figure 1. Impacts of water content and practical freezing rate on thaw exudate water (TEW) of DIC treated-dehydrofrozen apples. (Data are expressed as the mean  $\pm$  standard deviation. Values for the same practical freezing rate having the same letter (a, b and c) for thaw exudate water (TEW) are not significantly different at a confidence level of 95%. Values for the same water content level having the same letter (A, B and C) for thaw exudate water (TEW) are not significantly different at a confidence level of 95%).*

Figure 1 shows the impact of the two different practical freezing rates on the thaw exudate water (TEW) of dehydrofrozen DIC treated-apple samples with different water contents (200, 100, and 30% db) during thawing process. Thaw exudate water (TEW) of 200% and 100% db apple samples frozen at -30 °C was approximately 3 g exudate water /100 g water in the product at high practical freezing rate (PFR<sup>+</sup>) after thawing at a temperature of 4 °C. Indeed, it was lower than 0.5 g/100 g water for apple samples with 30% db water content and frozen at the same practical freezing rate (PFR<sup>+</sup>).

Previous researches have equally demonstrated that dehydration by hot air causes a diminution in drip loss during the thawing process in the case of dehydrofrozen strawberry and pineapple fruits [11,12]. These authors reported that air drying prior to freezing presents the advantage of decreasing the drip loss and the water exudate volume after thawing process as compared to osmotic dehydration [11,12].

As it is shown in Fig. 1, the higher the initial water content of dehydrofrozen apples, the higher the amount of TEW. Same results were obtained for several dehydrofrozen fruits such as strawberry, kiwi fruits, and pears [13,14]. The TEW decrease during thawing of DIC treated-dehydrofrozen samples may also be explained by a preservation of the structural and textural properties of apple samples as a consequence of the partial removal of water before freezing.

In the other hand, the impact of practical freezing rate on thaw exudate water (TEW) was significant and very important for high water content samples (200% and 100% db). It had less significantly detrimental effect on TEW for lower water content samples (30% db).

### 3.2. Texture variation

The maximum puncture forces (firmness) after thawing of DIC treated-dehydrofrozen apple samples, which were frozen at two different practical freezing rates (PFR<sup>+</sup> and PFR<sup>-</sup>) are shown in Figure 2.

*Figure 2. Impacts of water content and practical freezing rate on firmness of DIC treated-dehydrofrozen apples. (Data are expressed as the mean  $\pm$  standard deviation. Values for the same practical freezing rate having the same letter (a, b and c) for maximum puncture force are not significantly different at a confidence level of 95%. Values for the same water content level having the same letter (A, B and C) for maximum puncture force are not significantly different at a confidence level of 95%).*

As it is shown in Figure 2, firmness (maximum puncture force) of DIC treated-dehydrofrozen apple samples was constant (about 2 N) for high water content levels of 200% and 100% db, for both practical freezing rates. It increased for lower water content to reach 6.5 N for 30%-db samples, while no effect due to practical freezing rate was evidenced. ANOVA and LSD tests carried out for the firmness values statistically confirmed these differences. DIC-dehydrofreezing/thawing processes induced a significant ( $p < 0.05$ ) increase of firmness with the decrease of sample humidity. Moreover, according to the result of the simple range test (SNK test), two homogeneous groups were identified.

The first group includes 200% and 100%-db apples. The second group only included samples with water content of 30% db.

These results confirmed that the significant impacts of water content on firmness obtained in the case of dehydrofrozen apples without DIC pretreatment, with also an insignificant effect of practical freezing rate. Firmness values of dehydrofrozen/thawed and non DIC pretreated apples were about 2, 4.5, 7, and 12 N for samples with water contents of 700, 200, 100, and 30% db, respectively [7]. Firmness of dehydrofrozen apples was found to be higher for samples non-DIC treated. This difference on firmness is explained by textural modifications caused by DIC treatment applied before freezing as texturing process [6].

Similar results, concerning the impact of air drying performed as freezing pretreatment on textural properties, were obtained for dehydrofrozen/thawed strawberry and kiwi fruits [11]. Airflow drying as freezing pretreatment resulted in dehydrofrozen/thawed products with improved textural properties and higher firmness. Indeed, the low water content of dried samples prevents the cell wall damage and preserve the product structure during freezing and thawing processes [2,6].

#### **4. Conclusions**

Fruits and vegetables present a category of food products which is characterized by high water content generally higher than 500% db. This category of agriculture products can also be characterized by initial microbial contamination. Partial drying coupled to instant controlled pressure drop (DIC) as adequate pretreatment should present an intensification way for fruit and vegetable freezing process. The coupling of these operations presents several advantages concerning the product stability through a partial removal of water and a decontaminating pretreatment.

Thaw exudate water for DIC treated-dehydrofrozen apples during the thawing was approximately 3 g/100 g water for high water content samples (200 and 100% db). Whereas, it was lower than 0.5 g/100 g water for samples with 30% db water content. The impact of practical freezing rate on thaw exudate water was significant only for high water contents. For low water content level (30% db), practical freezing rate became a less important parameter for freezing process.

Water content had a significant effect on the textural properties of apple fruits after DIC-dehydrofreezing/thawing processes. In fact, fruit sample firmness increased when water content decreased for both practical freezing rates. Whereas, practical freezing rate had an insignificant impact on apple firmness.

In conclusion, partial removal of water constitutes a promising solution to reduce the negative impacts of freezing on textural quality. This process coupled with a texturizing pretreatment, showing perfect decontamination effects, can be suggested as an innovative fruit and vegetable conservation process. This new method allow obtaining dehydrofrozen

products with high textural quality after thawing and particularly without imposing a severe control of the partial drying step especially for the microbiological quality of products.

### ***Abstract***

*Apple samples were submitted to partially drying prior to freezing. Then, quality assessments were achieved in order to evaluate the quality of these various frozen samples during frozen-storage. Significant positive effects of water content were observed on thaw exudate water and total color difference of dehydrofrozen/thawed apples. Total polyphenol content and total flavonoid content losses were important for samples without any dehydration pretreatment. They noticeably decreased when water content decreased during the whole period of storage. Thus, a partial removal of water prior to freezing is a relevant way to maintain the stability of fruit quality during long-term frozen-storage.*

***Keywords:*** Apple fruits; dehydrofreezing; frozen storage; color; polyphenol.

---

## 1. Introduction

Dehydrofreezing is defined as a preservation method for fruits and vegetables characterized by their high water content. It is a process that involves a partial dehydration phase prior to freezing in order to diminish the amount of water and prevents the cell wall damage during freezing and thawing processes due to the increase of water volume during freezing. Previous investigations have demonstrated that dehydrofreezing reduces freezing time and improves freezing rates [1,2]. This combined process improves the textural firmness of frozen/thawed fruits and vegetables [3,4]. Dehydrofreezing reduces the thaw exudate water during thawing stage [3,5,8,10]. Several previous studies were interested on dehydrofreezing impacts on the global quality of fruits and vegetables through the assessment of different parameters such as color [6,7,10], ascorbic acid [3], and bioactive molecules [10]. Frozen fruits and vegetables undergo quality changes throughout the subsequent frozen storage. Moreover, physical changes during storage at negative temperatures may imply ice recrystallization, which results in deleterious textural and nutritional changes. It also would reverse the advantages of fast freezing. By inserting before freezing a pretreatment stage of partial dehydration, the quality loss of fruits and vegetables should be minimized not only during the freezing step but also during frozen storage. As far as we know, little information exists about the impact of the coupling of air drying and freezing processes on the nutritional quality and the bioactive composition of dehydrofrozen/thawed fruits and vegetables during long-period frozen storage. Thus, this study focused on studying the impact of the coupling of air drying and freezing, named dehydrofreezing process on the evolution versus frozen storage time at -18 °C and initial water content of 1/ color, 2/ total polyphenol content, 3/ total flavonoid content, and 4/ the thaw exudate water during thawing of apple fruits.

## 2. Materials and Methods

### 2.1. Process treatments

#### 2.1.1. Partial drying

1-cm *Golden delicious* apple disks with initial water content of about  $7 \pm 0.1$  g H<sub>2</sub>O/g db (dry basis) were dried in an airflow dryer under constant conditions of airflow temperature (45 °C), velocity (2 m/s), and relative humidity (12%). dehydration was stopped when selected water content levels were reached (2, 1, and 0.3 g H<sub>2</sub>O/g db).

#### 2.1.2. Freezing

Samples of fresh and partially airflow dried apple initially containing different water content levels (W); (7 (fresh), and 2, 1, and 0.3 g H<sub>2</sub>O/g db (for partially dehydrated

samples)) were frozen in a freezer (Whirlpool Model AFG 363/G, Italy) with an air temperature of  $-30\text{ }^{\circ}\text{C}$  at forced convection conditions.

#### 2.1.3. Frozen storage

Frozen and dehydrofrozen apple samples were stored at  $-18\text{ }^{\circ}\text{C}$  for 18 months as Frozen Storage Time FST period. Samples were retrieved each month during the first three months of storage and each 3 months until the end of the storage period for quality assessments.

#### 2.1.4. Thawing

Frozen and dehydrofrozen apple samples were thawed at  $4\text{ }^{\circ}\text{C}$  in a refrigerator (FAR Model RT 140, Romania) overnight just before starting the different analyzes.

### 2.2. Quality assessments

#### 2.2.1. Thaw exudate water

Thaw exudate water (TEW) of frozen or dehydrofrozen apple samples was measured in triplicate for each treatment during the thawing phase [5].

#### 2.2.2. Color measurement

For each sample, parameters L, a, and b were measured three times directly on the product using a colorimeter (Konica Minolta CR-410, Japan). Total color difference (TCD) between fresh and frozen and between dried and dehydrofrozen samples for each initial water content and storage time was calculated.

#### 2.2.3. Total polyphenol content

Total polyphenol contents of fresh, dried, frozen, or dehydrofrozen/thawed apples were assayed during frozen storage [13].

### 2.3. Statistical analysis

Bifactorial analysis of variance and SNK test were carried out using the Statistical Package for the Social Sciences (SPSS) version 20.

## 3. Materials and Methods

### 3.1. Thaw exudate water

Table 1 shows the thaw exudate water (TEW) of apple samples just frozen, dehydrofrozen and during long-term frozen storage at  $-18\text{ }^{\circ}\text{C}$  for 18 months.

**Table 1. Effect of -18°C-storage on thaw exudate water during thawing of dehydrofrozen apple.**

W: Initial water content g H<sub>2</sub>O/g dry basis db), TEW: Thaw exudate water (g/100 g initial water); FST: Frozen storage time (months). Data are expressed as the mean ± standard deviation. Different letters (A-D) within a same row differ significantly (P < 0.05). Different letters (a-b) within a same column differ significantly (P < 0.05).

As previously indicated, since apple samples have initially before freezing different water contents, the thaw exudate water (TEW) was expressed as gram of water exudate/100 g initial water of concerned product before freezing. The impacts of initial water content (W) of apple samples and frozen storage time (SFT) on thaw exudate water (TEW) were investigated.

During thawing at a temperature of 4 °C, TEW of fresh apple samples without previous dehydration (samples with 7 g H<sub>2</sub>O/g db as initial water content) was approximately of 15 g/100 g initial water. Fresh apple samples had significantly higher value of TEW than all partially air dried samples. This amount of TEW was important and significantly increased although slightly during the frozen storage time period of 18 months at -18 °C. According to Goncalves et al. [14], during frozen storage, recrystallization of ice crystals may cause more loss of cell turgor causing a leakage of fruit cell content and decrease of cell water holding capacity, resulting in increasing of thaw exudate water versus storage time.

Thaw exudate water was about 4 g/100 g initial water for apple samples with initial water content of 2 g H<sub>2</sub>O/g db, and about 0.5 g/100 g initial water for samples of 1 and 0.3 g H<sub>2</sub>O/g db initial water content. This low thaw exudate water level reveals high preservation of structural and textural quality issued from a better preservation of cell walls. This contributes to the slowing down of water loss from the internal cells [11].

From our point of view, the most important point, which is worth to be highlighted here is that, for previously dehydrated apple samples, TEW remained constant and negligible during the whole storage period. Partial removal of water before fruit freezing appeared as a

relevant way to preserve the structural and maintain the textural properties of frozen/thawed fruits. This improves its stability during storage.

### 3.2. Color

Table 2 shows the total color difference (TCD) induced by freezing/dehydrofreezing and thawing of apple samples during storage at -18 °C for 18 months and after thawing.

**Table 2. Effect of -18°C-storage during 18 month-freezing on total color difference of dehydrofrozen apple.**

FST (months)	TCD (-)			
	W (g H <sub>2</sub> O/g db)			
	7	2	1	0.3
0	33.56±5.94 <sup>aA</sup>	31.66±2.06 <sup>aA</sup>	21.88±7.71 <sup>aA</sup>	15.59±6.15 <sup>aB</sup>
1	29.28±3.49 <sup>aA</sup>	30.47±6.91 <sup>aA</sup>	25.14±5.76 <sup>aA</sup>	15.61±4.53 <sup>aB</sup>
2	28.20±5.19 <sup>aA</sup>	30.15±6.84 <sup>aA</sup>	25.72±2.86 <sup>aA</sup>	14.03±6.82 <sup>aB</sup>
3	31.44±7.12 <sup>aA</sup>	34.62±5.98 <sup>aA</sup>	22.57±3.67 <sup>aA</sup>	10.91±3.96 <sup>aB</sup>
6	32.70±1.93 <sup>aA</sup>	32.74±8.09 <sup>aA</sup>	26.51±7.45 <sup>aA</sup>	12.14±5.66 <sup>aB</sup>
9	32.71±2.42 <sup>aA</sup>	32.48±5.63 <sup>aA</sup>	21.09±2.86 <sup>aA</sup>	15.10±7.52 <sup>aB</sup>
12	27.74±6.21 <sup>aA</sup>	32.80±4.23 <sup>aA</sup>	25.20±7.54 <sup>aA</sup>	13.95±6.91 <sup>aB</sup>
15	30.94±5.88 <sup>aA</sup>	30.66±5.19 <sup>aA</sup>	20.90±6.39 <sup>aA</sup>	11.50±5.79 <sup>aB</sup>
18	29.34±5.47 <sup>aA</sup>	33.34±4.71 <sup>aA</sup>	20.81±5.19 <sup>aA</sup>	10.56±5.69 <sup>aB</sup>

W: initial water content (g H<sub>2</sub>O/g db), FST: Frozen storage time (months), TCD: total color difference (-). Data are expressed as the mean ± standard deviation. For each color parameter, different letters (A-B) within a same row differ significantly ( $P < 0.05$ ). Different letters (a-b) within a same column differ significantly ( $P < 0.05$ ).

As it is shown in Table 2, the global effect of freezing and thawing processes on color decreased and became negligible for apple samples with low water content. Indeed, the total color difference (TCD) was 33.5 and 15.5 for samples with initial water contents of 7 and 0.3 g H<sub>2</sub>O/g db, respectively (Table 2). The freezing/thawing effect decrease is explained by the lower water activity of samples and consequently lower rate of enzymatic browning reactions [22]. The freezing impact decrease on fruit color is also attributed to the air-drying step, which caused the reduction of phenolase activity and enzymatic browning [23]. On the other hand, partial removal of water from fruit cells could protect product color due to lower structural damage as a result of freezing decreasing the enzymatic browning in damaged tissue [4].

In contrast, total color difference was almost constant during the whole storage period of 18 months at -18 °C. According to Forni *et al.* [23], the air-drying step reduced the phenolase activity and thus increased color stability of dehydrofrozen/thawed apricot during storage. To conclude, the coupling of air drying and freezing processes induced lesser color changes at lower water content levels. These color losses are almost stable during the whole frozen

storage period. Thus, the combination of these two conventional food unit operations is very useful for the color stability of frozen/thawed fruit during storage.

### 3.3. Total polyphenol content

The results of total polyphenol contents (TPC) in frozen and dehydrofrozen apples with different water contents during frozen storage at -18 °C and after thawing are given in Table 3.

**Table 3. Effect of -18°C-storage on total polyphenol content of dehydrofrozen apples.**

FST (months)	TPC (g AGE/100 g DW)			
	W (g H <sub>2</sub> O/g db)			
	7	2	1	0.3
0	0.43±0.04 <sup>aA</sup>	0.19±0.03 <sup>aC</sup>	0.18±0.01 <sup>aC</sup>	0.29±0.01 <sup>aB</sup>
1	0.44±0.01 <sup>aA</sup>	0.21±0.03 <sup>aC</sup>	0.19±0.01 <sup>aC</sup>	0.28±0.01 <sup>aB</sup>
2	0.43±0.05 <sup>aA</sup>	0.19±0.01 <sup>aC</sup>	0.18±0.01 <sup>aC</sup>	0.27±0.01 <sup>aB</sup>
3	0.40±0.03 <sup>aA</sup>	0.20±0.02 <sup>aC</sup>	0.18±0.01 <sup>aC</sup>	0.28±0.01 <sup>aB</sup>
6	0.37±0.03 <sup>aA</sup>	0.21±0.02 <sup>aC</sup>	0.18±0.01 <sup>aC</sup>	0.28±0.01 <sup>aB</sup>
9	0.38±0.02 <sup>aA</sup>	0.20±0.01 <sup>aC</sup>	0.19±0.01 <sup>aC</sup>	0.27±0.01 <sup>aB</sup>
12	0.42±0.02 <sup>aA</sup>	0.21±0.01 <sup>aC</sup>	0.18±0.01 <sup>aD</sup>	0.28±0.01 <sup>aB</sup>
15	0.40±0.05 <sup>aA</sup>	0.20±0.01 <sup>aC</sup>	0.19±0.02 <sup>aC</sup>	0.28±0.01 <sup>aB</sup>
18	0.39±0.02 <sup>aA</sup>	0.20±0.01 <sup>aC</sup>	0.17±0.01 <sup>aD</sup>	0.26±0.01 <sup>aB</sup>

W: Initial water content (g H<sub>2</sub>O/g db); FST: Frozen storage time (months); TPC: total polyphenol content (g AGE/100 g DW). Data are expressed as the mean ± standard deviation. Different letters (A-D) within a same row differ significantly ( $P < 0.05$ ). Different letters (a-d) within a same column differ significantly ( $P < 0.05$ ).

Fresh *Golden delicious* apple samples present a total polyphenol content (TPC) of 0.62 g AGE/100 g db. Partial air drying results in significant reduction of TPC. TPC of partially dried apple samples were 0.26, 0.22, and 0.29 g AGE/100 g db for water contents of 2, 1, and 0.3 g H<sub>2</sub>O/g db, respectively. TPC losses as compared with fresh samples varied from 52 to 64%. According to Korus [26], hot air drying caused phenolic compounds degradation and promoted polyphenols oxidation by the oxygen absorbed from the air of convective drying. Loss in polyphenol content is also ascribed to their use as reactants in the Maillard reaction.

Similarly, freezing caused significant reduction in TPC. TPC losses were important for apple samples without any pre-dehydration stage and decreased for partially dried apples before freezing. Indeed, TPC losses caused by freezing and thawing processes are about 30, 25, 17, and 5% for samples with initial water contents of 7, 2, 1, and 0.3 g H<sub>2</sub>O/g db, respectively. In fact, freezing results in cell de-compartmentalization allowing reactions between genuine enzyme activities and their corresponding substrates [27,28]. Therefore, phenolic compounds may already be degraded during thawing due to their interaction with

oxidative enzyme activities such as polyphenoloxidases (PPO) which is more active at high water activity fruit samples [29,30].

As it is shown in Table 3, frozen storage time (FST) had insignificant effect on TPC for frozen and dehydrofrozen/thawed apple samples with different water contents. No data was found about the impact of coupling convective air drying and freezing on the polyphenol content of fruits and vegetables during their frozen storage.

#### 4. Conclusions

The dehydrofreezing performed by coupling airflow dehydration, as pretreatment for partial removal of water from apple fruit cells, prior to freezing resulted in higher preservation quality in terms of reduced thaw exudate water reflecting better texture quality, color retention, and ameliorating the bioactive composition. This combined process guarantees the stabilization of frozen product quality accomplished during subsequent long term frozen storage.

To conclude the partial dehydration of fruits before freezing is a pertinent way to minimize the quality alteration caused by freezing and thawing processes and to obtain products with high quality stability during storage. However, the pretreatment used for water removal must be optimized to minimize the quality losses at this step.

---

### **Abstract**

*Combined effects of sodium carbonate (SC) pretreatment and hybrid drying methods (freeze drying-instant controlled pressure drop drying (FD-ICPDD), hot air drying (HAD-ICPDD) on nutritional and antioxidant properties of Goji berries were investigated. Compared with distilled water pretreatment, SC pretreatment could obtain products with better quality. Goji dried by FD-ICPDD showed better overall quality than that dried by HAD or FD alone. FD-ICPDD products exhibited higher contents of total Lycium barbarum polysaccharide (140 g/kg), total carotenoids (2.4 g/kg) as well as the strongest ABTS.<sup>+</sup> radical scavenging activity (57.6 μmol TE/g). FD-ICPDD could be an alternative drying method for processing valuable agro-products.*

**Keywords:** *sodium carbonate, instant controlled pressure drop drying, nutritional properties, antioxidant activity*

---

## **1. Introduction**

Goji is in the Solanaceae family that has been used as a functional food and traditional herb in Asian countries <sup>[1]</sup>. It contains many active compounds including phenols, carotenoids and polysaccharides possessing biological activates such as anti-aging, antioxidant properties and so on <sup>[2]</sup>. For preservation, drying is still the main processing method to prolong the shelf-life of Goji <sup>[3]</sup>. Several drying methods, such as sun drying, hot air drying, vacuum drying, and freeze drying, have been conducted on Goji <sup>[4,5]</sup>. Each drying technique has advantages and restrictions. However, combined drying process can integrate the strengths of different drying methods so as to preserve quality of final products <sup>[6]</sup>. Instant controlled pressure drop drying (ICPDD), also called explosion puffing drying (EPD) <sup>[7]</sup>, is an emerging drying technology which always in conjunction with other drying methods like hot air and freeze drying and produce the products with better quality <sup>[8]</sup>. Drying of fresh Goji is difficult owing to the wax layer on the surface which could block moisture transport. Sodium carbonate (SC) was used as a traditional pretreatment to break the wax layer of Goji so as to accelerate the drying rate. But there is little report about the effect of SC pretreatment coupled with combined drying especially on ICPDD of Goji. Hence, to enhance drying efficiency and improve the overall quality, combined effects of sodium carbonate pretreatment and hybrid drying methods (FD-ICPDD and HAD-ICPDD) on the nutritional and antioxidant properties of Goji was evaluated. Freeze drying and hot air drying were used as comparative study.

## **2. Materials and Methods**

### **2.1 Sample preparation**

#### *2.1.1 Raw material*

Goji was grown in Yinchuan, Ningxia Hui Autonomous Region, China with initial water content was about  $804 \pm 2$  g/kg dry base (d.b.). Those without mechanical damage and decay were used and the fruit pedicles were removed before experiment.

#### *2.1.2 Pretreatment*

Goji fruits were immersed into the SC solution (20 g/kg) for 1 min at room temperature with the liquid to solid ratio of 10:1 (ml:g). Control samples were treated by distilled water (DW) under the same condition. Fresh Goji fruits were used for HAD and HAD-ICPDD. For FD and FD-ICPDD processing, samples were frozen at  $-80^{\circ}\text{C}$  before used.

### 2.1.3 Equipment and Drying Process

Freeze dryer (Alpha 1-4Lplus, MARIN CHRIST Co. Ltd Osterode, Germany), hot air dryer (HDS-D120B-D, Haiti Sheng Machinery Co. Ltd., Liaoning, China) and instant controlled pressure drop dryer (Tianjin Qin-de New Material Technology Co. Ltd., Tianjin, China) were used. The drying conditions of four different drying methods are exhibited in **Table 1**. The dried products were ground into powder and pass through a 60 mesh sieve, which were then kept at 4°C for further chemical analysis.

*Table 1. Drying conditions of four different drying methods*

Drying Methods <sup>a</sup>	Pretreatments <sup>a</sup>	Drying Conditions	Drying Time(h)
Freeze drying	DW	First drying stage: at -55°C and 0.37 kPa; Second drying stage: at 25°C	58 h
Freeze drying	SC	The drying conditions was the same as DW	58 h
Freeze drying -instant	DW	Freeze drying at -55°C and 0.37 kPa for 14 h; explosion puffing of 90°C for 15 min, then	15.5 h
controlled pressure drop drying	SC	vacuum drying at -0.1 MPa and 60°C for 1.5 h. The drying conditions was the same as DW	15.5 h
Hot air drying	DW	The drying time and temperature of air drying was 40°C (2 h)-50°C (4 h)-60°C (12 h), air velocity 1.2 m/s, relative humidity 40%	18 h
	SC	The drying time and temperature of air drying was 40°C (2 h)-50°C (4 h)-60°C (8 h), air velocity 1.2 m/s, relative humidity 40%	14 h
Hot air -instant	DW	Hot air drying: 40°C (2 h)-50°C (4 h); explosion puffing at 90°C for 15 min, then vacuum drying at -0.1 MPa and 60°C for 1.5 h.	7.5 h
controlled pressure drop drying	SC	Hot air drying: 40°C (2 h)-50°C (2.5 h); explosion puffing at 90°C for 15 min, then vacuum drying at -0.1 MPa and 60°C for 1.5 h	6 h

## 2.2 Sample extraction

Methanol-water solution was applied for sample extraction in this study. The extraction method was the same as Istrati et al. (2013)<sup>[9]</sup>. Samples were then filtered pass through a 0.45 µm microporous membrane for the analysis of total phenolic content, total flavonoid content, and antioxidant activity on the UV-visible spectrophotometer (UV1800, Shimadzu Co. Ltd., Kyoto, Japan).

## **2.3 Nutritional properties**

### *2.3.1 Total carotenoids content*

Total carotenoids content (TCC) was measured according to Knockaert et al. (2012) <sup>[10]</sup>.

### *2.3.2 Total Lycium barbarum Polysaccharide content*

The total *Lycium barbarum* polysaccharide (LBP) content was performed according to the procedure presented by Zhao et al. (2015) <sup>[4]</sup> with slight modification. Goji powder was extracted by ultrasonic at 40 kHz for 2 h. After centrifuged, the supernatant was condensed to a proper volume and precipitation was dissolved with ethanol until the concentration of ethanol is over 80%. Then the solution was placed at 4°C for 24 h to make the LBP settled. The settling was dissolved with distilled water and set to 100 mL. Solutions were analyzed for LBP, by the phenol–sulfuric acid method and concentrations determined against a glucose standard.

### *2.3.3 Total phenolic content*

Briefly, 0.4 mL of the extracts was transferred to the volumetric flask (10 mL) followed by 1 mL of Folin-Ciocalteu's reagent (10 times dilution) and after 6 min 2 mL of sodium carbonate solution (75 g/kg) was added. Then the volumetric flask was adjusted to the total volume with the distilled water and mixed thoroughly. The mixture was allowed to stand for 60 min at 30°C and measured at 765 nm <sup>[11]</sup>. The TPC was presented as mg/g dry base (d.b.) of gallic acid equivalents (GAE).

## **2.4 Antioxidant activity (FRAP and ABTS assay) measurement**

The FRAP and ABTS assay were measured according to the method of Wang et al. (2012) <sup>[13]</sup> and Jihyun et al. (2010) <sup>[14]</sup>, respectively.

## **2.5 Statistical Analysis**

All the experimental data was conducted in three replicates and the results were expressed as mean ± standard deviation. The SPSS V21.0 Software (IBM Corporation, Chicago, USA) was used for statistical analysis, applying a one-way analysis of ANOVA test and Duncan's multiple comparison test at  $P < 0.05$ .

## **3. Materials and Methods**

### **3.1 Total carotenoids content**

The reddish-orange color of Goji fruits comes from a group of carotenoids, which can be easily oxidized by heat, light, and high oxygen tension <sup>[15]</sup>. The TCC for fresh Goji was 3.6 g/kg extract and the values of dried Goji was shown in **Table 2**. DW-fruits exhibited lower

TCC values than SC-ones and the lowest TCC (1.6 g/kg) was obtained in HAD (DW) samples, owing to the effect of coexistence of high temperature, oxygen and longer drying time. The highest retention of TCC (71.4%) was observed in FD (SC) samples, possibly because of the lower temperature and vacuum conditions during FD dehydration [16]. Similarly, less losses of TCC (36%) in FD-ICPDD (DW) sample than that of HAD-ICPDD (DW) (43%) ones.

**Table 2** Different drying methods and pretreatments on nutritional components and antioxidant activities of *Lycium Barbarum*

Treatments	TCC (g/kg)	LBP (g/kg)	TPC (mg GAE/g)	FRAP ( $\mu$ mol TE/g)	ABTS ( $\mu$ mol TE/g)
Fresh	3.6 $\pm$ 0.1a	169 $\pm$ 6a	6.7 $\pm$ 0.1e	24.5 $\pm$ 1.0f	28.1 $\pm$ 1.3g
FD(DW)	2.5 $\pm$ 0.0c	105 $\pm$ 7c	8.1 $\pm$ 0.5d	29.7 $\pm$ 2.7e	50.1 $\pm$ 1.3c
FD(SC)	2.6 $\pm$ 0.1b	107 $\pm$ 1c	8.4 $\pm$ 0.1d	30.2 $\pm$ 2.4e	51.8 $\pm$ 0.9bc
FD- ICPDD(DW)	2.3 $\pm$ 0.1d	135 $\pm$ 9b	10.5 $\pm$ 0.1bc	39.1 $\pm$ 2.0bc	53.3 $\pm$ 0.8b
FD-ICPDD(SC)	2.4 $\pm$ 0.0cd	140 $\pm$ 0b	11.3 $\pm$ 0.3a	43.7 $\pm$ 1.0a	57.6 $\pm$ 0.5a
HAD(DW)	1.6 $\pm$ 0.1g	90 $\pm$ 3d	8.1 $\pm$ 0.3d	34.3 $\pm$ 1.2d	40.0 $\pm$ 2.3f
HAD(SC)	1.7 $\pm$ 0.1f	91 $\pm$ 5d	10.1 $\pm$ 0.4c	37.9 $\pm$ 1.9c	43.4 $\pm$ 1.7e
HAD- ICPDD(DW)	2.1 $\pm$ 0.1e	95 $\pm$ 1d	11.0 $\pm$ 0.4ab	40.9 $\pm$ 2.5abc	45.1 $\pm$ 0.4de
HAD- ICPDD(SC)	2.3 $\pm$ 0.1d	110 $\pm$ 1c	11.4 $\pm$ 0.3a	41.7 $\pm$ 1.7ab	45.7 $\pm$ 0.8d

Dates are expressed as dry base. Each value is expressed as mean value  $\pm$  SD (n = 3). Different letters in the same column indicate significant differences at  $p < 0.05$ , the same below. GAE: gallic acid equivalent; RE: rutin equivalent; TE: trolox equivalent

### 3.2 Total LBP content

LBP was one of the major active components in charge of biological activities of Goji [17]. There were significant distinctions of the LBP values between different drying processing. As shown in **Table 2**, the highest retention of LBP (82.9%) was observed in the FD-ICPDD (SC) products, possibly because vacuum conditions of most of drying process. The LBP of FD-ICPD-dried Goji was higher than that of the HAD-ICPD-dried ones. The lowest content of LBP (90 g/kg) was found in HAD (DW) because of the longer drying time (12 h) at relatively higher drying temperature (60°C). The content of LBP had no significant difference under the DW and SC pretreatments of the same drying method except the HAD-ICPDD.

### **3.3 Total phenolic content (TPC)**

The TPC of dried Goji was significantly influenced by the different pretreatments and drying methods ( $p < 0.05$ ). As shown in **Table 2**, TPC for the fresh samples was 6.7 mg GAE/g, which was similar to that had been reported in the article [5]. The SC pretreatment exhibited higher TPC values than that of DW pretreatment in all the drying methods. For example, the TPC of FD-ICPDD dried samples with SC pretreatment were 7.8% higher than that of DW ones. The highest retention of TPC (11.4 mg GAE/g) was found in HAD-ICPDD (SC) method, whereas the FD (DW) samples had the lowest value (8.1 mg GAE/g). It may be attributed to heat treatment that could liberate some phenolics and flavonoids which are mainly found in bound form in plant matrix [18]. On the other hand, the activity of polyphenol oxidase, which is responsible for oxidation of phenolics, tends to deactivation because of exposure to high temperature [19]. During thermal treatment, the liberation of phenolics might occur due to the decomposition of cellular components and covalent bonds [20]. Hence, the released phenolics tend to be more amenable for extraction. Chang et al. (2006) [21] also found that the values of TPC and TFC of tomatoes had a significant increase compared to the fresh ones either through FD or HAD. The TPC content of FD-ICPDD (SC) were higher than that of the FD (SC) samples (25.3%), which indicated that phenolics could be was liberated after ICPDD treatment.

### **3.4 Antioxidant Activity**

Antioxidants like phenolic compounds could inhibit oxidation reaction by acting on hydrogen donors or free radical acceptors [22]. Due to the complex composition of oxidative processes, the antioxidant activity could not be evaluated only using one single method. FRAP and ABTS assay was used in this study. As shown in **Table 2**, the antioxidant activities of all dried samples were enhanced compared to the fresh ones. Chang et al. (2006) [21] also showed similar results. Besides FD dried samples, significant increase of antioxidant activity of dried Goji was observed after SC pretreatment. The strongest ferrous iron chelating capacity (43.69  $\mu\text{mol TE/g}$ ) and ABTS.<sup>+</sup> radical scavenging activity (57.55  $\mu\text{mol TE/g}$ ) were found in FD-ICPDD-dried Goji. The fact that higher TPC were found in dried samples conducive to higher antioxidant activities compared to the fresh ones (**Table 2**). The FRAP values of FD-ICPDD-dried (SC) samples were 44.5% higher than the FD-dried (SC) samples, respectively, which were in good agreement with the increase of TPC contents (25.3%). Therefore, the ICPDD processing also can increase the antioxidant activity of dried Goji.

## **4. Conclusions**

Nutritional and antioxidant properties of dried Goji were significantly affected by different pretreatments and drying conditions. Compared to DW-pretreated samples, the SC pretreatment was more favorable because its improvement in overall qualities of dried Goji

no matter which drying method was used. In detail, the SC pretreatment products exhibited shorter drying time, higher TPC, LBP, TCC and antioxidant activity.

Under SC-pretreatment, the FD-ICPDD was a more beneficial drying method compared with the FD, HAD and HAD-ICPDD because of the highest retentions of TPC, LBP and antioxidant activities (FRAP and ABTS). For obtaining high-quality and valuable Goji-products, FD-ICPDD should be the best choice. But the increased manufacturing cost because of the FD pre-drying should also be taken into account. HAD-ICPDD could be another alternative technique when energy saving was more considered.

### **Abstract**

*The paper presents results of experiments of gas admixing foam spray drying of maltodextrin in co-current spray tower. Significant effect of feed foaming on particle sphericity, angle of repose, apparent and bulk density, Hausner ratio and porosity was found. Number of broken particles achieved 60 % for high foaming gas rate (GLR) and inlet air temperature due to particle overheating and bubble expansion. Analysis of the experiments results allowed to determine optimal range of operating conditions to reduce number of damaged particles, to around 15 % for the highest GLR and to minimize product degradation.*

**Keywords:** *foamed materials, gas admixing, powder properties, powder quality*

## **1. Introduction**

Standard spray drying process can be modified by foaming of feed solution. This technique, called “foam spray drying”, can be carried out in two ways: by gas desorption or gas admixing method [1]. In gas desorption process, the feed is foamed due to the bubbles nucleation inside supersaturated droplets after atomization. In gas admixing method, foaming gas is directly injected into the slurry before spraying [2]. Powders obtained after foam spray drying are characterized by lower bulk density, higher porosity and particle sizes, better solubility and wettability than from conventional spray drying. Bubbles trapped in the particles during foaming can expand or deflect during drying producing hollow, spherical or damaged particles.

Properties and quality of powders in foam spray drying results from type of dried material, hydrodynamics of continuous and dispersed phase and operating process parameters [3,4]. Concentration of solid, type of solvent and rheological properties of feed effect particle shape and morphology [5]. Hollow particles are produced from “skin-forming” materials whereas porous and irregular particles are developed from suspensions or colloids [6,7]. In co-current flow of phases agglomeration hardly occur as particle collisions are rare. In counter-current or mixed phase flow, due to intensive air recirculation in drying chamber, particles collide frequently and agglomerate which increases average particle size in the final product [8]. Agglomeration can be also stimulated by the configuration of the nozzles or by the returning of the smallest fractions of particles into the atomization zone. Parameters of spray drying process like feed rate, air flow rate and temperature, air humidity effect drying rate and the final powder properties, e.g. improperly selected will result in particle cracking and degradation due to overheating.

The aim of this paper was to determine optimal parameters of foam spray drying process to produce high quality powders.

## **2. Materials and Methods**

### **2.1. Spray drying measurement system**

Co-current foam spray drying experiments were carried out in spray drying tower at Lodz University of Technology [2]. Drying air was filtered and then heated up by the electrical heaters with power 62 kW. To reduce heat losses to the ambient air, the tower was insulated with the 40 mm layer of glass wool. Feed from thermostated tank was pumped to the top of the dryer, foamed and atomized by pressure nozzle. Dry powder was collected from the set of cyclones installed at the dryer bottom.

## 2.2. Foaming system

Gas admixing foaming system consisting of a static mixer and capillary dispensing gas to the solution and high speed homogenizer was installed at the top of the dryer.

Feed, foamed with nitrogen, was atomized by pressure nozzle LN-1 (Spraying System Co., USA). The nozzle operates with pressure up to 3.0 MPa with spray angle up to 70° which reduce powder deposition on the column wall. Initial density and mass flow rate of feed were measured using Coriolis flow meter (Micro-Motion 2400S, Emerson, USA). All parameters were registered using data acquisition system (National Instruments, USA).

## 2.3. Materials

As a particle crust material maltodextrin DE12 (Nowamyl S.A, Poland) was used in all experiments. Uniform bubble diameters distribution in the emulsion was obtained applying Tween<sup>®</sup>80 produced by Croda International (UK).

## 2.4. Experiments conditions

Foam spray drying experiments were carried out for two initial maltodextrin DE12 concentrations 20% and 35%, constant mass flow rate of feed, 14 kg/h, four initial air temperatures 150°C, 175°C, 200°C and 215°C, for mass flow rate of foaming gas from 0.01 to 0.09 kg/h. Additional spray drying test without foaming of feed was carried out as reference case.

## 3. Measurements results

Samples of dry powder were collected and analyzed to determine particle size distribution (PSD), sphericity, angle of repose, apparent and bulk density, Hausner ratio and porosity.

PSD and particle shape were found from the analysis of images taken from the optical microscope OE4 (PZO, Poland) connected to Nikon E4500 camera with support of Image-Pro Plus software (Media Cybernetics Inc., USA). At least 1000 particles per sample were analyzed to obtain representative results of powder morphology. Apparent density of the product was found with application of helium pycnometer AccPyc TC Micromeritics (USA). Bulk density of the powder was determined according to polish standard PN-80/C-04532 whereas angle of repose following polish standard PN-89/C-04840. HR - Hausner ratio was calculated from relation bulk/tapped density.

Examples of selected results of particle morphology are presented in Fig. 1 to 3. Average particle sphericity ( $\Psi_k$ ) for two different initial MDX concentrations (20 % and 35 %) and for different drying gas temperatures as a function of gas-liquid ratio (GLR) are shown in Fig. 1.

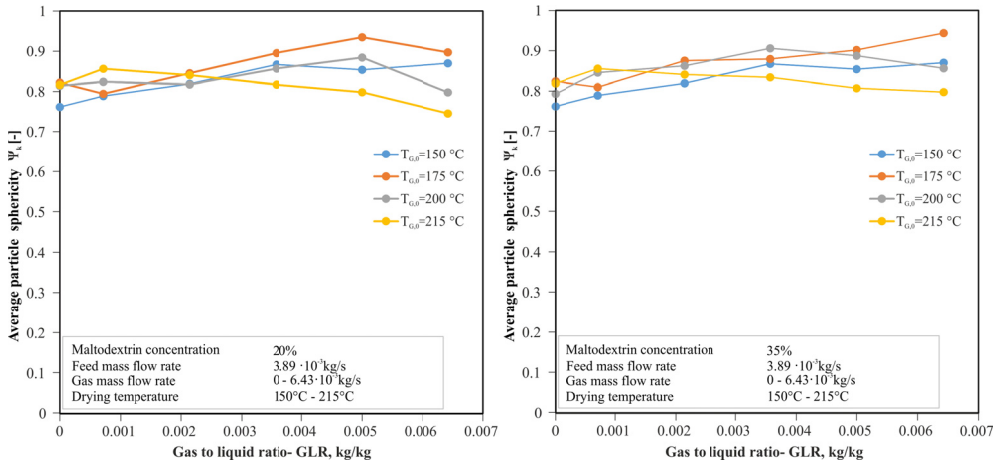

Fig. 1 Average sphericity of particles in collected powders.

Analysis of Fig. 1 shows that number of fully spherical particles increases with increasing of GLR. For the highest GLR and highest inlet air temperature ( $T_{G,0} = 215^\circ\text{C}$ ) particles sphericity decreases to 0.7 and 0.8 which is a result of particles breakage due to high thermal expansion of the bubbles.

Table 1 shows average Sauter diameter of particles in the product for different GLR and gas temperatures. We can observe increase of average Sauter diameter with increasing of GLR due to thermal expansion of the gas bubbles. Slight effect of initial gas temperature on average Sauter diameter was found.

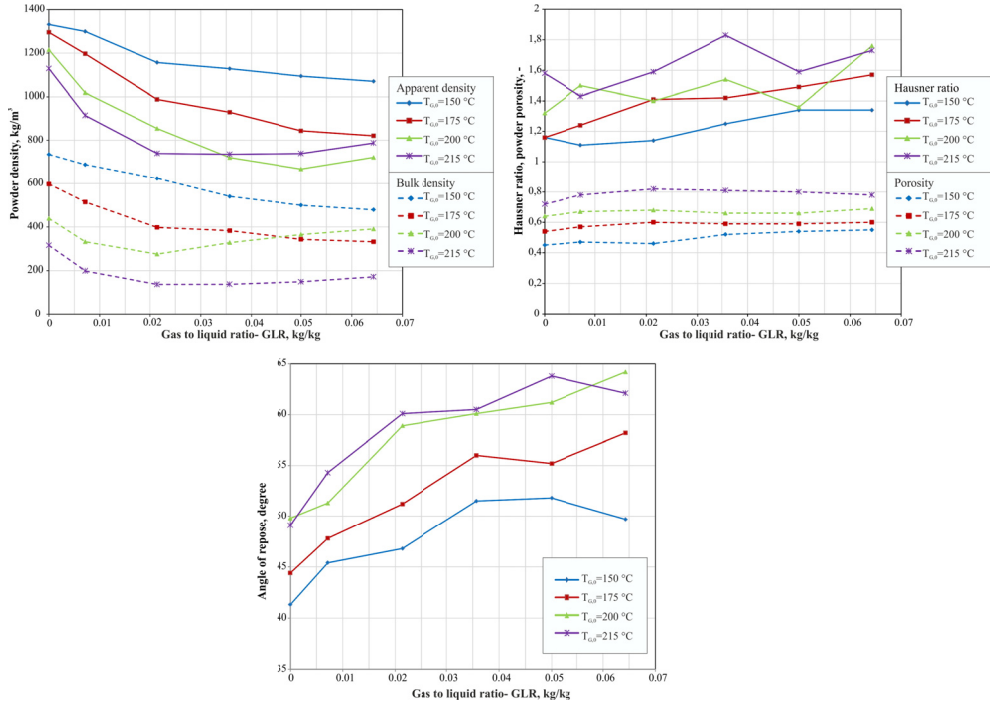

For highest GLR and high initial gas temperature increased number of smaller particles was observed as a results of particles breakage in the product.

Table 1. Average Sauter diameter of particles in the product.

Gas to liquid ratio- GLR	Average Sauter diameter, $\mu\text{m}$			
	$T_{G,0} = 150^\circ\text{C}$	$T_{G,0} = 175^\circ\text{C}$	$T_{G,0} = 200^\circ\text{C}$	$T_{G,0} = 215^\circ\text{C}$
$7.14 \cdot 10^{-4}$	52.96	52.98	51.84	51.91
$2.14 \cdot 10^{-3}$	55.82	55.05	55.22	51.07
$3.57 \cdot 10^{-3}$	54.82	58.05	58.00	55.80
$5.00 \cdot 10^{-3}$	59.82	59.71	55.94	55.07
$6.43 \cdot 10^{-3}$	57.72	61.91	56.62	57.06

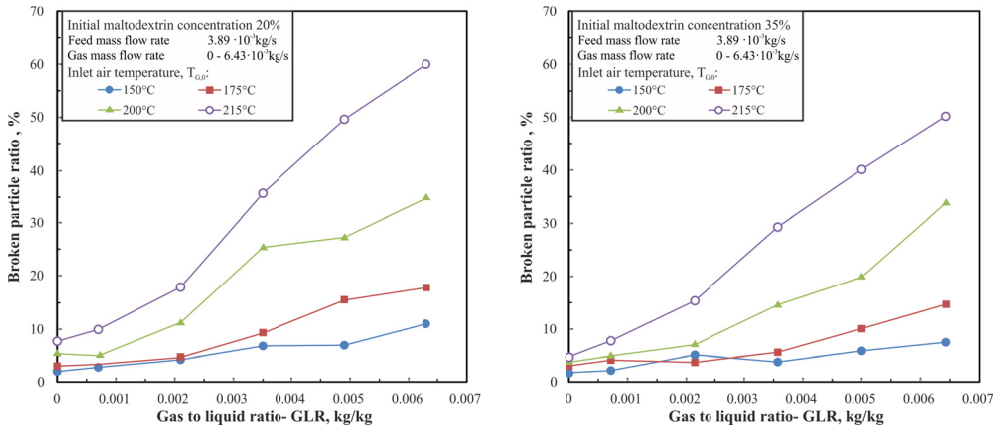

Fig. 2 displays selected morphological properties of the powders: apparent and bulk density, porosity and Hausner ratio and angle of repose as a function of GLR. Analysis of results presented in Fig. 2 shows significant effect of feed foaming on final powder properties.

**Fig. 2 Morphological properties of the powders.**

We observe almost twofold decrease of bulk density of foamed materials in relation to non-foamed feed. Angle of repose and Hausner ratio are growing with increasing of foaming gas flow rate (GLR) and initial temperature of drying air. Flowability of the powder changed from flowable (HR around 1.1) to cohesive (HR above 1.3). For the highest GLR (over  $5.00 \cdot 10^{-3}$ ) and air inlet temperature above 200 °C, increase of bulk and apparent density is observed which is a result of filling of free spaces between the particles in the product by fragmented particles. Similar conclusions can be drawn from Fig. 1, where sphericity of particles decreases to  $\Psi_k < 0.8$  with increasing of GLR which indicates particle breakage.

Fig. 3 presents experimentally determined ratio between number of broken and undamaged particles as a function of foaming gas flow rate, GLR, for different initial maltodextrin concentrations.

**Fig. 3** Broken particle ratio of powder obtained from foamed spray drying experiments for different operating conditions.

Number of broken particles dramatically increases with GLR and inlet air temperature. For GLR above 0.006 kg/kg and the highest drying air temperature, amount of broken particles in the product varies from 5% to 50-60 % due to particle overheating and bubble expansion. Proper selection of foam spray drying process parameters allow to reduce significantly number of damaged particles, to around 15 % even for the highest GLR.

#### 4. Conclusions

Co-current gas admixing foam spray drying tests was carried out in pilot-plant tower to determine physical and morphological properties of maltodextrine powder. Significant effect of feed foaming on sphericity, particle size distribution, angle of repose, apparent and bulk density, Hausner ratio and porosity of the powder was found.

Increase of a number of large and hollow particles with high sphericity and low bulk density, change of Hausner ratio from flowable (HR around 1.1) to cohesive (HR above 1.3) with increase of GLR was found.

For the highest GLR and air inlet temperature above 200°C an increase of bulk and apparent density was observed due to product degradation and fragmentation of particles as a result of high thermal expansion of bubbles.

Number of damaged particles can be significantly reduced, to around 15 % for the highest GLR for properly selected operational foam spray drying process parameters.

### **Abstract**

*Spray drying is widely used for powder production from liquid concentrates. Often low input temperatures are desired, as many materials, like proteins, are sensitive to heat. However, this demand leads to increased concentrate viscosities. Commonly used pressure swirl atomizers are limited concerning maximum processible viscosity. In this study, a so called Air-Core-Liquid-Ring Atomizer is used for pilot scale spray drying of whey protein concentrate (WPC80) at 40 °C and hence a viscosity of 0.09 Pa s. The produced powder was compared to an industrially produced reference. As a result, no significant differences in particle size distribution and particle morphology were observed.*

**Keywords:** *spray drying, atomization, ACLR, high viscous feeds, whey protein concentrate.*

## 1. Introduction

Spray drying is an important and widely used processing technique for powder production from liquid concentrates<sup>[1]</sup>. The process consists of three main steps: atomization, drying and powder separation. In the atomization step, the bulk concentrate is disintegrated into small droplets, in order to accelerate convective drying. For sufficient drying, all droplets have to be small enough to dry within the given residence time inside the spray dryer<sup>[2]</sup>. Consequently, mean droplet size and distribution width, generated in the atomization step, are of high importance for the subsequent processing steps. Generally, spray dryers should be operated at the highest possible input dry matter content, in order to insure economic operation<sup>[3]</sup>. Moreover, low input temperatures are desired, as many spray dried materials are sensitive to heat. Both demands lead to high concentrate viscosities<sup>[4]</sup> which complicates atomization for all known atomizer techniques<sup>[5]</sup>. On industrial scale, mainly pressure swirl atomizers are used. In this type of atomizer, high liquid pressures are used to deliver the required atomization energy. This type of atomization is very energy efficient, but the maximum processible viscosity is comparably low<sup>[5]</sup>. In laboratory or pilot scale spray dryers, often external mixing pneumatic atomizers are used. In this type of atomizer, the kinetic energy of compressed gas is used for droplet disintegration. In contrast to pressure swirl atomizers, the applied disintegration energy can be increased independently of the liquid flow. This allows the production of very small droplet sizes, even at high concentrate viscosity. However, high gas consumption rates of these atomizers do not allow economic operation on larger scales<sup>[3]</sup>.

Internal mixing pneumatic atomizers (IMPA) offer the possibility to atomize high viscous concentrates at low gas consumption rates<sup>[6-11]</sup>. One specific IMPA, proposed for spray drying purposes, is the so called Air-Core-Liquid-Ring (ACLR)<sup>[12]</sup> atomizer (see Fig. 1). In this atomizer, liquid concentrate and atomization gas are brought into contact with each other in a mixing chamber, shortly before the exit orifice. The specific gas injection geometry induces a continuous core of compressed gas in the middle of the liquid stream, leading to an enforced annular two phase flow inside the exit orifice. This kind of flow pattern is known to deliver constant spray droplet distributions at high viscosities<sup>[12,13]</sup>.

In the here presented study, a fresh liquid whey protein concentrate WPC 80, delivered by a dairy company, was processed in a pilot scale spray dryer, equipped with an ACLR atomizer. In order to investigate the potential of the ACLR atomizer to process high viscous concentrates, the input temperature before atomization was lowered (40 °C) in comparison to the corresponding industrial process (60 °C) of the supplier, leading to an increase of the viscosity by 50 % up to 0.09 Pa s. The produced powder was compared to the industrially produced reference by means of particle size distribution, water activity, moisture content and particle morphology.

## 2. Materials and Methods

### 2.1 Whey protein concentrate WPC 80

For the performed investigation, a fresh whey protein concentrate WPC 80 was used. The concentrate was delivered by Sachsenmilch GmbH, Leppersdorf, Germany. The concentration was executed in a membrane process. The dry matter content was given by the supplier as 36.1 %.

As reference, an industrially spray dried WPC 80 powder of the same supplier was analyzed for comparison to the powder, produced in the pilot scale spray drying process using the ACLR atomizer (See section 2.4).

### 2.2 Rheological characterization of liquid concentrates

The rheological characterization of the liquid concentrate was performed in a rotary rheometer (MCR 101, Anton Paar GmbH, Graz, Austria), equipped with a coaxial cylinder geometry (CC 27). The measurements were conducted at temperatures of 25, 40 and 60 °C and shear rates between 1 and 1000 s<sup>-1</sup>.

### 2.3 Process equipment

#### 2.3.1 ACLR Atomizer

A scheme of the used ACLR atomizer is given in Fig. 1. All parts are produced from stainless steel. The atomization gas is injected into the liquid stream, shortly before the exit orifice. For this purpose, a gas capillary with a diameter of 1.5 mm is used, leading to gas injection area of 1.76 mm<sup>2</sup>. The mixing chamber length is 2.4 mm. Diameter and length of the exit orifice are 1.5 mm each.

**Fig. 1: Scheme of the used ACLR atomizer. ( $l_{\text{mixing chamber}} = 2.4 \text{ mm}$ ,  $l_{\text{exit orifice}} = 1.5 \text{ mm}$ ,  $d_{\text{exit orifice}} = 1.5 \text{ mm}$ )**

### 2.3.2 Media supplies

The concentrate was supplied by an eccentric screw pump (MD 006-12, seepex GmbH, Bottrop, Germany). The flow rate was adjusted to 15.7 L/h and measured by a flow meter (VSI 044/16, VSE GmbH, Neuenrade, Germany). The concentrate was preheated before atomization to 40 °C in a tube heat exchanger. As atomization gas, compressed air, supplied by a compressor (Renner RSF-Top 7.5, Renner GmbH, Güglingen, Germany), was used. Air pressure was adjusted to 0.55 MPa by a pressure regulator. The gas volume flow through the atomizer's mixing chamber, resulting from gas pressure and liquid flow rate, was measured by a gas flow meter (ifm SD6000, ifm electronic, Essen, Germany) as 3.7 Nm<sup>3</sup>/h. The resulting gas to liquid ratio by mass (GLR) was 0.28.

### 2.3.3 Pilot scale spray drying process

A pilot scale spray dryer (Werco SD20, Hans G. Werner Industrietechnik GmbH, Reutlingen, Germany) with a maximum water evaporation capacity of 20 kg/h was used. The dryer was operated at an inlet temperature of 180 °C, an outlet temperature of 95 °C and a drying air flow of 470 kg/h.

## 2.4 Powder characterization

The powders were characterized by measurement of particle size distribution, moisture content, water activity and morphology. Particle size distributions were measured by a laser diffraction spectroscope with powder dispersion unit (Horiba LA950, Retsch Technology GmbH, Haan, Germany). Moisture contents were calculated by weight loss after oven drying at 105 °C to constant mass. Water activities were measured by a dedicated measuring instrument (AW Sprint, Novasina, Lachen, Switzerland). Investigations on particle morphology were performed with an environmental scanning electron microscope (FEI Quanta 650 ESEM) at the Laboratory of Electron Microscopy of KIT, Karlsruhe.

## 3. Results and Discussion

### 3.1. Rheological characterization of liquid concentrates

In the first step, the shear rate dependent viscosity of the fresh whey protein concentrate WPC 80 was investigated at different temperatures of 25, 40 and 60 °C. All investigations were performed in triplicate. The concentrates showed shear thinning behavior with increasing shear rate at all investigated temperatures. However, the decrease of viscosity between shear rates of 1 and 1000 s<sup>-1</sup> was pronounced with increasing temperature level. Moreover, the viscosity decreases with decreasing temperature at constant shear rate. (data not shown)

As high shear rates are expected in the atomization process, the viscosity at the highest shear rate, applicable in the used rheometer ( $1000 \text{ s}^{-1}$ ) are given in Table 1.

*Table 1. Concentrate viscosity at a dry matter content of 36.1 % at a shear rate of  $1000 \text{ s}^{-1}$  and different temperatures.*

Temp. / °C	Viscosity / Pa·s	
	mean	std
25	0.15	0.001
40	0.09	0.001
60	0.06	0.001

In the industrial process the concentrate is preheated to  $60 \text{ °C}$  before atomization. According to the here presented data, the viscosity in the moment of atomization is  $0.6 \text{ Pa}\cdot\text{s}$  in this case. However, it is reported in literature, that the viscosity of whey protein concentrates might increase in the first hours of storage<sup>[14]</sup>. As the concentrate had to be transported from the production plant of the supplier to our pilot plant, the viscosities in the industrial process might be lower than the here presented values. In order to observe the viscosity increase over time, rheological measurements were performed directly after receiving the concentrate, as well as one and two days later, though no changes in viscosity were observed (data not shown).

In order to investigate the potential of the used ACLR atomizer to process concentrates at lower preheating temperatures and therefore higher viscosities, the preheating temperature was lowered by  $20 \text{ K}$  to  $40 \text{ °C}$  in the performed pilot scale trial. This procedure led to an increase of the viscosity by  $50 \text{ %}$  up to  $0.09 \text{ Pa}\cdot\text{s}$  in comparison to the industrial process.

### 3.2. Spray drying process and powder characterization

The spray drying process with an ACLR atomizer was undisturbed during the whole trial time of  $83 \text{ min}$ . No sticky deposits in consequence of insufficiently dried particles were found inside the drying chamber after the trial. In Fig. 2 cumulative volume distributions of the powder particle sizes produced in the pilot scale spray dryer, as well as of the reference powder, are shown. The particle size measurements were performed fivefold. Both particle size distributions are similar. Small differences were found in fine particles, as well as in particles with sizes larger than  $100 \text{ }\mu\text{m}$ . The latter can most probably be traced back to agglomeration of primary particles, as the moisture content of the powder, produced in the pilot scale dryer, was significantly higher ( $9.1 \text{ %}$ ) than the one of the reference powder ( $5.4 \text{ %}$ ). Powders with increased moisture content are known to show increased stickiness and a tendency to build agglomerates<sup>[3]</sup>. However, it can be assumed, that the moisture content of powder can be reduced to the value of the reference powder, when the dryer height, and therefore the residence time inside the drying chamber, is increased to industrial level.

Nevertheless, water activity values of 0.20 (ACLR) and 0.12 (reference) show, that microbial stability is insured in both cases.

*Fig. 2: Cumulative volume distributions  $Q_3$  of powder particles, using ACLR atomization based processes (preheating temperature = 40 °C), as well as of an industrially produced reference powder.*

In Fig. 3, overview images of the industrially produced reference powder (left) and of the powder produced in the pilot scale process with ACLR atomizer (right) are shown. Regarding particle morphology, no significant differences between the powder samples were observed. Although, in the reference powder more wrinkled and irregularly shaped particles were found. This fact might be also based on the more progressed drying process, indicated by a lower moisture content.

*Fig. 3: Scanning electron microscope images of the industrially produced reference powder (left) and of the powder produced in the pilot scale process with ACLR atomizer (right)<sup>[15]</sup>.*

## 4. Conclusions and Outlook

In the presented study, the potential for use of an ACLR atomizer in pilot scale spray drying of a high viscous whey protein concentrate was shown. By decreasing the preheating temperature in comparison to the industrial reference process, the concentrate viscosity was increased by 50 % to a value of 0.09 Pa·s. The produced powder showed similar particle size distribution and particle morphology as the industrially produced reference powder. The moisture content was significantly higher (9.1 %) than the reference value (5.4 %). This is based on the comparably short residence time inside the pilot scale dryer. Increasing the dryer height, and therefore the residence time in the drying chamber, to industrial level, should lead to similar moisture contents. Nevertheless, a microbial stable product was produced in the pilot scale process, according to the water activity value of 0.2.

Further research will be performed in order to use the ability of the ACLR atomizer to atomize high viscous concentrates in spray drying processes. Besides the application of lower preheating temperatures this ability could also be used to atomize concentrates with higher initial dry matter contents, compared to currently used pressure swirl nozzles. Hence, the use of the ACLR atomizer offers the opportunity of energy savings and capacity increases in spray drying processes<sup>[16]</sup>.

### **Abstract**

*This paper deals with energy savings by the heat recovery of waste vapour from moist biomass drying in energy systems. Drying is an energy-intensive process. Energy consumption can be reduced by using indirect drying by recuperating the heat of waste vapour generated in the process; however the vapour is polluted by air and small mechanical particles. Experiments with green wood chips were realized on an indirect dryer with a condensing heat exchanger to experimentally verify the grade and conditions of heat recovery from waste vapour. On the basis of the experimental results, the potential of the heat recovery from waste vapour was evaluated.*

**Keywords:** *Indirect drying; Biomass; Waste vapour; Heat recovery.*

## 1. Introduction

Drying is an important process for creating optimal conditions for further material processing in many kind of industrial use. Industrial drying occurs by creating vaporization of the liquid by supplying heat to the wet feedstock. Heat may be supplied by convection (direct dryers) or conduction (contact or indirect dryers) [1]. In direct dryers, the material comes into direct contact with the heating medium, it is often hot air, flue gas or steam. In indirect dryers, the material and the heating medium (steam or hot water) are separated by a heat transfer surface. The heat is fed to the dried material through this surface, which defines the drying space. Generally, indirect dryers are more energy efficient. The typical energy consumption of direct dryers is in the range of 4.0 – 6.0 kJ per kg of evaporated water compared to indirect dryers which consume 2.8 – 3.6 kJ [1]. Additionally, if generated waste vapour is not mixed with drying or penetrating air, it leaves the dryer at a temperature close to 100 °C and its condensing heat can be recovered efficiently.

Drying is an energy-intensive process. The way to reduce the energy intensity of energy systems with drying is through the appropriate integration of contact drying with the use of heat recovery of the released waste vapour from the drying process [2]. The essence of heat recovery is vapour condensation together with gaining the vapour latent heat in an eligible heat exchanger. The main parameters limiting the further usage of this vapour are its purity and sufficient temperature level. The aim of the article is concentrated on an experimental evaluation of the potential and conditions of heat recovery from waste vapour which is generated during the drying of moist biomass in heating and power plants. Examples of heat recovery in the systems with integrated drying are shown in Fig. 1 [2]. The first case is a biomass fired steam power plant with an integrated indirect dryer heated

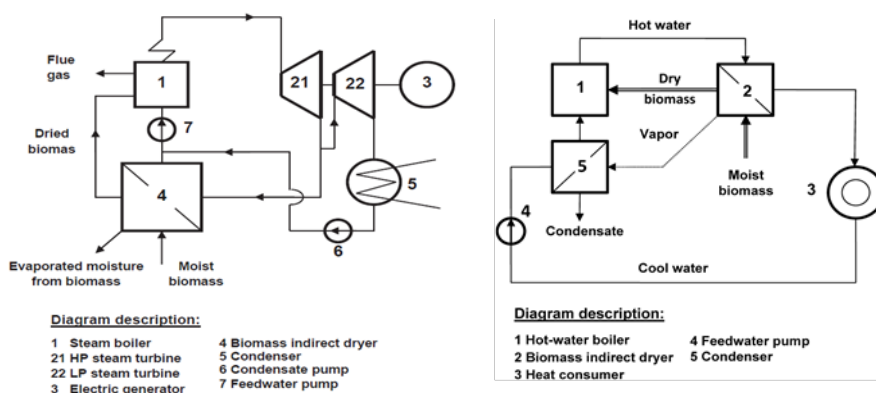

Fig. 1 Energy systems with indirect drying and waste vapour recuperation [2]

by low-pressure steam extracted from the turbine. The integration of the dryer increases the cycle efficiency and power production and allows for further use of the waste vapour for preheating the feed water, external consumption in the heating system or preheating the air for pre-drying the biomass in the convective air dryer. The second system is the integration of an indirect dryer and a waste vapour condenser to a hot-water heating cycle. The indirect dryer is heated by hot water from the boiler while the cooled backwater is preheated in the condenser by the waste vapour from the dryer.

## 2. Waste vapour recuperation

Waste vapour from biomass drying may contain infiltrated air, aromatics or small mechanical particles released from the biomass during drying, which complicates its energy utilization. A big problem is the infiltrated air contained in the vapour which has a significant influence on the heat transfer during vapour condensation even in small concentrations. Specifically, this negative effect is caused by a reduction in the heat transfer coefficient and at the same time by a decrease in the condensation temperature during the process caused by the decreasing concentration of the condensing water vapour in the mixture [3].

If a mixture of steam with inert gases condenses, non-condensable gases cause a difference in the concentrations of the steam in the bulk gas mixture  $C_{\infty}$  and at the condensation phase interface  $C_i$  equally with corresponding steam partial pressures  $p_{\infty}$  resp.  $p_i$  and temperatures  $T_{\infty}$  resp.  $T_i$  (see Fig. 2). The molecules of steam diffuse through an inert gas towards the vapour-liquid interface and mass transfer occurs [3]. Steam concentrations also decrease along the length. On the other hand, in the case of pure steam condensation, the temperatures  $T_{\infty}$  and  $T_i$  are identical and constant during the process.

Fig. 2 Heat transfer in a condenser surface

In the examined case, a constant value of the heat flux  $\dot{q}$  is considered for calculation of the heat balance (a constant heat flux from condensing steam, through condensate film, through the tube wall and to the cooling water). To determine the condensation temperature at the

phase interface  $T_i$ , it is necessary to take into account the mass transfer generated by the different partial pressures at the interface between the gas and the liquid phases  $p_i$ , and at the bulk gas mixture  $p_\infty$ . The process of waste vapour condensation was studied inside the tubes of the vertical tube condenser, and the effect of the operation parameters and a comparison with the pure steam condensation process were analysed in detail in [4].

### 3. Experimental set-up

The experimental set-up consists of a steam heated indirect dryer and a recovery heat exchanger (Fig. 3).

Fig. 3 Scheme of the experimental set-up

The dryer is designed as a rotating drum with a diameter of 600 mm and a length of 2000 mm. The drum walls and wings for material blending consist of heated tubes with condensing steam inside. Dried material is continuously fed inside the drum by a screw conveyer, and leaves it on the opposite side. The drying capacity is about 20 kg of evaporated water per hour. The recovery heat exchanger is designed as a vertical shell-and-tube condenser. The condensing water vapour flows downwards inside vertical tubes and the cooling water flows in a counter current in the outer shell. This configuration is used due to the potential fouling of tubes by small solid particles in the waste vapour from the drying biomass. These particles, which can stick to the tube wall, are spontaneously carried away from the tubes by the condensate blowing out. The heating surface consists of the tube bundle with 49 tubes 854 mm in length and with an internal diameter of 24 mm.

### 4. Results

Green wood chips with a moisture content from 62 to 66% were used for drying tests with waste vapour utilization (see Fig. 7). In the drying experiments, the moisture reduction in the drying material and the temperature of the outgoing waste vapour during the drying process was investigated. The entire drying process was described by a drying curve, which defines

the decrease in water content in the drying material over time [1]. An example of a drying curve for the dryer filled with material to 24% of the volume is shown in Fig. 4. The initial drop in temperature of the waste vapour is influenced by the heating of the material from the exchange of the inlet temperature to the evaporated temperature and by the air content which is gradually pushed out from the dryer by the generated vapour.

**Fig. 4 Drying curve and corresponding waste vapour temperature**

The stable temperature and waste vapour generating period between 60 and 180 min of the process in Fig. 4 was chosen for the evaluation of the waste vapour recovery potential. This state would correspond with the continuous operation of a large energy system. The investigated parameters were the amount of gained heat and its temperature level. In Table 1, the measured parameters of the recovery heat exchanger operation and the evaluated results are shown for three repeated experiments. The cooling water flow rate was set to reach its temperature near to a constant level due to better evaluation of a decrease in the condensing vapour temperature along the tube length. The vapour velocity at the inlet of tubes was about 2 m/s.

**Table 1. Utilization of waste vapour in the recovery heat exchanger**

Measurement	1	2	3
Waste vapour temperature – in / out (°C)	97.6 / 70.4	97.3 / 70.2	97.5 / 70.0
Air concentration in vapour – in / out (%)	8.9 / 77.1	10.1 / 77.4	9.4 / 77.6
Water temperature – in / out (°C)	54.9 / 55.9	54.7 / 55.7	54.6 / 55.6
<b>Results</b>			
Waste vapour utilization – exp. (%)	97.1	96.7	97.0
Waste vapour utilization – teor. (%)	98.8	98.5	98.3

The temperature of the waste vapour leaving the actual biomass dryer was between 99 and 97 °C with an air content of about 8 to 10%. The obtained results were compared with the

theoretically balanced and calculated values based on principles for heat and mass transfer for the case of steam condensation in a binary mixture [3] according to the proposed and experimentally verified model of heat transfer for air-steam condensation in a vertical tube condenser described in [4]. The experimentally determined vapour recovery is in good agreement with the theoretically calculated values for this case. Experimental verification of this process makes it possible to estimate the operation of the device beyond the measured parameters and allows for future optimization.

The bulk gas temperatures  $T_{\infty}$  and the condensation temperature  $T_i$  are different and decreasing during condensation. For this reason, some of the waste vapour always flows through the exchanger and does not condense. The temperature courses along the length of the condenser tube for measurement no. 3 are shown in Fig. 5. These courses were theoretically calculated through the use of a model of the heat transfer in a vertical tube condenser [4] regarding the measured temperatures at the inlet and outlet. The growth of the cumulative heat output along the heat transfer area, respective the tube length, was also analysed in Fig 5. An important conclusion for the heat exchanger design and optimization is that the majority (approx. 80%) of the recovered heat was obtained in the first half of the heat transfer surface. When increasing the amount of air to 20%, the surface would be extended by more than 50% to maintain the heat exchanger output. On the contrary, decreasing the air content to 5% would result in a reduction to 72% of the surface.

**Fig. 5 Parameters change in waste vapour condensation process**

In Fig. 6, the dependence of the utilization rate of waste vapour on the amount of infiltrated air (mass concentration) is shown for conditions approaching those of the actual industrial operation. The results are calculated according to the heat transfer model of the vertical tube condenser [4] for inlet temperatures of cooling water at 60 °C, 70 °C and 80 °C. For an appropriate comparison of the heat recovery potential, the geometry of the heat exchanger is

optimized for each case to heat the water by 5 °C, to maintain a vapour velocity at the inlet of 2 m/s and a temperature difference at the vapour outlet and water inlet of 2 °C. This value was chosen as the limit, if we sought to achieve a lower temperature difference, it would be necessary to increase the size of the exchanger with very little impact on increasing the heat output.

**Fig. 6 Potential of waste vapour heat recovery and temperature level of this heat**

For the value of infiltrated air of approximately 10% corresponding with the experiments above, the utilization rate would be above 90% for water heating at a temperature of 80 °C, more for water temperatures of 70 °C and 60 °C. However, optimization of the device could result in lower amounts of infiltrated air and a higher level of vapour utilization. On the other hand, a higher level of air penetration significantly decreases the utilization rate.

**Fig. 7 Tested material – green wood chips before and after drying**

**Fig. 8 Waste vapour condensate**

The obtained condensate from biomass drying contains aromatic and dust particles which were released from the raw fuel during the drying process and carried away by the waste vapour from the dryer. For this reason, the condenser is designed with vertical tubes in which

these particles are spontaneously washed out by the condensate. A comparison of the waste vapour condensate with the pure steam condensate is shown in Fig. 8.

After a series of experiments, a visual inspection of the heat exchanger surface was made and no visible fouling was observed. It can be stated that the proposed heat exchanger configuration is suitable for the condensation of waste vapour from biomass drying.

## **5. Conclusion**

Based on the results of the experiments with the heat recovery from biomass drying, we can conclude that the waste vapour generated in indirect drying systems with limited air penetration has a sufficient potential for further energy utilization. The waste vapour exiting the tested drying device at atmospheric solution reached temperatures ranging from 97 to 99 °C with an air content of about 10%. These conditions correspond with the potential of recovering more than 90% waste vapour condensing heat at the level of gained heat of 80 °C e.g. for water preheat.

The following principles are important in the design of a system with heat recovery of the waste vapour from indirect drying. Even small amounts of air in the waste steam cause a significant decrease in the heat transfer coefficient and the heat output of the recovery heat exchanger. The majority of the heat output is transferred in the first part of the recovery heat exchanger, which allows for economical optimization of its size. Waste vapour from some solid materials can contain small mechanical impurities, which can stick to the heating surface of the recovery heat exchanger, therefore it needs to be customized for cleaning. Condensers with vertical tubes seem to be a good solution in this case.

### **Abstract**

*We carried out drying studies on a 2.5D micromodel based on a thin section of a carbonate rock to investigate the impact of wettability on the capillary disconnect, the moment when liquid films de-pin from the external evaporating surface. While this is coincident with the transition to low evaporation rate (diffusion limited) for deionized-water, our experiments show, the corner wetting films persisted after the transition to low evaporation rate for both water-wet and mixed-wet micromodels for brine, as solid salt continued to build up at the external evaporating surface. Fully oil wet micromodels showed a drying rate transition coincident with de-pinning.*

## 1. Introduction

Understanding the underlying physics of the drying process in contaminated porous media is central to many of its applications, such as soil remediation, gas injection into geological formations for enhanced oil recovery and CO<sub>2</sub> sequestration processes, etc. Although many studies have been done on the kinetics of the drying process in porous media. There are still some knowledge gaps, especially when it comes to adequately predicting the extent of the different stages of evaporation in porous media of varying wettability. Classically, early stages of evaporation from a porous media are characterized by a relatively fast and “almost” constant evaporation rate, known as the constant rate period (CRP). This is followed by a transition period characterized by a large drop in evaporation rate, known as the falling rate period (FRP). The late stage of evaporation is characterized by a very slow evaporation rate limited by vapour diffusion through the porous media, this stage is known as the falling rate period (FRP) Materials and Methods [1-6].

The kinetics of the three periods are controlled by different mechanisms. For de-ionized water in a water-wet porous media, early stage evaporation is by water mass transfer by capillarity through wetting films to the evaporating surface, due to the stronger adhesion of water molecules to the pore walls compared to cohesive between water molecules [2]. Drying here is said to be controlled by external demand such as temperature, the flow rate of drying gas, relative humidity, the surface area of the evaporating surface and so on. During this period, the porous media behaves as though it is fully saturated because the mass transport through capillarity is sufficient to sustain evaporative demand at the surface [3, 5]. Simply, the constant rate period is dominated by capillarity due to hydraulically connected pores [7]. In time, gravity and viscous forces will overcome the capillary driving forces at some depth down the porous media, hydraulic connectivity to the evaporating surface will cease at this point and the drying surface will move to within the porous medium. This marks the end of the constant rate period (stage-1 evaporation) and the beginning of the falling rate and receding front periods (stage-2 evaporation) [4, 5, 7].

There is a very sharp drop in evaporation rate during the falling rate period and , this period can also be called a transition stage as evaporation quickly transitions from a capillarity dominated period to a diffusion dominated period with continued drop in evaporation rate [1, 5, 8] until complete drying (i.e. from CRP to RFP). Hence, internal mass transfers such as vapour diffusion, pore space geometry, thermal and hydraulic conductivities etc. control drying during stage-2 evaporation. Here, the drying rate varies linearly with the square root of time [5, 9]. The drying of brine-containing porous media such as saline aquifers, oil and gas reservoirs, building materials etc. causes the dissolved salt to crystallise within (sub-florescence) and outside (efflorescence) the porous media when the solubility limit of the salt is exceeded [10]. Salt crystallization (crystallisation/dissolution cycles) can cause a

lasting damage to building materials, and these problems have been studied extensively within the civil engineering research community [11-15]. Salt crystallisation can also lead to a significant decrease in porosity and permeability of underground reservoirs like saline aquifers. This decrease in permeability can lead to an increase in injection cost and a reduction of storage potential during CO<sub>2</sub> sequestration processes.

A number of phenomena affect drying dynamics and the consequent salt deposition in a porous medium, some of these phenomena have been studied and reported in past literature. For example, the drying rate is strongly influenced by the spatial distribution of the liquid and that, in turn, is controlled by capillary forces at the pore scale. However, the effect of the wetting films and corner menisci on drying kinetics and salt crystallization is still somewhat unclear. In the present study, we aim to shed more light on the effect of porous media wetting conditions on the different stages of evaporative drying. Given that oil reservoirs have a wide range of contact angles (wetting states) and with the fact that capillarity through corner wetting films is strongly dependent on the wetting states of the pore walls. One can assume that the disconnection in capillarity or depinning of the wetting films from the evaporating surface (marking the end of stage-1 evaporation) will be strongly affected by the wetting state of the porous media. Lastly, we have carried out this study with a model porous media, a micromodel based on a thin section image of a carbonate rock. Working with micromodels allow us faster observations (better time resolutions) and direct visual observation of pore-scale processes in a network of pores.

## 2. Materials and Methods

This study was done using micromodels that are based on a thin-section image of a sucrosic dolomite rock [5, 9]. These micromodels were fabricated with a silicon wafer, covered with a transparent glass, allowing direct real-time visualization of pore-scale processes. The micromodel has a constant etch depth of 25 $\mu$ m, with a matrix dimensions of 2.5 x 1cm<sup>2</sup>. A DSLR (digital single-lens reflex) camera (D800E, Nikon) and an inverted light microscope (AxioObserver A1.m, Zeiss) was used to obtain a wide field of view and high-resolution images respectively. Freshly prepared NaCl solutions were prepared for the different concentrations used in this study, i.e. 0 wt% (deionized water), 18 wt% (3M NaCl solution) and 36 wt% NaCl solution (6M or saturated NaCl solution). Fluorescein (46960-2SG-F, Sigma-Aldrich. 1:700000 v/v) was added to the brine solutions for easier phase differentiation. Brine was injected with a 10 mL syringe (BD Plasipak, BD300013) using a programmable syringe pump (BS-80000, Braintree Scientific Ltd.). After saturating the micromodel with brine, dry air flow-line was attached to one of the inlet ports, while its adjacent port was opened to the atmosphere for continuous flow of dry air through one of the fracture channels in front of the matrix for evaporative drying. As the drying front moves back into the matrix, images of the dry-out evolution were taken at different time intervals and the salt precipitation in its wake was observed in real time. To obtain

quantitative data from the images, ImageJ was used to calculate the dry pore area (equivalent to mass lost by evaporation) of each of the captured images. More explicit details on the micromodels, imaging techniques, experimental procedure and quantitative data acquisition are provided in two recently published papers [5, 9].

### 2.1 Micromodel Wettability Alteration Technique

The micromodels were originally water-wetting by oxidation of the silicon wafer at high temperature during the manufacturing process. To obtain, mixed-wet and oil-wet conditions, the micromodels were treated with a new wettability alteration technique. Well established techniques based on silane chemistry [16] could not be used because the silane reacts with the water phase (necessary to the generation of mixed wettability) during the treatment. Also, alteration with crude oil [17] could not be used because it renders the micromodel opaque after treatment. The new technique involves a solution of silicone caulk (151 Products Ltd.) (10v/v %) dissolved in Dodecane ( $\geq 99\%$ , Sigma-Aldrich) (90v/v %). For mixed-wetting conditions, this solution was injected into the micromodel initially saturated with deionized water and then left to age for about 2 days at ambient conditions. Note that this leaves water wet corners in channels that are otherwise altered to oil wet. The micromodel was then dried by passing dry compressed air through it, before placing it in an oven at 60°C for 24 hours. For uniformly oil-wetting conditions, the silicone solution was injected straight into a dry micromodel. More details of this new technique are provided in a recently published paper [9].

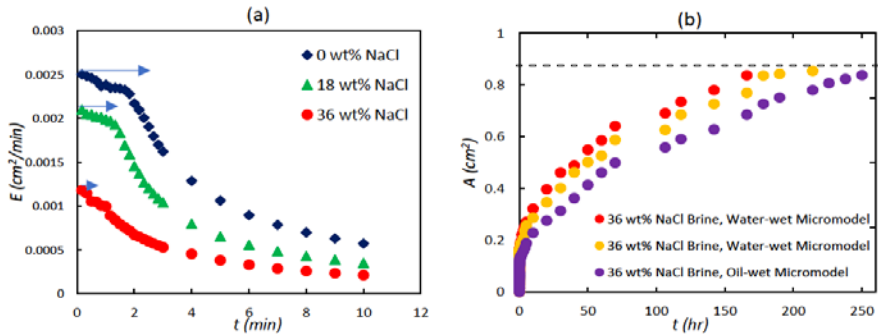

## 3. Results and Discussion

We determined the evaporation rates from the experiments by calculating the pore dry area as a function of time. The evaporation rates at ambient conditions and a relative humidity approximately equal to zero for 0 wt% NaCl (deionised water), 18 wt% NaCl brine and 36 wt% NaCl (saturated brine) solution in a water-wet micromodel are plotted in figure 1a. The evaporation rates were initially almost constant before a sharp drop after about 2mins for deionised water, 1min for 18 wt% NaCl and almost immediately for saturated NaCl brine. For deionised water these periods correspond to the classical periods of evaporation expected from earlier experiments and modelling in porous media drying: stage-1 evaporation (or the CRP) in which liquid remains connected to the drying surface through capillary forces, and the stage-2 evaporation (a combination of the FRP and the RFP) at which the hydraulic capillary connection to the evaporating surface is broken and water transport becomes dominated by vapour diffusion.

From figure 1a, the same trend of two stages can be seen for the plots of 18 wt% NaCl brine and saturated NaCl brine albeit with different duration for their stage-1 evaporation. The stage-1 evaporation is almost non-existent for the saturated NaCl brine. However, unlike the deionized case, the transition to stage-2 with brine is not due to capillary

disconnect to the evaporating surface because we continue to see a gradual increase in the amount of salt deposited at the fracture channel, figure 2a and the salt can only be transported in the liquid phase.

**Figure 1. Evolution of drying: (a) Evaporation rate as a function of time for the water-wet micromodel (blue arrows signify the extent of the stage-1 evaporation) and (b) Dry pore area as a function of time for saturated NaCl brine at the three different wetting states ((horizontal black dotted line shows the total pore dry area =  $0.7\text{cm}^2$ ).**

The change in slope for the brine solutions is due to the deposited solid salt acting as a physical mass transfer to the surface, as well as the increase in the viscous resistance due to the relatively higher viscosity of the NaCl brine compared to deionized water.

The same evaporative drying procedure used for the water-wet micromodel was used for the mixed-wet and oil-wet micromodel. Figure 1b shows the plot of the area of the micromodel occupied by air (equivalent to mass lost by evaporation) as a function of time for complete dry-out of saturated NaCl brine in the three wetting states. Although the trends in the plot of the three wetting states are very similar, the duration of complete dry-out increases systematically from the water-wet to oil-wet micromodel. This is as a result of the absence of corner wetting films needed for the high evaporation rate, especially during stage-1 evaporation. Less salt was deposited in the fracture channel of the mixed-wet micromodel compared to the water-wet micromodel as seen in the images in figure 2b.

**Figure 2. Images showing deposited salt in the evaporating surface and in the matrix below at the end of complete drying (i.e. liquid saturation = 0) for (a) Water-wet micromodel, (b) Mixed-wet micromodel and (c) Oil-wet micromodel.**

Further, only a very small amount of salt (probably from the brine solution present in the channel prior to drying) were deposited at the evaporating surface for the oil-wet micromodel, figure 2c. The reason for this is the absence of wetting films needed to maintain hydraulic connectivity to the surface in the fully oil wet case.

Finally, results for the 36 wt% NaCl brine in a water-wet micromodel and oil-wet micromodel are compared directly in figure 3 below. The schematics show liquid films at the corners of the micromodel grains percolating at the onset of drying. The thickness of the films decreases as drying continues until no connected pathway remains to the external evaporating surface. For deionized water, this would mark the onset of slower, stage-2, evaporation. However, from our experiment, the corner wetting films persisted after the transition to low evaporation rate, as sold salt continued to build up at the external evaporating surface.

**Figure 3.** Dry pore area as a function of time for a 36 wt% NaCl brine (saturated) solution in a water-wet micromodel and oil-wet micromodel. The inset images are schematic representations of a section of the micromodel (fracture and matrix) at different times. (a) At the onset of drying with fracture full of gas and thick corner wetting films ( $t \approx 10$ s). (b) During drying in an oil-wet micromodel, with little solid salt in fracture and no corner wetting films ( $t \approx 30$ mins). (c) During drying in a water-wet micromodel, with solid salt in fracture and very thin corner wetting films ( $t \approx 30$ mins). Model grains are represented in black, wetting films are indicated in light blue while deposited solid salt is represented in red.

#### 4. Conclusions

During the CRP (stage-1 evaporation), dry air entering the micromodel to balance the water loss becomes saturated with water vapour, leading to little evaporation occurring at this stage. We studied the effect of capillarity, wetting state and salt precipitation on the duration of the CRP from a model porous media. Evaporation from water-wet and mixed-wet micromodels saturated with deionized water (0 wt% brine) were similar and follow the well-established theory of drying from a porous media: a constant, high evaporation rate maintained by capillary forces through wetting films to the evaporating surface, followed by a transition (break in capillarity to the evaporating surface) to a much lower evaporation rate (stage-2 evaporation) characterized by vapour diffusion. However, for the brine solutions (18 wt% and 36 wt% NaCl brine), capillarity to the evaporating surface was maintained even during stage-2 evaporation, evidenced by the continuous deposition of salt in the fracture of the micromodel well into the FRP (stage-2 evaporation). Hence, the capillary connection can be maintained even during the FRP for the drying of brine contaminated porous media.

The evaporation dynamics for a mixed-wet micromodel and a water-wet micromodel are very similar, the only difference is the slightly earlier transition observed in the mixed-wet micromodel. On the other hand, the oil-wet micromodel emphasized the effect of the wetting state on the evaporation dynamics. The evaporation rate dropped as soon as drying started as a result of the absence of corner wetting films needed to supply evaporative demand at the surface. This leads to very little deposited salt at the fracture as well as an increase in the overall drying time.

### **Abstract**

*An ultrasonic design based on the indirect transmission of ultrasonic energy from the ultrasound emitter through to the material to be dried was investigated to assist in low temperature drying of food materials. The application of the improved design tested in this work was found to enhance the low temperature drying by shortening the overall drying time of up to 45% (i.e., lower energy consumption and may enable better retention of product quality). This offers a promising approach towards a better applicability of ultrasound in industrial operation, since no direct contact between the sample and the ultrasonic emitter is needed.*

**Keywords:** *ultrasound; drying; low temperature; drying intensification.*

---

## **1. Introduction**

Many drying techniques evolved due to the need to produce high quality products that are highly heat-sensitive. Such drying systems include the utilization of low temperatures, but often require a very long drying time, highly energy consuming and detrimental to the product quality. These limitations can be overcome by the combined application of ultrasound, which has been demonstrated in previous studies to intensify the convective drying processes.<sup>[1,2]</sup> However, the development of ultrasound assisted drying technology at an industrial scale has progressed at a slow pace due to the difficulties in achieving an efficient transmission of ultrasonic energy from the plate transducers to the product while ensuring easy adaptability to conventional drying processes.

The ultrasonic systems reported in the literature for food drying application may be grouped into two main types. The first type is made up of ultrasonic devices that are directly coupled to the food material during drying. The direct contact system can promote an accelerated drying process because this system permits good transfer of ultrasonic energy from the vibrating element to the food material. Nevertheless, the main drawback of this technique may be its difficulty to adapt to traditional airflow drying processes and in operation other than a batch-wise process.

Another type was developed based on the application of airborne ultrasound. The airborne ultrasonic system works without direct contact between the vibrating element and the food material, which seems to offer much better adaptability to conventional air drying processes. However, the main difficulties in this system arise from the inefficient generation of ultrasonic energy in air and the transfer of such ultrasonic energy from air into the product due to the acoustic impedance mismatch and the energy absorption by the air at ultrasonic frequencies.<sup>[3]</sup>

The aim of this work was to develop and test an improved design concept for an effective application of ultrasound at high frequencies that would allow easy adaption in continuous processing while facilitating efficient ultrasonic energy transmission to intensify low temperature drying of food materials.

## **2. Materials and Methods**

Fresh apples (cv. Granny Smith) obtained from a local market (Werribee, Victoria, Australia) were used as the model test material and were stored at 4°C until further processing. The sample preparation has been described in detail by Sabarez et al.<sup>[2]</sup> The fresh apple samples were found to have an average initial moisture content of 86.0% (wet basis).

Drying experiments were carried out in a computerised ultrasound-assisted convective drying setup as described elsewhere<sup>[2,4]</sup>, which had been modified to retrofit the improved ultrasound transmission system (Fig. 1). The ultrasonic transmission system consisted of a transmission platform, cooling unit (Model BL-130, Thermoline, Australia) to control the temperature of the transmission platform, and a plate transducer using Blackstone-Ney Ultrasonic Generator (Blackstone-Ney Ultrasonics Inc., Jamestown, New York, USA).

*Fig. 1. Ultrasound transmission setup (1=transmission plate; 2=frame for containing the cooling/heating liquid; 3=cooling/heating liquid; 4=transducer).*

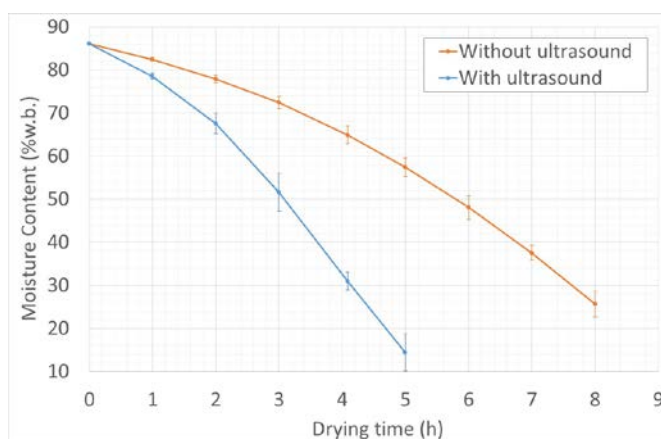

The advantage of this experimental drying system is that it consists of a number of additional sensors (i.e., thermocouples, infrared noncontact temperature sensors, air velocity sensors, humidity sensors, etc.) that are interfaced to a computer-based data acquisition and control system for continuous online monitoring and recording of the various processing conditions (i.e., drying time, material temperatures, air temperature, air relative humidity, and air velocity).

Two sets of drying experiments were carried out without ultrasound and with ultrasound at a frequency of 40 kHz. In these experiments, the apple ring samples were directly placed on the transmission platform. Four annular apple rings prepared as outlined above were used for each drying experiment. All drying experiments were replicated at least twice. The details of the drying procedure can be found elsewhere.<sup>[2,4]</sup>

### 3. Results and Discussion

Figure 2 shows a typical example of the drying kinetics during the convective air drying of 5 mm apple samples (about 100 g) at 40°C temperature (T) without and with ultrasound at 40 kHz frequency with power level of 466 W. These experiments were conducted with drying air velocity (V) and relative humidity (RH) maintained at about 1.2 m/s and 25%, respectively.

It is clear from Figure 2 that the application of ultrasound in combination with convective air drying significantly reduced the overall drying time. To achieve the target moisture content of 25% in wet basis (i.e, typical moisture content of ready-to-eat fruit snacks), analysis of the drying curves revealed that it took about 8.0 hours to dry the apple samples without ultrasound and just 4.4 hours with ultrasound using the improved ultrasonic transmission system. The results indicate a significant reduction in drying time of about 45% with the simultaneous application of ultrasound on the convective drying of apple slices (corresponds to a 32% reduction of energy consumption).

**Fig. 2. Effect of ultrasound (40 kHz frequency; 466 W power) on the drying kinetics of apple slices ( $T=40\text{ }^{\circ}\text{C}$ ;  $RH=25\%$ ;  $V=1.2\text{ m/s}$ ; 5mm thickness).**

The plot clearly shows that the ultrasonic transmission system developed and tested in this work was highly effective in intensifying the convective drying process. It also demonstrates that high frequency ultrasound can assist in enhancing the convective drying process. Although most of the physical mechanisms by which low frequency ultrasound enhanced the drying process are highly suppressed at high frequency, the observed enhancement in drying with high frequency ultrasound may be explained by Stokes' law of attenuation. Higher frequency ultrasound undergoes more attenuation, inducing more microstreaming (a non-thermal effect that occurs due to a pressure gradient generated by absorption of ultrasound during propagation) thereby increasing the diffusivity of water. So far, no studies have been reported on the application of ultrasound at higher frequencies in assisting food drying processes. Most of the studies were carried out at low frequencies (20-26 kHz) with drawbacks of low energy efficiency and high noise levels, with the ultrasonic

energy transmitted either in direct contact between the vibrating plate and the product<sup>[5,6]</sup> or airborne to the surface of the product.<sup>[2,3,4,7,8]</sup> These studies have reported significant reductions in drying time with the application of ultrasound, depending on ultrasonic parameters, drying conditions and properties of the materials to be dried.

Sabarez et al.<sup>[2]</sup> found a significant reduction in drying of up to 57% with the application of airborne ultrasound during drying of 5 mm apple samples. Under these drying conditions, an approximately up to 54% reduction in energy consumption during drying could be achieved with the application of airborne ultrasonic energy. Similarly, Garcia-Perez et al.<sup>[7]</sup> found a significant reduction in drying time (up to 70% at acoustic power of 90W) with the application of power ultrasound for convective drying of eggplant cylinders. Ortuno et al.<sup>[9]</sup> observed that the application of ultrasound (power level of 90 W) provided an average reduction in drying time of over 45% for drying of orange peels. They found that the energy saving was close to 30% with ultrasonic application.

The differences in drying time reduction and energy saving between these studies and the present work could be due to the differences in the raw material properties, drying conditions and ultrasonic parameters (i.e., particularly ultrasonic frequency, power and mode of ultrasound transfer). In the present study, high frequency ultrasound is transmitted indirectly through to the transmission platform (liquid and steel) and into the material to be dried. This allows for an efficient transmission of ultrasound to the material to be dried as the mismatch of acoustic impedances of these materials (steel, liquid and food) is minimized, and would enable for operation in conjunction with traditional air drying, along with easy integration in continuous processing as there is no direct contact between the ultrasonic emitter and the food samples to be dried.

#### **4. Conclusions**

The application of an improved ultrasound transmission system was found to significantly intensify the low temperature air drying of apple samples by reducing the overall drying time (i.e., lower energy consumption and may enable better retention of product quality). This offers a promising non-thermal means for gentle (i.e., low temperature) drying of food materials to produce premium quality food products, with better applicability at industrial scale as no direct contact between the food material and ultrasonic transducer is needed. In addition, the present study demonstrates that high frequency ultrasound can assist in enhancing convective drying with much reduced noise levels. The results from this work will provide the basis to build upon the development of this technology and justifies further investigations for implementation in industrial drying operations.

### **Abstract**

*The drying kinetics of celery in a microwave assisted fluidized bed dryer was studied at different drying air temperatures (45°C, 55°C and 65°C) and at different initial microwave power densities (0W/g, 1W/g and 2W/g). Dried product quality, product mass, air temperature, air relative humidity, and electric power consumption were used to monitor the performance of the drying process. The results showed that the Midilli-Kucuk model was best in predicting the moisture ratio as a function of drying time. At any given temperature, the utilization of the microwave energy reduced by more than 50% the drying time.*

**Keywords:** *drying; celery; MWFBD.*

---

## **1. Introduction**

The ethical implications involved with increasing world food insecurity and food wastage has led researchers to look for methods to reduce food wastage. Drying is one of the oldest and best methods that can be successfully used to reduce food loss and increase shelf-life. Drying results in reduction of spoilage of perishable food, and requirements for product storage and transportation. Various drying methods can be used to achieve the desired dried products; the choice of the dryer depends upon product requirements and process parameters.

Drying using hot air is efficient for falling rate period but takes longer time for constant drying rate period due to high resistance to moisture transfer and reduction in thermal conductivity of the product. Application of microwaves, in addition to hot air, helps in reducing drying times and results in better efficiencies for the constant drying rate period. This increase in efficiency can be attributed to the volumetric heating of the product exposed to microwave energy which leads to evaporation of internal moisture, which creates a pressure gradient for liquid and vapor transfer [1]. In addition, use of hot air with fluidization moves the evaporated moisture away from the surroundings of the product [1].

Celery is a high moisture commodity and it is extremely perishable. Celery is a popular ingredient used in soups and stews to enhance the flavor and aroma [2, 3]. Celery has significant amount of essential oils with different terpenes and limonenes [4], and it is a good source of various vitamins and minerals [2, 4]. It has been used as aphrodisiacs, anthelmintics, antispasmodics, sedatives, stimulants, and tonics. Some authors have reported its beneficial effects to treat against asthma, bronchitis and rheumatism [2-4]. Celery can be used by diabetics or people on low sodium diets due to the presence of an active component similar to insulin [3].

Several studies can be found on drying celery and celery leaves such as microwave drying of celery leaves [5, 6], effect of microwave power on celery leaves in microwave drying [2], and vacuum drying of celery [3]. Zaremba (2007) developed a model and concluded that drying time for sliced celery in fluidized bed was less than fixed bed for same drying temperature [7]. Karathanos (1993) reported on the effects of freeze drying and air drying on the internal structure and final product quality [8].

Drying kinetics is used for the design of drying processes [9]. Drying kinetics behavior helps in the design, optimization and simulation of the drying process [10]. Also, mathematical modeling and simulations are commonly used to optimize the drying process and to improve the final product quality [9]. Optimizing process parameters such as air temperature, microwave power density and air flow rate [11] ensure that the quality attributes such as color, shape, nutritional composition and texture are preserved [12].

The aim of this study was to investigate the drying kinetics of celery in microwave fluidized bed dryer and to assess the effects of drying conditions on the quality of final dried product.

## **2. Materials and Methods**

### **2.1 Experimental Procedure**

A central composite design was used to study the effects of initial microwave power density (IMPD) and air temperature on the quality of celery in a microwave assisted fluidized bed dryer. The IMPD (W/g) was the applied microwave power at the start of the drying process divided by the initial mass of the product. Both factors had 3 levels each; with initial microwave power density of 0W/g, 1W/g and 2W/g, and drying air temperature of 45°C, 55°C and 65°C. No pretreatments were done in this study. Data acquired was used to determine optimum drying conditions based upon product quality parameters and drying time. Parameters recorded and compared were the drying time, change in color, rehydration ratio, and texture of the rehydrated product. The product mass, air velocity, air and bed temperature were recorded at 10mins intervals. At start, the dryer was run empty to reach steady state conditions. The sliced celery was then added to the drying chambers and the drying cycle was started. A data acquisition system (DAQ) Agilent 34970A was used to record and store process conditions measured by different sensors connected to the dryer. Drying time of the product was the time required to reach final moisture content of 15% wet basis (wb). All trials were performed with 250g of freshly sliced celery pieces. As the drying progressed, the air velocity was adjusted to maintain good fluidization.

### **2.2 Celery**

Fresh celery was bought from local markets and stored in plastic bags in a refrigerator at 4°C. Initial moisture content of celery was determined before each run. It averaged at  $94.5 \pm 0.5\%$  wb. Prior to drying, the celery was sliced into pieces using an onion chopper (Starfrit model 093413, Atlantic Promotions Inc., Canada). The chopper blades assembly had opening of 12mm by 12mm.

### **2.3 Microwave Fluidized Bed Dryer**

The schematic diagram of the microwave fluidized bed drying system is presented in Figure 1. An experimental microwave oven (Panasonic Inc., CA) with a maximum output of 700W at 2450 MHz was modified for the drying experiments. Two 2 kW hot-air heaters were used to preheat the air and they were controlled by the same PID controller (CN9500, Temperature Controller, Omega, USA). The fluidization chamber was made of glass with dimensions of 100 mm in diameter by 300 mm in length and it was installed inside the microwave cavity. Perforated plates made of polypropylene were placed at the bottom and top of the fluidizing chamber, and attached to the wall of the microwave cavity. Humidity sensors, temperature probes, and anemometers were installed at different locations inside the air distribution system (Figure 1). Power sensors were used to monitor electrical consumption of heaters, blower and microwave.

Figure 1. Schematic diagram of the fluidized bed dryer

## 2.4 Drying Kinetics

Predictive mathematical models found in the literature [13] were used to study the drying kinetics of sliced celery in the microwave assisted fluidized bed dryer. These models express the relationship between the moisture ratio (MR) and the drying time.

MR is dimensionless and it was calculated using the following equation:

$$MR = \frac{M_t - M_e}{M_0 - M_e} \quad (1)$$

where MR is the moisture ratio (dimensionless),  $M_0$  is the moisture content dry basis (db) at time  $t = 0$ ,  $M_t$  is the moisture content (db) at time  $t$ , and  $M_e$  is the equilibrium moisture content (db) (=17.647%).

Drying time to reach 15% moisture content (wb) was also calculated and compared to assess the effects of drying conditions.

## 2.5 Dried Product Properties

The final moisture content of the product was determined by oven drying at 70°C until constant mass was achieved.

Rehydration capacity is an important factor in products that can be used for instant soups [14]. The rehydration capacity of the dried product was determined by immersing 1g of the dried celery in boiling water for 20 mins. It was done in triplicates for all drying conditions.

$$RR = \frac{M_r}{M_d}, \quad (2)$$

where RR is the Rehydration Ratio (dimensionless),  $M_r$  is the mass of the rehydrated product (g), and  $M_d$  is the mass of the dried product (g).

Visual and textural attributes are important sensory parameters of a food product. Reactions such as pigment degradation (such as carotenoids and chlorophyll), and browning reactions takes place during thermal processing of food products leading to color changes and need to be monitored [5]. A Minolta Chromameter Model CR-300 (Minolta Co. Ltd., Japan) was used to measure the color of the rehydrated samples using the CIE Lab color space. These values were then used to measure the change in color ( $\Delta E$ ) between the fresh and the rehydrated sample. The mechanical properties of the rehydrated samples were measured with an Instron Universal Testing Machine (Instron-4502, Instron Corporation, USA) equipped with a Kramer shear press. The Kramer shear cell was used because it simulates the effect of a single bite. The parameters recorded included the energy required to compress and shear the sample, and the maximum force applied. Texture measurements were made in triplicates.

### 3. Results and Discussion

#### 3.1 Drying Kinetics

A typical curve representing the changes of moisture content against the drying time is shown in Figure 2.

*Figure 2. Moisture content vs drying time for drying air temperature 55°C and initial microwave power density (IMPD) 1W/g*

Figures 3 and 4 represent typical MR curves for microwave assisted fluidized bed drying of celery at different temperatures and microwave power density. Slope of the drying curves indicate the speed of mass transfer within the sample for the operating conditions used in the drying process. As seen in Figures, the slope of the drying curves increased with increase in temperature and microwave power density.

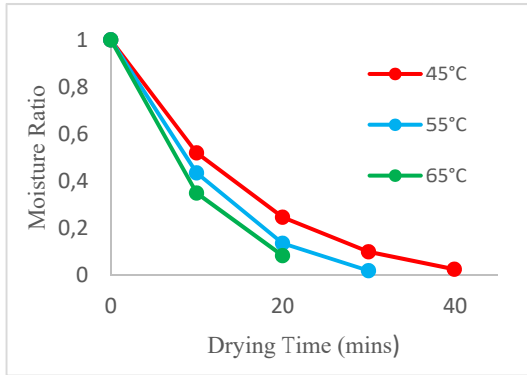

Figure 3. Effect of air temperature at initial microwave power density (IMPD) of 2W/g on moisture ratio during the drying process

Figure 4. Effect of initial microwave power density at drying air temperature 55°C on moisture ratio during the drying process

### 3.1.1 Mathematical Model

Out of all the models studied, the Midilli-Kucuk equation was the best model to predict the MR as a function of drying time for drying celery in a microwave assisted fluidized bed dryer at 55°C and 1W/g (Figure 5). The general form of the Midilli-Kucuk equation can be written as:

$$MR = ae^{-k(t)^n} + bt, \quad (3)$$

where a is a coefficient (dimensionless), b is a coefficient ( $\text{min}^{-1}$ ), t is the drying time (min), k is the drying rate constant ( $\text{min}^{-1}$ ), and n is a dimensionless parameter.

The model had highest  $R^2$  and lowest SSE values amongst 9 drying models used in this study (Table 1) and similar results were reported by Demirhan and Ozbek (2011) for microwave drying of celery leaves [2].

Figure 5 Moisture ratio against drying time for experimental and mathematical model at  $T = 55^\circ\text{C}$  and  $\text{IMPD} = 1\text{W/g}$  (Midilli-Kucuk Equation).

*Table 1 Statistical values for different drying conditions*

### 3.1.2 Drying Time

The drying time to reach 15% moisture content was calculated for all drying conditions studied and a predictive model was derived (Figure 6). This model can be used to predict drying time as a function of air temperature and IMPD and it is presented below:

$$t = 222.9276 - 1.683 \times T - 50.725 \times \text{IMPD}, (R^2 = 0.9187) \quad (4)$$

where  $t$  is the drying time (mins),  $T$  is the Temperature (°C); and IMPD is the initial microwave power density (IMPD) (W/g).

Over the range studied, it was observed that IMPD had more effect on drying time than air temperature. At any given temperature, the drying was reduced by more than 50% when microwave energy was added to the drying process. These results are in agreement with those reported by Alibas [6] on microwave drying of celery leaves. Similar results have been reported by Reyes et al. [15] on microwave drying of potato slices and by Maskan [16] on Kiwifruits. In addition to the positive effect of microwave energy on drying time, fluidization ensured that the product is uniformly dried and it minimized the formation of agglomerates. [17]

Figure 6. Response surface of the predicted drying time as a function of IMPD (W/g) and air temperature (°C)

## 3.2 Product Quality Characteristics

### 3.2.1 Color

Color measurements made on the rehydrated samples indicated that the lowest values of  $\Delta E$  were obtained at 55°C. The analysis of variance performed on the collected data indicated that the drying air temperature had no significant effect on  $\Delta E$  and only microwave power had induced changes in color. Changes in color  $\Delta E$  was therefore modeled as a function of IMPD and yielded the following equation:

$$\Delta E = 11.712 - 1.5325 \times \text{IMPD} - 0.6705 \times \text{IMPD}^2, (R^2 = 0.411125) \quad (5)$$

where IMPD is the initial microwave power density (W/g).

This equation indicates that  $\Delta E$  was inversely related to IMPD, i.e., color change decreases with increase in microwave power density.

### 3.2.2 Rehydration Ratio

The analysis performed on the rehydration ratio indicated that only air temperature had a significant effect. It was observed that rehydration ratio decreased with increasing air temperature. The predictive model for the rehydration ratio as a function of drying air temperature is as follows:

$$\text{RR} = 27.90 - 0.781 \times T + 0.00649 \times T^2, (R^2 = 0.6283) \quad (6)$$

where T is the drying air temperature (°C).

### 3.2.3 Texture

The effect of process conditions on the mechanical properties of the rehydrated celery pieces was measured and compared. The collected data indicated that mechanical properties

were affected by the drying conditions. Both energy to break and maximum force recorded increased with increasing drying air temperature. Although the IMPD did not have significant effect on the energy to break, it did affect the maximum force recorded. The predictive model describing the effects of temperature and IMPD on the maximum force is as follow:

$$F = -151.120 + 8.330 \times T - 38.016 \times \text{IMPD}, (R^2= 0.5649) \quad (7)$$

where F is the maximum force applied to crush the sample (N), T is the drying air temperature (°C), and IMPD is the initial microwave power density (W/g).

#### 4. Conclusion

In the current study, drying kinetics of celery in microwave fluidized bed drying was investigated. The results showed that the drying time reduced with the addition of microwaves and higher temperatures. Among the different predictive models studied, the Midilli-Kucuk model was found to be the best model for celery in microwave assisted fluidized drying. Rehydration ratios of celery were found to decrease with increasing air temperature and they were not affected by the application of microwave. Amounts of energy to crush the rehydrated samples increased with increasing air temperature but it was not affected by microwave energy. On the other hand, the maximum force required to crush the sample were found to be affected by both temperature and microwave power density.

## 1. Introduction

Lignite, a kind of low rank coal, is widely used as feeding fuel for power plants. However, power plants directly using raw lignite always have low efficiency and high pollutant emissions. Pre-drying is a proved method to improve the utilization efficiency of lignite<sup>[1]</sup>. Many types of dryers could be applied to dry lignite. The heat consumption rate is usually used to evaluate the performance of dryers, which is defined as the amount of energy consumed to evaporate 1 kg water with the unit of kJ (kg H<sub>2</sub>O)<sup>-1</sup>. However, energies used to dry lignite are in different grades. The heat consumption rate could not perfectly reflect performances of dryers based on the second law of thermodynamics. Exergy is a concept of thermodynamics expressing the maximum useful work possible contained in energy<sup>[2]</sup>. It is widely used to evaluate energy grades and the performance of energy processes.

Exergetic analyses were conducted on various lignite dryers in this study. Lignite drying technologies were reviewed firstly and thermodynamic analysis models were then developed. The exergy feeding and consumption rates are defined to evaluate the performance of dryers in the viewpoint of exergetic analysis and are compared quantitatively for various lignite dryers.

## 2. Materials and Methods

### 2.1. Lignite drying technologies

Drying of lignite could be classified to evaporative drying and mechanical-thermal dewatering. In this paper, we focus on the evaporative drying technologies. The evaporative drying is an energy intensive process, because water in lignite needs to absorb a lot of heat to evaporate. For the evaporative drying technologies, flue-gas or steam could be applied as the drying heat sources. Dryers uses steam as heating source are classified as steam dryers, including rotary-tube dryer and steam fluid-bed dryer. Characteristics and working parameters of steam dryers are listed in Table 1. When flue-gas is used to pre-dry lignite, the dryers are classified as flue-gas dryers. Characteristics and working conditions of flue-gas dryers are listed in Table 2.

*Table 1 Operation parameters of steam dryers<sup>[3]</sup>*

Dryer type	Characteristics	Heating medium parameters	
		Inlet	Outlet
Rotary-tube dryers	Using air as carrier as evaporative moisture; consisted of a drum equipped with tubes.	~180°C/0.4~0.5MPa	~Saturated water
Steam fluid-bed dryers	Lignite drying in slightly superheated steam; steam fluid-bed with internal heaters.	~140°C /0.32MPa	~Saturated water

Table 2 Operation parameters of flue-gas dryers<sup>[4]</sup>

Dryer type	Characteristics	Heating medium temperature /°C	
		Inlet	Outlet
Rotary	Drying along with disintegration; cocurrent mode.	750	120
Pneumatic	Short drying time; Lignite lifted by drying gas during pneumatic transport drying.	600	100
Fluid-bed	Easy to control; High drying intensity due to good mixing and high temperature heating medium.	450	75
moving bed	Possibility of full automation; compact construction and simple design.	175	80

## 2.2. Thermodynamic analysis models

### 2.2.1 Dryer model

The dryer model is indicated in Fig.1. As shown in Fig.1, 1 kg raw lignite is fed into the dryer, and  $\lambda$  kg water contained in lignite is dried out.  $m_a$  kg air is leaked into or used as carrier gas for drying 1 kg raw lignite.  $m_h$  kg heating medium (flue-gas or steam) releases heat in the dryer to dry lignite. In some types of dryers the heating medium directly contacts with lignite and leaves the dryer as dryer exhaust. While in some indirect dryers (rotary-tube dryer, etc.), the heating medium only exchanges heat in the dryer.

Fig. 1 Schematic diagram of Dryer.

The degree of pre-drying,  $\lambda$ , is defined to express the mass of water removed from per unit mass of raw lignite as

$$\lambda = \frac{M_{raw} - M_{upg}}{1 - M_{upg}} \quad (1)$$

where  $M_{raw}$  and  $M_{upg}$  are the mass of water contained in per unit mass of raw and dried lignite, respectively.

The minimum energy consumption, which is only absorbed by lignite to increase temperature and water to evaporate, for drying 1 kg lignite could be evaluated with

$$q_{d0} = \lambda \cdot (h_{dw} - h_{w0}) + (1 - \lambda) \cdot (h_{c1} - h_{c0}) \quad (2)$$

where  $h_{dw}$  and  $h_{w0}$  are enthalpies of the water contained in dryer exhaust and raw lignite respectively,  $\text{kJ kg}^{-1}$ ;  $h_{c1}$  and  $h_{c0}$  are enthalpies of dried lignite at the outlet and inlet temperatures respectively,  $\text{kJ kg}^{-1}$ .

The energy absorbed by possible in-leaking or carrier air is

$$q_{da} = m_a \cdot C_{p_a} (t_d - t_0) \quad (3)$$

where  $C_{p_a}$  is the specific heat capacity of air,  $\text{kJ kg}^{-1} \text{K}^{-1}$ ;  $t_{d1}$  and  $t_{a0}$  are temperatures of dryer exhaust and ambient respectively,  $^{\circ}\text{C}$ .

Based on the energy balance in the dryer, the mass of heating medium is

$$m_h = \frac{q_{d0} + q_{da}}{\eta_d \cdot (h_{h0} - h_{h1})} \quad (4)$$

where  $h_{h0}$  and  $h_{h1}$  are enthalpies of heat medium led into and output from the dryer,  $\text{kJ kg}^{-1}$ ;  $\eta_d$  is the thermal efficiency of dryer,  $\text{kJ kg}^{-1}$ .

To evaluate the mass flow rate of drying heat source, the rate of drying medium to dry out 1 kg water is defined as

$$K_h = \frac{m_h}{\lambda} \quad (5)$$

### 2.2.2 Exergetic analysis model

The dead point is the benchmark for the exergetic analysis. When the exergy carried by the dryer exhaust is recovered by cooling, the dryer exhaust could be cooled to the ambient temperature and becomes saturated moist gas. Therefore, the compositions of saturated moist gas is defined as the deadpoint compositions. The deadpoint pressure and temperature for the exergetic analysis are

$$p_0 = 0.1 \text{MPa} \quad (6)$$

$$T_0 = 293.15\text{K} \quad (7)$$

In the drying process, substances include lignite, gas (flue-gas and air), water (liquid and steam) and dryer exhaust. Assumptions of ideal gas mixture for the dryer exhaust are used. The exergy of water component is calculated with

$$E_w = h_w - h_{w0} - T_0(s_w - s_{w0}) + \bar{R}_w T_0 \ln \frac{y_w}{y_{w0}} \quad (8)$$

where  $h_w$  and  $h_{w0}$  are the enthalpies of water at calculation and deadpoint conditions respectively,  $\text{kJ kg}^{-1}$ ;  $s_w$  and  $s_{w0}$  are the entropies at calculation and deadpoint conditions respectively,  $\text{kJ kg}^{-1} \text{K}^{-1}$ ;  $\bar{R}_w$  is gas constant of water vapor,  $\text{kJ kg}^{-1} \text{K}^{-1}$ ;  $y_w$  and  $y_{w0}$  are volume fractions of water vapor at calculation and deadpoint conditions.

It is assumed that the flue-gas or air component has constant specific heat (average specific heat  $Cp_g$ ,  $\text{kJ kg}^{-1} \text{K}^{-1}$ ). Then the exergy of gas component is

$$E_g = Cp_g (T_g - T_0 - T_0 \ln \frac{T_g}{T_0}) + R_g T_0 \ln \frac{y_g}{y_{g0}} \quad (9)$$

where  $T_g$  is temperature at calculation condition,  $\text{K}$ ;  $\bar{R}_g$  is gas constant of gas,  $\text{kJ kg}^{-1} \text{K}^{-1}$ ;  $y_g$  and  $y_{g0}$  are volume fractions of gas at calculation and deadpoint conditions.

The physic exergy carried by the dried lignite is

$$E_l = Cp_l (T_d - T_0 - T_0 \ln \frac{T_d}{T_0}) \quad (10)$$

where  $Cp_l$  is the constant specific heat of lignite,  $\text{kJ kg}^{-1} \text{K}^{-1}$ ;  $T_d$  is the temperature of lignite at the outlet of dryer,  $\text{K}$ .

To quantitatively compare the thermodynamic performance of various dryers, the exergy feeding rate is defined as

$$e_f = \frac{E_h}{\lambda} \quad (11)$$

where  $E_h$  is the exergy fed into the dryer by drying heat source,  $\text{kJ}$ .

The exergy carried by the dried lignite or dryer exhaust can be recovered by heat recovered, whereas the internal exergy loss (exergy destruction) in the dryer and external exergy loss

along with heat loss of the dryer could not be recovered. The exergy consumption rate is defined as

$$e_c = \frac{E_h - E_l - E_e}{\lambda} \quad (12)$$

The exergy feeding rate  $e_f$  (kJ (kg H<sub>2</sub>O)<sup>-1</sup>) expresses the exergy feeding amount to dry 1 kg water out from raw lignite, and the exergy consumption rate  $e_c$  (kJ (kg H<sub>2</sub>O)<sup>-1</sup>) expresses the irreversibilities and heat loss of lignite dryers.

### 3. Results and discussions

We use Yimin lignite as the reference coal to carry out quantitative analysis<sup>[5]</sup>. Moisture contents of raw lignite is 39.5% and it is assumed to be dried to 15% in the dried lignite. The constant specific heat of lignite is 1.3 kJ kg<sup>-1</sup>.

#### 3.1. Heat balance of lignite dryers

The heat balance of lignite dryers listed in Tables 1 and 2 is calculated. The mass flow rate of heat source for drying 1 kg water out from lignite is compared in Fig.2. As shown in Fig.2, the mass flow rate of heat source varies greatly. The heat released by per unit flue-gas is significantly lower than that released by per unit steam. Therefore,  $K_h$  for flue-gas dryers is bigger than that for steam dryers. The  $K_h$  is above 29 for the moving bed dryer, because the temperature drop of flue-gas for the moving bed dryer is only 95 °C. For the steam fluid-bed dryer and rotary-tube dryer, the rates of drying medium are 1.38 and 1.49, respectively.

Fig. 1 Schematic diagram of Dryer.

### 3.2. Comparison of exergy feeding and consumption rates

Based on the heat balance of lignite dryers, exergetic analyses were conducted. The exergy feeding and consumption rates for lignite dryers were compared in Fig.3. As shown in Fig.3, the exergy feeding rate and exergy consumption rate for dryers vary greatly. The flue-gas of 750 °C is used to dry lignite in the rotary dryer, so the exergy feeding rate is as big as 1837.9 kJ (kg H<sub>2</sub>O)<sup>-1</sup>. If the exergy contained in dryer exhaust and dried lignite could be recovered, the exergy consumption rate could be decreased to 1424.8 kJ (kg H<sub>2</sub>O)<sup>-1</sup>. The low temperature heat source is used to dry lignite for the steam dryers. The exergy feeding rates for rotary-tube dryer and steam fluid-bed dryer are 1131.7 and 955.2 kJ (kg H<sub>2</sub>O)<sup>-1</sup>, respectively. In the steam fluid-bed dryer, no air is used as carrier gas, so more exergy could be recovered from dryer exhaust. The exergy consumption rate for steam fluid-bed dryer is only 432.6 kJ (kg H<sub>2</sub>O)<sup>-1</sup>.

Air is always used as carrier gas for the rotary-tube dryer. In Fig.3, the mass flow rate of air for drying 1 kg water is assumed as 3 kg. The mass flow rate of carrier gas for rotary-tube dryer will indeedly influence the exergy feeding rate and exergy consumption rate, which is shown in Fig.4. As shown in Fig.4, the exergy feeding rate increases linearly with mass flow rate of carrier air. For more exergy can be recovered in dryer exhaust when less air is used as the carrier gas, the exergy rate reduction of exergy consumption rate compared with exergy feeding rate decreases with the increase of mass flow rate of carrier gas.

Fig. 3 Comparison of exergy consumption rate.

Fig. 4 Influence of carrier air on exergy feeding and consumption rates for rotary-tube dryer.

#### 4. Conclusions

The heat consumption rate for lignite drying is a conventional indicator to evaluate the performance of lignite dryers. However, the drying temperature for various drying technologies are different, which means that energy at different grades is used in these drying technologies. The heat consumption rate could not evaluate the irreversibilities in drying process. Therefore, the exergetic analysis models are developed in this paper, and the exergy feeding rate and exergy consumption rate are defined as indicators for exergy analysis. Quantitative analyses on lignite dryers reveal that irreversibilities vary greatly for lignite drying technologies. Dryers using low temperature heat as dryer heat source consume less exergy in the drying process. The exergy consumption rate for steam fluid-bed dryer is the smallest, which is 432.6 kJ (kg H<sub>2</sub>O)<sup>-1</sup>. The aim of this paper is to provide a guidance for the development and study of lignite drying technologies in the viewpoint of reduction for exergy consumption.

### **Abstract**

*The drying of Eucalyptus nitens is a troublesome process as the species is extremely prone to drying defects. This paper reports ongoing research to improve the understanding of surface checking and cell collapse in Chilean grown Eucalyptus nitens during drying. Computed tomography (CT) scanning was used as a powerful tool for studying the internal changes in the wood-material during the drying process. Different levels of temperatures have been tested with the same equilibrium moisture content (EMC) conditions and low air velocity. The results confirm that a low drying temperature and a low air velocity, which results in a slow rate of drying, reduce internal cell collapse and surface checking .*

**Keywords:** Cell collapse; computed tomography; surface checks; wood drying; internal checks

---

## 1. Introduction

Eucalyptus is the largest single source of market pulp in the world [1]. In Chile, 35% of the forest plantations are eucalyptus (mainly *Eucalyptus globulus* and *Eucalyptus nitens*) [2]. The production of eucalyptus wood in Chile has been increasing during the last 40 years, but the volume of eucalyptus used as sawn timber has nevertheless decreased during that period.

The desire to increase the use of eucalyptus and to improve its processing has driven research in various fields. Blackburn [3] provides a wide picture of the existing knowledge of eucalyptus wood from different points of view: materials science, genetics, forest management and commercialized products. More recently, Sharma et al. [4] studied a new method to improve the quality of *Eucalyptus nitens* and *Eucalyptus bosistoana* solid wood by eliminating growth stresses. Kong et al. [5] investigated the use of steaming as pre-treatment for *Eucalyptus grandis* and *Eucalyptus urophylla* wood and identified potential ways to improve the drying process.

One of the reasons for the low use of eucalyptus in solid wood products is the difficulties in the drying process, which usually result in an unacceptable level of defects, often due to cell collapse [6-8]. Cell collapse is a process that occurs mainly when there is free water in the wood cells and thin-walled cells cannot withstand the tension forces generated when the liquid water is displaced [9]. The literature reports research that addresses surface and internal checking and cell collapse of different eucalyptus species from various viewpoints, e.g. anatomical [10-12], materials science [6, 13-14] and genetics [15-16].

The topic of collapse in wood drying has been studied extensively. Recently, Yang and Liu [9] provided an extensive review of the literature on the collapse behaviour of different eucalyptus species and, based on these reports, proposed different measures to reduce it, such as pre-heating (both with steam and with microwaves), re-conditioning and several methods to control the drying parameters.

Different scanning technologies have been applied to study the cell collapse: Wentzel-Vietheer et al. [17] tried to identify collapse zones in *Eucalyptus globulus* with near infrared spectroscopy (NIR). Ananías et al. [18] used a Quintek Xray Ring Tree Analyzer to measure the width and density of annual rings while studying how the location of the cell within the stem influences collapse.

The work presented in this article is a part of a larger project where the drying of *Eucalyptus nitens* is studied. To study internal cell collapse, an unique equipment that combines a drying chamber and a medical computed tomography (CT) scanner is used in such a way that the wood specimens can be scanned during drying in controlled conditions.

It is then possible to explore what happens in the interior of a wood piece during the drying process and also to study the changes in dimension and density.

## 2. Materials and Methods

*Eucalyptus nitens* was harvested from Chilean plantations, sawn and shipped in the green state to northern Sweden, where the experiments took place. The specimens were sawn in dimensions of 47 x 162 x 600 mm and 27 x 162 x 600 mm with different orientations in the log cross-section (**Fig. 1**). Prior to drying, the cross-sections of the specimens were sealed with a heat-resistant silicone.

A specially designed laboratory drying kiln that fits within the void of a Siemens Somatom Emotion Duo medical CT-scanner was used (**Fig. 2**). With this equipment, it is possible to scan the inside of the kiln without interrupting the drying process, and thus to inspect in real time internal features of the wood specimens as they are drying. The control parameters are the air velocity and the dry and wet bulb temperature ( $T_d$  and  $T_w$ ).

**Fig. 1:** CT-images of the cross section of the specimens before (Left) and after drying - experiment No. 4 in Table 1 (Right).

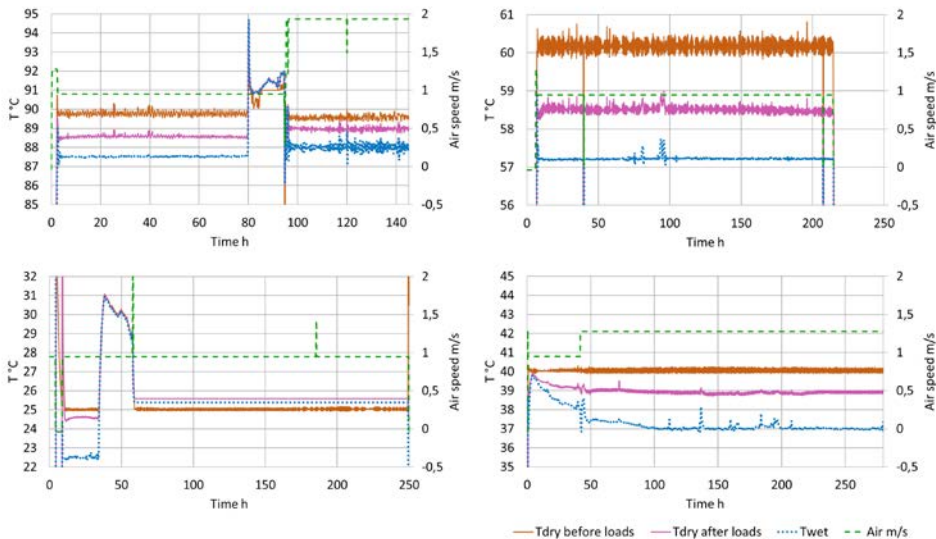

**Fig. 2:** Drying kiln and CT-scanner. The specimen is located in the metal tube that fits within the gantry of the scanner.

### 2.1. Drying processes

The part of the project presented here consisted of slow drying under stable conditions. The aim was to maintain a constant air velocity just below 1 m/s, and conditions for the same equilibrium moisture content (EMC) 16% (modifying the psychrometric difference in each run) and under these conditions to apply different drying schedules at four different temperatures, with four samples in each run in the chamber (*Table 1*). This was not always possible, as such a low air velocity made it difficult for the control system to hold the climate because the humidity in the chamber is controlled by the psychrometric difference, which requires a higher air velocity. *Fig. 3* shows the actual temperature and humidity trends in each experiment, showing the difficulties of reproducing such schedules in some cases (compared with the set points shown in *Table 1*) and the consequences of several malfunctions of the equipment that had to be dealt with while the tests were running.

**Table 1: Temperatures set points for each experiment.**

Experiment No.	Dry-bulb T (°C)	Wet-bulb T (°C)
1	90	87.9
2	60	57.3
3	25	22.5
4	40	36.9

**Fig. 3: Actual temperature and air velocity trends in the four experiments using the set points indicated in Table 1: 1 (top left), 2 (top right), 3 (bottom left) and 4 (bottom right).**

### 2.1.1. Experimental issues

Several issues arose during the experiment that made it necessary to change some of the parameters so that the drying kiln would continue running. During experiment No. 1, the steam valve broke and it could not be replaced with the chamber in operation. To keep the experiment running and the EMC at a reasonable level, the air velocity was increased to around 1.9 m/s. The chamber also experienced malfunction early on during experiment No. 3, and the data for wet-bulb temperature ( $T_w$ ) and dry-bulb temperature ( $T_d$ ) after loads are not reliable after about 60 h. Experiments No. 2 and No. 4 ran reasonably well. During experiment No. 4, the chamber had problems in reaching the working conditions for the test, and the air velocity was therefore incremented after around 40 h.

## 2.2. Data processing

The data obtained from the CT-scanner are images in DICOM format, which translate into grey-scale images in which a lighter colour represents a high density and a darker colour represents a low density (*Fig. 1*). Each pixel of the image represents a volumetric entity (so called voxel) defined by the pixel size and the thickness of the scanning beam. In these experiments the voxel size was  $0.49 \times 0.49 \times 10 \text{ mm}^3$ . Being a grey-scale image, each pixel has one numeric value associated with it (the CT-number), and the images can thus be processed as matrixes in mathematical software like, for example, Matlab, and this is the case with the data here presented. Making use of the density relationship between the CT-number and the density of the scanned material, mass can be inferred and, thus, real time studies of moisture content (MC), defined as the ratio of the weight of the water in the wood to the dry weight of the wood, can be made.

The MC is calculated from the CT-images by dividing the difference between the average mass of the wood pixels in the wet wood image and the average mass of the wood pixels in the dry wood image by the average mass of the wood pixels in the dry wood image. This method is somehow analogous to the gravimetric method, which consist on dividing the difference in weight of a wood specimen at a given MC and in totally dry condition by the weight of the wood specimen in totally dry condition.

## 3. Results and Discussion

Two main aspects were studied: the drying rate and the evolution of internal cell collapse and surface checking.

### 3.1. Drying rate

As shown in *Table 2*, the lowest temperature gave the best drying rate, which is a confirmation of the validity of the traditional drying schedules used in Chile, which are performed at around  $28^\circ\text{C}$  with very low air velocity. A dry shell can be seen in experiment No. 3 ( $25^\circ\text{C } T_d$ ), and to a shorter extent in experiment No. 4 ( $40^\circ\text{C } T_d$ ), but not in the

experiments at higher temperatures. Nevertheless, the results show that the drying rate is almost as high at 90°C as it is at 25°C, which was one the hypothesis. Unfortunately, there is a high spread on the results, which suggest that conclusions should be drawn carefully.

**Table 2: The drying rate of the different specimens sorted by dimension.**

Experiment No.	Temp. °C	27 x 162	27 x 162	47 x 162	47 x 162	Mean
1	90	-0.45	-0.19	-0.25	-0.30	-0.30
2	60	-0.30	-0.18	-0.15	-0.16	-0.20
3	25	-0.39	-0.37	-0.27	-0.29	-0.33
4	40	-0.26	-0.25	-0.25	-0.19	-0.24

### 3.2. Cell collapse and surface checking

Table 3 shows how the checking and cell collapse varied in each experiment. Fig. 1 shows, as an example, the checking and collapse occurring during experiment No. 4. If time were the only parameter to evaluate, experiment No. 4 (at 40°C T<sub>d</sub>) could be considered to show the best behaviour regarding the appearance of surface checks, while the CT-images showed that collapse took place more slowly in experiment No. 3 (at 25°C T<sub>d</sub>).

**Table 3: Visibility of the first checks (surface) and cell collapse (internal checks) shown in hours into the drying process.**

Experiment No.	First checks after: (h)	Visible collapse After: (h)
1	35	72
2	58.5	68.5
3	56	77
4	71	71

Nevertheless, the comparison between these results must take into account the differences in the processes and in the drying rate in the different experiments.

### 3.3. Future work

More research will be performed trying to take into account all the factors that may influence the quality of the final product regarding both surface checking and cell collapse. Multivariate statistical studies may be useful in the future. The development of the equipment and the method to replicate these drying schedules also needs more work, as processes with low temperatures and air velocities has shown to be troublesome. Furthermore, research on the implementation of pump-drying is currently being carried out, which shows a potential for energy savings as the fans are intermittently stopped during much of the drying time.

#### 4. Conclusions

The drying of *Eucalyptus nitens* has been shown to differ to some extent with regard to the appearance of checks and cell collapse-related features depending on the temperature, but the drying rate does not seem to be greatly affected by temperature. It can be concluded from these studies that *Eucalyptus nitens* should be dried at a low temperature and a low air velocity, as is done industrially in Chile, to avoid damage. Improving the efficiency of the drying process in terms of time and, thus, energy, does not seem likely as the process must be slow in order to avoid surface checking and cell collapse. The results do not suggest that high temperature drying would give higher drying rate, thus the increase in energy consumption would not be worth it.

### **Abstract**

*Nanoencapsulation is an efficient process to incorporate high nutritional oils, such as high oleic palm oil (HOPO). Several drying technologies can be applied for obtaining HOPO powders. The aim of this work was to study the effect of two different drying methods (spray-drying, SP and freeze-drying, FD) on some physical properties and microstructure of powders obtained from HOPO nanoemulsions. Results showed that FD powders presented lower  $a_w$  and bulk density, and higher dissolution rate than SD powders. Results suggest that SD could be a more economical alternative to FD in order to obtain HOPO powders with low moisture and  $a_w$ .*

**Keywords:** freeze-drying; high oleic palm oil; nanoemulsion; spray drying.

---

## **1. Introduction**

Nanoencapsulation is an efficient process to encapsulate bioactive compounds and thus allows the incorporation of high nutritional oils, such as high oleic palm oil (HOPO) [1]. Nanoencapsulation often begins with the production of nanoemulsion [2]. One of the techniques used for obtaining nanoemulsions is microfluidisation; it has been widely used and represents a highly efficient method for producing nanoemulsions containing small-sized droplets (100-500 nm) [3].

Several drying technologies can be applied for obtaining HOPO powders such as freeze-drying and spray-drying. The final product obtained from these methods may differ in physicochemical properties and microstructures [4]. Spray drying is widely used in commercial production of milk powders, fruits and vegetables [5]. This method has several advantages such as rapid drying, large throughput and continuous operation. During the drying process, the feed solution is sprayed in droplets in a stream of hot air [6]. The liquid droplets are dried in seconds as a result of the highly efficient heat and mass transfers [7]. The finished product can be made in the form of powder, granules or agglomerates [8]. Freeze drying, also known as lyophilisation, is a drying process in which the food is first frozen then dried by direct sublimation of the ice under reduced pressure. To carry out a successful freeze drying operation, the pressure in the drying chamber must be maintained at an absolute pressure of at least 620 Pa [7]. Freeze drying is generally considered as the best method for production of high quality dried products [9]. But, it suffers from high production costs, high energy consumptions, and low throughputs [10].

So, the aim of this work was to study the effect of two different drying methods, spray drying and freeze drying on some physical properties and microstructure of powders obtained from nanoemulsions of HOPO.

## **2. Materials and Methods**

### **2.1. Materials**

HOPO (Fedepalma, Bogotá, Colombia); whey powder was bought in a local market (Bogotá, Colombia); soy lecithin (Belchem International, Medellín, Colombia); and native corn starch (Cimpa SAS, Bogotá, Colombia).

### **2.2. Nanoemulsion preparation**

The coarse emulsions were homogenised in an mixer (Imusa, Bogotá, Colombia), incorporating whey powder (29.76%, w/w), followed by the sequential addition of native corn starch (0.24%, w/w), and HOPO (14%, w/w) to the distilled water over 2 min. Subsequently, such emulsions were processed to obtain the nanoemulsions. The soy lecithin

concentration was held constant at 10% w/w with respect to the HOPO concentration (1.4%, w/w). The nanoemulsions were obtained following the methodology of Quintanilla-Carvajal et al., [11] with some modifications at 20,000 psi pressure for 2 cycles.

### 2.3. Drying technologies

Two different drying methods were applied: spray-drying (SP), and freeze-drying (FD).

#### 2.3.1. Spray drying

HOPO powders produced by SD (SDP) were obtained in a pilot scale spray dryer (Niro MM-PSR, GEA Process Engineering A/S, Denmark) using two-fluid nozzle as atomisation device at 1 bar of pressure. The nanoemulsions were fed into the atomiser by a peristaltic pump (Watson-Marlow, United Kingdom). The inlet and outlet temperatures of the drying air were 190 and 90°C, respectively.

#### 2.3.2. Freeze drying

HOPO powders produced by FD (FDP) were obtained in a pilot scale freeze dryer (Labconco, USA). The nanoemulsion was poured into a stainless pan to form a layer of 10 mm. The samples were frozen at -40 °C with a cooling rate of 0.5°C/min for 16.5 h. Then, the samples were sublimated at a temperature of -20°C for 12 h and a desorption temperature of 20°C for 24 h. The pressure on the chamber was 0.018 mbar. Then, an analytical batch mill (A 11 M Basic, IKA, USA) at 28,000 rpm during 10 s was used for the obtention of the FDP.

### 2.4. Physical properties of the powders

#### 2.4.1. Moisture

The moisture content of the powders was measured from 0.3 g of sample employing an EM 120-HR moisture analyser (Precisa Gravimetrics AG, Dietikon, Switzerland). Measurements were performed in triplicate.

#### 2.4.2. Water activity ( $a_w$ )

The water activity of the powders was measured using an AquaLab Series 4 aw meter (Decagon Devices, Inc., Pullman, WA) after the samples were stabilised at 25 °C for 30 min. The measurements were performed in triplicate.

#### 2.4.3. Dissolution rate (DR)

The dissolution rate was carried out by adding 2 g of the powders into 50 mL of distilled water [12]. The mixture was agitated in a 100 mL low form glass beaker with a magnetic stirrer (Heidolph, Schwabach, Germany) at 900 rpm. The time (s) required for the material to completely dissolve was recorded. The measurements were performed in triplicate.

#### 2.4.4. Bulk density (BD)

The bulk density of the powders was measured by weighing 2 g of sample and placing it in a 10 mL graduated test tube. The test tube was tapped by hand and the bulk density was calculated as the ratio between the mass (g) of powder contained in the test tube and the volume occupied [13]. The measurements were performed in triplicate.

### 2.5. Microstructure

For the analysis of the structure of the HOPO powders a scanning electron microscope (Phenom Pro, Cocoltec Ltda, Bogotá, Colombia) was used. Samples were placed on the SEM slides with the aid of colloidal silver. An acceleration voltage of 5 kV and two different magnifications of 1000x and 4000x were used.

### 2.6. Statistical analysis

Data were subjected to variance analysis (ANOVA), using the least significant difference (LSD) test with a 95% ( $p < 0.05$ ) confidence interval to compare the test averages (Statgraphics Plus 5.1, Manugistics, Inc., Rockville, MD, USA).

## 3. Results and Discussion

### 3.1. Physical properties

Physical properties of the HOPO powders obtained using two different drying methods, SD and FD are shown in Table 1. Results showed that no significant differences ( $p > 0.05$ ) were obtained between the moisture of FDP compared to that obtained in SDP (Table 1). Although no significant differences in moisture content were found, both methods are totally adequate for emulsion drying because in industrial food, moisture values under 15% prevent microorganism growth, increase structural stability and retards deterioration reactions as sugar crystallization, non enzymatic browning and aroma losses [14].

Table 1. Physicochemical properties of HOPO powders obtained by two different drying methods

Drying method	Moisture (%)	$a_w$	DR (s)	BD (g/mL)
SD	2.43 <sup>a</sup> (0.05)	0.1621 <sup>a</sup> (< 0.01)	83.00 <sup>a</sup> (9.9)	0.6366 <sup>a</sup> (0.01)
FD	2.31 <sup>a</sup> (0.01)	0.0701 <sup>b</sup> (0.01)	146.00 <sup>b</sup> (5.7)	0.5154 <sup>b</sup> (< 0.01)

DR: dissolution rate; BD: bulk density.

The values in parenthesis are the standard deviations.

<sup>a,b</sup>In the same column, means without the same letter reveal significant differences ( $p < 0.05$ ) according to the LSD multiple range test.

On the other hand, FDP presented lower  $a_w$  values ( $p < 0.05$ ) than SDP (Table 1). This may be caused because the high vacuum used. The high vacuum gradient can affect the water transfer rate within the molecular structure, resulting in a lower residual  $a_w$  in the final product [15]. In the SD method, increasing the temperature of the inlet air, increases the temperature gradient between the air flow and the emulsion, which results in the increase of heat transfer and, therefore, the rate of evaporated water [16]. In addition, the rapid drying in the SD method produces a homogeneous particle size that helps a faster contraction of the particles after water evaporation, generating a minimum amount of available water [17]. It is known that with an  $a_w$  below 0.3, the water present is not enough to behave like a solvent, which decreases the mobility of the products available for degradation reactions and microbial growth [18]. In this sense, both drying technologies allow obtaining stable products from the point of view of water activity.

In relation to bulk density (BD), FDP presented lower BD values ( $p < 0.05$ ) than SDP (Table 1). Baeghbali et al, [19] when studying the effect of different drying methods on the physical properties of pomegranate juice obtained that spray dried samples had higher BD compared to refractance window dried samples because of the fine structure of the spray dried sample. It is known that BD is directly related to the moisture content of the powders. With less moisture content, less water will be present in the structure, which allows more empty spaces between the particles and the interior of these. In this way, increasing the porosity, will increase the surface area per unit volume, and finally will decrease the BD [20]. This fact would explain the higher BD obtained in spray dried HOPO powders due to its high moisture content compared to that obtained by FD.

Finally, FDP presented higher DR values ( $p < 0.05$ ) than SDP (Table 1). Similar results were obtained by Caparino et al., [4] when studying the effect of different drying methods on the physical properties and microstructure of mango powder. These authors obtained higher solubility (lower DR) on the spray dried mango powder compared to freeze dried product. They established that the atomization of mango puree during spray drying could contribute to solubility of spray-dried product. This fact would explain the higher solubility obtained in spray dried HOPO powders compared to that obtained by FD.

### 3.2. Microstructure

Scanning electron micrographs of HOPO powders obtained by different drying processes are shown in Fig.1. Spray-dried HOPO powders (Fig. 1A and 1C) has spherical or oval shape and smooth surface particles due to effect of spray-drying condition, which was maintained at inlet temperature of 190°C during drying. On the other hand, freeze dried HOPO powders (Fig. 1B and 1D) showed a skeletal-like structure. Similar results were obtained by Caparino et al [4] when studying the effect of different drying methods on the

physical properties and microstructure of mango powder. These authors obtained a more spherical shape, and more smooth and porous surface on spray dried mango powder compared to freeze dried product. The smooth spherical-shaped HOPO powder could contribute to its high solubility and BD compared to the freeze drying method.

*Fig. 1 Scanning electron microscopy micrographs for powders of HOPO nanoemulsions obtained using spray drying (A, C) and freeze drying (B, D). Magnification: 1000x (A,B), 4000x (C, D).*

#### 4. Conclusions

Results showed that of the four response variables analysed, three were significantly affected by the drying method applied ( $p < 0.05$ ). No significant differences ( $p > 0.05$ ) were obtained between the moisture of FD powders compared to those obtained by SD. Moreover, FD powders presented lower activity water and BD, and higher DR than SD powders. These important changes in the physicochemical properties of the powders of HOPO could be related to structural modifications observed. So, results suggest that SD could be a more economical alternative to FD in order to obtain HOPO powders with low moisture and activity water and higher solubility.

## 5. Acknowledgements

The authors wish to acknowledge to Banco de Desarrollo de América Latina (CAF) for the support to this research and to the Universidad de La Sabana for its help in this investigation through the funding of the ING-170-2016 project. Moreover, the authors thank to Cenipalma (Colombia) for kindly supplying the High Oleic Palm Oil used in this study and to Alexandra Mondragón Serna, Leader of the project of Health and Nutrition of Cenipalma.

### **Abstract**

*Drying process represents one of the main energy-consuming stages for a broad variety of manufacturers. However, despite its significant impact on energy efficiency, most implementations at manufacturing level do not operate within the optimal conditions.*

*This work investigates the interplay among different parameters involved into the paper-drying process. To do so, we analyze both experimental and numerical results. The theoretical approach couples a non-isothermal flow, along with the heat transfer and transport of different fluids participating. Our results, experimental and numerical, show a good agreement according to the characteristic drying time scale. The results thus enable to estimate the impact of different mechanisms into drying process.*

**Keywords:** *paper-drying process; free water; bound water; papermaking.*

## **1. Introduction**

Drying porous media is an experience surrounding us every single day. Food, building material, paper pulp, textiles or tissues are some examples of the engineering applications wherein the drying process has a central impact.

Porous media refers to materials presenting a pores network. In most applications, these cavities are filled with different fluids: gases and liquids. The interaction between those fluids and the solid matrix is what ultimately regulates the mass transfer concurring in this complex pores network. Indeed, understanding the complex dynamic of drying rate has been of interest for the past decades. At high saturation level, the water may be described using its bulk properties, that is called free water[1]. Although the latter represents a significant percentage of the water inside the structure (roughly 80% in most cases), drying the remaining water, physical or chemically adsorbed into the solid matrix (bound water), requires a considerable energetic effort.

Unfortunately, an exact description about bound water demands a microscopic approach for the solid-fluid interaction. Such description involves knowing the peculiarities of geometrical irregularities as well as forces at the molecular level between walls and fluid, which turns the problem into a challenge both theoretical and numerical. Nonetheless, in most practical cases, a so accurate insight is unnecessary or leads to an impossible undertaking.

To tackle this multi-scale scenario, we investigate the drying process on paper using the porous media theory. We followed, therefore, a macroscopic approach which provides an intuitive description averaging all minutiae at the microscopic level. We turn in this way the micro-scale effects into volume and surface terms in the governing equations at macro-scale[2]–[4].

This paper analyze a real case in which a non-isothermal flow is addressed to the porous medium, initially wholly saturated. We explore thus the interplay among mass and energy transfer, pressure distribution, or the evolution of evaporation front among other parameters. To do so, we combine a numerical approach with experimental results. Our results enable to clarify the transition between free and bound water, elucidating the role played by the main control parameters during the experiment.

Section 2 presents the problem formulation, discussing the physics and assumptions considered in the macroscopic approximation. Section 3 details the numerical and experimental results. Finally, Section 4 brings together the leading conclusions, highlighting potential mechanisms to investigate in future works to incorporate the bound water effect at low saturation level.

## **2. Problem formulation**

In this section, we motivate the macroscopic formulation of the porous medium and its interaction with the flow passing it through as well as the heat transfer induced. The first paragraph is dedicated to the geometrical setting since that helps to bear in mind an intuitive workflow to formulate the corresponding governing equations later.

### **2.1. Geometrical setting**

Fig. 1 shows a schematic sketch about the geometrical setup modeled in this work. As the

Fig. 1. Schematic sketch of the setting investigated in this work.

figure illustrates, we simulate the problem in a two-dimensional case. For low Reynolds numbers, that is a reasonable assumption that trims the computational effort considerably.

## 2.2. Governing equations: A miscible fluids formulation

The macroscopic approach comes up averaging over a representative elementary volume[5]. At this high level, there is no trace of surface topology at micro-scale, and the porous medium is then reduced to a continuum view. Solid-fluid interaction is thus modelled via a distributed energy loss induced by the flow going through the solid matrix.

Hence, at such high level, the flow field for the gas phase (dry air and water vapor) is governed by a single Navier-Stokes equation (NSE)[6]. Indeed, inside the porous medium, the energy losses induced by the solid matrix require some additional considerations. Those are, essentially, concerning on the way the solid matrix modulates different contributions in the NSE, turning eventually this into a Brinkman equation (BE)[7]. Thus, outside the porous medium, the gas-phase flow is described by a non-isothermal NSE:

$$\begin{aligned} \frac{\partial \rho_g}{\partial t} + \nabla \cdot [\rho_g \mathbf{u}_g] &= 0, \\ \rho_g \left[ \frac{\partial \mathbf{u}_g}{\partial t} + \mathbf{u}_g \cdot \nabla \mathbf{u}_g \right] &= \nabla \cdot \left[ -p \mathbf{I} + \mu_g (\nabla \mathbf{u} + \nabla \mathbf{u}^T) - \frac{2}{3} \mu_g (\nabla \cdot \mathbf{u}) \right], \end{aligned} \quad (1)$$

where  $\rho_g$  and  $\mu_g$  are air density and dynamic viscosity, respectively. Inside the porous structure, however, Equation (1) must be modified considering the drag induced by the solid matrix, what eventually results in the BE[3]

$$\left( \frac{\rho_g}{\varepsilon} \right) \left[ \frac{\partial \mathbf{u}_g}{\partial t} + \mathbf{u}_g \cdot \nabla \mathbf{u}_g \right] = -\nabla p + \mu_g \tau \nabla^2 \mathbf{u}_g - \frac{\mu_g}{k} \mathbf{u}_g - \frac{c}{k^{1/2}} \rho_g |\mathbf{u}_g| \mathbf{u}_g, \quad (2)$$

where the last two terms of the RHS represent Darcy[8] and Forscheimer[9], [10] resistances, respectively. The coefficients  $\varepsilon$ ,  $k_g$  and  $\tau$  are the porosity, permeability of the gas phase, and tortuosity, respectively. The coefficient  $c$  comes from an experimental fitting; we consider the experiments carried out by Hoang et al.[11] which are an example of such empirical relationship between  $c$  and  $k$ .

Water vapor velocity field may be described in terms of  $\mathbf{u}_g$ , including the diffusion of vapor into the dry air (binary diffusion, Bird et al.[12])

$$\mathbf{u}_v = \frac{\mathbf{u}_g}{S_g \varepsilon} - \frac{M_a D_e}{M_v \rho_v} \nabla \rho_v, \quad (3)$$

where an effective porosity ( $S_g \varepsilon$ ) and diffusivity ( $D_e$ ) are considered. The first one according to the saturation level, whereas the effective diffusivity depends on the local temperature, porosity, and tortuosity[13]

$$D_e = D_v \varepsilon^{4/3} S_g^{10/3}, \quad (4)$$

where  $D_v$  is the bulk diffusivity of the water vapor in the air.

Liquid phase (water), conversely, not require such a sophisticated formulation to compute its velocity field. Water inside the porous media reaches velocities much smaller than the gas phase. This fact enables to describe the water velocity field using a Darcy's law, depending solely on the pressure gradient induced into the gas phase dynamic

$$\mathbf{u}_l = - \frac{k_l}{\mu_l S_l \varepsilon} \nabla p, \quad (5)$$

where  $S_l \varepsilon$  reflects an effective porosity as a function of local saturation level.

The lack of concrete pores, conceptually, leads to the impossibility to track the interaction between two phases concurring within the porous medium. Essentially, because there is no way to define an interface, and consequently the interfacial energy stored. Even though, mechanisms such as capillary or evaporation may be included in the transport of different phases considering their average contribution over the REV. Phases are thus represented as miscible fluids; which is entirely consistent with the mean-field character of REV approximation. Transport of liquid and gas phases are formulated then as a conventional balance equation:

$$\begin{aligned} \frac{\partial c_l}{\partial t} + \mathbf{u}_l \cdot \nabla c_l - D_{\text{cap}} \nabla^2 c_l &= -\dot{m}_{\text{evap}}, \\ \frac{\partial c_v}{\partial t} + \mathbf{u}_v \cdot \nabla c_v - D_e \left( \frac{M_a}{M_g} \right) \nabla^2 c_v &= \dot{m}_{\text{evap}}, \end{aligned} \quad (6)$$

where  $D_{\text{cap}}$  represents the diffusivity induced by the capillary effects[3], and  $\dot{m}_{\text{evap}}$  is the mass flux evaporating

$$\dot{m}_{\text{evap}} = V_{\text{evap}} (a_w c_{\text{sat}} - c_v). \quad (7)$$

The coefficient  $v_{\text{evap}} [\text{s}^{-1}]$  accounts the evaporation rate, whereas  $a_w$  represents the water activity[4];  $c_v$  is the concentration of water vapor at a given time; and  $c_{\text{sat}}$  is the saturation

concentration

$$c_{\text{sat}} = \frac{p_{\text{sat}}(T)}{RT}, \quad (8)$$

where  $p_{\text{sat}}$  is the saturation pressure, and  $R$  is the gas constant.

Nonetheless capillary, water activity, or intrinsic porous properties depend overall on the water saturation level[4]. Those levels are, however, closely related to the corresponding concentration via the relationship:

$$S_l = \frac{c_l M_l}{\rho_l \varepsilon}, \quad (9)$$

which, ultimately, means the ratio of mass of a given species in an elementary volume over the total. On the other hand, given that phases are connected each other in an elementary volume via conservation of mass, the gas saturation level turns out to be:

$$S_g = 1 - S_l. \quad (10)$$

Saturation variables alleviate the heat transfer problem inside the solid structure, reducing it to the general energy balance for a single phase flow;

$$\rho_m C_{p,m} \left[ \frac{\partial T}{\partial t} + \mathbf{u}_m \cdot \nabla T \right] = \nabla \cdot (k_m \nabla T) - \mathcal{L}_{\text{evap}} \dot{m}_{\text{evap}}, \quad (11)$$

where the subscript  $\dot{m}_{\text{evap}}$  indicates the average thermal properties, which results from a weighted average between the two phases coexisting within the porous structure

$$\begin{aligned} \rho_m &= S_g \rho_g + S_l \rho_l, \\ C_{p,m} &= \frac{C_{p,g} S_g \rho_g + C_{p,l} S_l \rho_l}{\rho_m}, \\ k_m &= S_g k_g + S_l k_l, \\ \mathbf{u}_m &= \frac{\Gamma_g C_{p,g} + \Gamma_l C_{p,l}}{\rho_m C_{p,m}}, \end{aligned} \quad (12)$$

where

$$\Gamma_{l,g} = \rho_{l,g} \mathbf{u}_{l,g} \quad (13)$$

is the flux of each phase.

Finally, according to the modeling detailed in this section, the water dynamic inside the porous structure is described as a combination of different mechanisms interconnected with each others. Hence, free and bound water concepts are not considered as discrete states within the continuum approach, but rather as asymptotic modes induced by a combination of mechanisms involve in drying process.

### 2.3. Implicit assumptions and limitations

The theoretical model above mentioned connects micro- and macro- scales via water activity and solid matrix properties. There are two critical points, however, assumed in such

continuum description:

- *Water activity.* Although the theoretical model is part of a macroscopic framework, water activity (Eq. (7)) brings in the microscopic dynamic of water via sorption isotherms. We followed the IUPAC recommendations[14], which mainly divide the physisorption mechanisms into five classes according to the original classification carried out by Brunauer et al.[15]. In particular, we implemented the type I (Langmuir isotherm), since that is commonly exhibited in micropores.
- *Average properties.* Porous media properties used in this work were chosen from both theoretical and experimental relationships for different porous media including foods[4].

### 3. Results and discussion

This section itemizes the major findings derived from the theoretical model introduced in the previous section.

#### 3.1. Drying curve

Fig. 2 (left) shows the numerical drying curve. The evolution of moisture content exhibits, mostly, two different areas: a linear region, which is linked in the literature to free water; and another nonlinear region at low saturation levels associated with bound water wherein surface effects become dominant.

As we mentioned above, the theoretical model presented in this work is not aimed at differentiating between free and bound water, at least in the conventional manner. Mainly, because these concepts revolve around discrete states, which is hardly fit with the continuum framework proposed. Water activity and the corresponding sorption isotherm are used then

**Fig. 2. (Left) Drying curve. (Right) Temperature evolution at surface center. Both graphs are referred to the drying time scale,  $\tau_{\text{Drying}}$ ; time required to reach a 0.2% water saturation level. That enables a qualitative comparison between experimental and theoretical results. Experimental curves were obtained according to the setup detailed by Farzad et al. [16].**

as the natural way to connect micro- and macro-scales concurring along the transient. Therefore, the nonlinear region appears as a combination of different factors involving not only fluid-wall interaction at micro-scale via water activity, but also the evolution of others macroscopic magnitudes as the pressure and temperature distributions.

The good agreement (qualitatively) between numerical and experimental curves supports the theoretical insight proposed in this work. Such validation enables to explore the role of each macroscopic control parameters in the sorption process, and thereby in the drying dynamic.

### **3.2. Temperature evolution at surface center**

Fig. 2 (right) displays another characteristic response throughout the drying process evolution: temperature evolution at the surface center of the sample.

Surface center is the point at which the flow is addressed (Fig. 1). The flow outside porous structure quickly reaches a steady situation. As the curve details (Fig. 2–right), the two-step profile reveals the dependency with other factors such as the evolution of evaporation front. Otherwise, the combination of convection and conduction mechanisms would lead to a single step curve.

## **4. Conclusions**

Recent work about the drying dynamic inside porous media provides a continuum theoretical framework to deal with multiple scales concurring during the drying process. Free and bound water are posed as asymptotic water modes inside the solid structure rather than two different and discrete states. Our results are in good agreement (qualitatively) with their experimental counterparts. Drying curve exhibits not only the linear part usually assigned to free water, but also nonlinearities associated with bound water at low saturation levels. In its turn, the temperature evolution at the surface center of the sample presents the two-step profile observed experimentally. On the other hand, the pressure and temperature distributions inside the solid structure unveil the way the evaporation front advances through the solid matrix. The nonlinear advancement of the evaporation front through the porous structure pushes the water to the edge of the domain where the heat transfer drops considerably

Nevertheless, these results must be analyzed with extreme care since we assumed two critical points. First, we considered a Langmuir adsorption isotherm as the sorption dynamics modulating the water activity inside the solid structure. While it is true that it is commonly used in micropores, there is not enough experimental evidences to support this assumption in the case we worked with. For instance, capillary condensation is a potential adsorption isotherm to be considered, since it explains the way alternating wide and narrow parts of pores may enhance evaporation or condensation processes. On the other hand, solid matrix properties were considered as an average based on a bunch of theoretical and experimental relationships including different porous media.

Therefore, given that the theoretical framework presented in this work connects the micro- and macro- scales via porous medium properties and the adsorption isotherm, a more complete description of these two factors is required. They do are currently under a more in-depth investigation in our laboratory both experimental and theoretically.

### **Abstract**

*This study aims to determine the drying behavior of quince puree and as an adverse effect powdered sugar added quince puree with the addition of maltodextrin. The addition of powdered sugar increases the drying time and the total amount of energy and the same time slightly decreases the moisture content and water activity values. The color values and the properties on these values changed both with the addition of maltodextrin and powdered sugar. The density values, flow properties and reconstitution properties are significantly affected by the amount of maltodextrin in plain or powdered sugar added samples.*

**Keywords:** *quince, freeze-drying, maltodextrin, powder properties.*

## **1. Introduction**

Quince which is rich in vitamins A, B and C, sugar, crude fiber and minerals such as potassium, phosphorus and calcium [1]. Fresh fruits and vegetables are easily deteriorated due to their high moisture content, which can be prevented by a variety of preservation methods and one of these methods is the drying process. The drying process was first initiated by drying in the sun, but due to the lack of long processing times and standard product handling, industrial drying methods have been developed such as freeze-drying. The freeze-drying process is based on the principle of free water sublimation in freezing under low pressure, and desorption removal of bound water. Therefore, the water is removed by the vacuum in the solid phase and the loss of the valuable components such as minerals, vitamins and aromas are minimized in the product structure. Freeze dried products are well known with high nutritional value and having a porous structure.

This study aims to determine the drying behavior of quince puree and as an adverse effect powdered sugar added quince puree with the addition of maltodextrin. In addition, the physical, and powder properties of the obtained quince powders and the energy consumption through the freeze drying operation was also determined.

## **2. Materials and Methods**

### **2.1. Material**

The fresh quince fruits were obtained from a local supermarket in Izmir, Turkey. They were washed, peeled, seeds removed, and grounded into puree by using a home type blender (Tefal Smart, MB450141, Turkey). Maltodextrin (MD) with Dextrose Equivalence (DE) value of 10-12 (AS Chemical Industry and Commerce Limited Company, Turkey) was added directly to puree and to the powdered sugar (PS) containing puree in suitable amounts (4-6-8-10% by weight).

### **2.2. Methods**

#### *2.2.1. Freeze Drying*

The experiments were performed in a pilot scale freeze dryer (Armfield, FT 33 Vacuum Freeze Drier, England). The ground powders were stored in aluminum polyethylene packaging material (ALPE) in the dark at  $20\pm 1^\circ\text{C}$ .

#### *2.2.2. Analysis applied to powders*

The moisture content of the quince puree powders was carried out with 0.5-1 g of samples, which were dried in an oven at  $105^\circ\text{C}$  until reaching a constant weight. The water activity values were measured by using a Testo-AG 400, Germany water activity measurement device. The color ( $L^*$ ,  $a^*$ , and  $b^*$  values) values of the quince puree powders were

measured with a Minolta CR-400 Colorimeter, Japan and the results were expressed in accordance with the CIE Lab. System. The total color change ( $\Delta E$ ), Chroma, Hue Angle ( $^\circ$ ), Browning (BI), whiteness (WI) and yellowness (YI) index were calculated according to the method of Pathare and Opara, 2012 [2]. For the determination of bulk density, tapped density, flowability and cohesiveness values in terms of Carr index (CI), and Hausner ratio (HR), the average wettability time (s) and solubility of powder were determined with the method of Jinapong, 2008 [3]. The dispersibility, porosity and hygroscopicity values were determined according to Gong et al., 2008, Jinapong 2008 and Cai and Corke, 2000 respectively [3, 4, 5].

### 2.2.3. Statistical Analysis

Data were analyzed using statistical software SPSS 16.0 (SPSS Inc., Chicago, IL, USA). The data were also subjected to analysis of variance (ANOVA) and Duncan's multiple range test ( $\alpha=0.05$ ) to determine the difference between means. The drying experiments were replicated twice and all analyses were triplicated.

## 3. Results and Discussions

The drying time of samples, the energy consumption of the freeze dryer, the moisture content and water activity values of the dried quince puree powders are given in Table 1.

*Table 1. The energy consumption, moisture content, and water activity values of the samples*

Samples	Energy Consumption (KWH)	Moisture Content (% Wet Basis, wb)	Water Activity
4% MD	8.47±0.01 <sup>xp</sup>	8.61±0.43 <sup>xp</sup>	0.43±0.01 <sup>yr</sup>
6% MD	8.47±0.01 <sup>xp</sup>	8.40±0.44 <sup>xp</sup>	0.41±0.01 <sup>xr</sup>
8% MD	8.47±0.01 <sup>xp</sup>	7.77±0.42 <sup>xp</sup>	0.41±0.01 <sup>xr</sup>
10% MD	8.47±0.01 <sup>xp</sup>	7.72±0.13 <sup>xp</sup>	0.44±0.01 <sup>zr</sup>
4% PS+4% MD	10.06±0.01 <sup>xr</sup>	7.67±0.21 <sup>xp</sup>	0.43±0.002 <sup>tp</sup>

4% PS+8% MD	10.06±0.01 <sup>xr</sup>	7.05±0.22 <sup>xp</sup>	0.37±0.008 <sup>yp</sup>
4% PS+10% MD	10.06±0.01 <sup>xr</sup>	6.78±0.11 <sup>xp</sup>	0.37±0.01 <sup>xp</sup>

x-t Different letters in the same column indicate a significant difference between the concentration of MD at  $P < 0.05$ .

p-r Different letters in the same column indicate a significant difference between the samples with MD or 4%PS+MD at  $P < 0.05$ .

To determine the energy efficiency of drying the energy consumption and the product quality have been identified as the key factors. The first and second sets of samples were dried for 15 hours and 18 hours, respectively.

Considering the energy consumption per hour of drying (0.559 kWh), the highest energy consumption value (10.06 kWh) was in the sample set where MD was added to quince puree with 4% PS. The moisture content of the samples was not significantly different. Dried foods (with water activity values of 0.20-0.40) were considered as stable for browning, microbial growth and enzymatic reactions [6]. According the Table 1, the water activity (aw) values of the powders are very near or slightly higher the upper limit.

The measured color values of the dried samples are given in Figure 1. The highest L (brightness) value was achieved in the samples added with only 4% maltodextrin, while the highest brightness value was attained by addition of maltodextrin at 6% concentration together with the powdered sugar. Positive values of a\* and b\* indicate redness, yellowness, respectively. The highest values were observed from quince powder with 10% MD. As the amount of added maltodextrin increased, a decrease in L value was observed.

Fig. 1 The color values of quince puree powders.

The properties of the powders based on the color measurement are given in Table 2. Considering the results of color measurement, the highest total color change ( $\Delta E$ ) was detected in samples of added with 8% MD and PS and a significant increase in the total color change was observed as the amount of MD added to the samples increased. In the Hue angle, a significant decrease was observed with the addition of MD to quince puree but no effect was observed for PS containing puree ( $P < 0.05$ ). sample with 10% maltodextrin, which has the highest Chroma value, was accepted as the sample with the highest color intensity perceived by humans. In food products containing powdered sugar, the highest browning index value, which is one of the most common indicators of browning, has been detected on the level of quince with 8% maltodextrin added. The whiteness index (WI), which indicates the degree of discoloration during the drying process, represents the extreme whiteness of food products [7].

**Table 2. The total color change, hue angle, chroma values, browning, whiteness, and yellowness index of the powders.**

x-t Different letters in the same column indicate a significant difference between the concentration of MD at  $P < 0.05$ .

p-r Different letters in the same column indicate a significant difference between the samples with MD or 4%PS+MD at  $P < 0.05$ .

As shown in Table 2, as the maltodextrin content increases, a decrease in this value is observed. Yellowness value is related to general product degradation by light, chemical exposure and processing. This value is basically used to measure the amount of such degradation with a single value [8]. The results showed that increasing the MD content resulted in a significant increase in the yellowness value whereas increasing the MD and PS cause decrease in these values ( $P < 0.05$ ).

The results of the powder properties of the freeze dried quince powders are given in Table 3 and 4. The powder properties are important for the functional, economical, and commercial consideration of the powder products [10]. The average wettability and solubility times of the freeze-dried quince powders were found to be as 3 seconds and the amount of maltodextrin and the addition of powdered sugar did not affect the wettability and solubility times of the samples ( $P > 0.05$ , data was not given.). The highly porous structure and similar residue moisture content may be the reason for the low wettability and solubility times.

x-t Different letters in the same column indicate a significant difference between the concentration of MD at  $P < 0.05$ .

p-r Different letters in the same column indicate a significant difference between the samples with MD or 4%PS+MD at  $P < 0.5$ .

The bulk and tapped density values of freeze-dried quince powders with MD significantly increased depending on the increasing amount of (P<0.05). Comparatively higher bulk and tapped density values were observed for the quince powders with powdered PS and MD (P<0.05). It may be due to the higher solid amount of quince puree with 4%PS+MD compared to the quince puree with MD. Cai and Corke (2000) [5] reported that the increase in solid concentration in the feed which makes the particles heavier resulted in higher bulk density. For this reason, the higher bulk density values were obtained at the higher MD concentrations and the 4%PS addition. The flowability and cohesiveness properties of the quince powders in terms of the CI and HR were evaluated, the higher CI and HR values mean that the powder is more cohesive and less able to flow freely. The higher CI and HR values were observed for the sample with 4%MD and 4%PS+6%MD, 4%PS+8%MD, and 4%PS+10%MD. The CI and HR values significantly decreased according to the addition of the amount of MD (P<0.05). The addition of MD to the quince puree improved the flowability of the powders. Comparatively higher CI and HR values were observed for the quince powders with 4%PS and MD (P<0.05). It may be due to lower glass temperature of

powdered sugar which causes the stickiness.

**Table 4. The other powder properties of freeze-dried quince powders**

Samples	Particle Density (kg/m <sup>3</sup> )	Porosity (%)	Dispersibility (%)	Hygroscopicity (%)
<b>4%MD</b>	1690.50±183.14 <sup>up</sup>	90.24±1.06 <sup>yp</sup>	75.83±5.12 <sup>xp</sup>	12.93±0.82 <sup>yp</sup>

<b>4%PS+6%MD</b>	1863.39±36.26 <sup>zt</sup>	81.10±3.68 <sup>xp</sup>	77.74±1.54 <sup>xp</sup>	17.69±0.51 <sup>yt</sup>
<b>4%PS+8%MD</b>	1622.21±16.59 <sup>xr</sup>	84.65±0.13 <sup>xp</sup>	81.78±2.41 <sup>yp</sup>	18.32±0.52 <sup>zt</sup>
<b>4%PS+10%MD</b>	1745.24±49.81 <sup>yt</sup>	82.86±4.89 <sup>xp</sup>	81.18±3.59 <sup>yp</sup>	16.13±0.13 <sup>xr</sup>

x-t Different letters in the same column indicate a significant difference between the concentration of MD at  $P < 0.05$ .

p-r Different letters in the same column indicate a significant difference between the samples with MD or 4%PS+MD at  $P < 0.5$ .

The particle density of quince powders with MD and 4%PS+MD ranged between 746.63-1690.50 kg/m<sup>3</sup> and 1622.21- 1977.09 kg/m<sup>3</sup> and the particle density of the powders significantly decreased depending on the increasing MD concentration ( $P < 0.05$ ). The porosity values (%) of the quince powders significantly decreased depending on the increasing MD concentration ( $P < 0.05$ ). The higher porosity values were observed for quince powders with MD compared to the quince powders with 4%PS+MD, however, the differences between the samples generally were not found to be significantly important ( $P > 0.05$ , except quince powder with 6%MD). No significant differences were observed between the dispersibility values of the quince powders on MD concentration ( $P > 0.05$ ) and the addition of the powdered sugar to the quince pure with MD did not affect the dispersibility values of the quince powder ( $P > 0.05$ ). The hygroscopicity values of quince powders with MD were not found to be statistically different ( $P > 0.05$ ). The higher hygroscopicity values were generally obtained from the samples, which have lower moisture (quince powder with 4%PS+MD) contents.

#### 4. Conclusion

In this study, the physical and the powder properties of the quince powders with maltodextrin and powdered sugar were determined. In a result of the physical analysis, as the amount of added maltodextrin increased, a decrease in L value was observed while a\* and b\* is the highest value at 10% concentration. Furthermore, quince powder with 10% maltodextrin and powdered sugar has the lowest value of moisture content and water

activity. Besides, the drying process time of the samples with only maltodextrin is shorter than another group. According to analysis of the powder properties, the addition of maltodextrin and powdered sugar did not affect the wettability and solubility times of the samples. The porosity values, CI and HR values decreased depending on the addition of the amount of MD. The hygroscopicity values and dispersibility of quince powders with MD were not found to be statistically different.

### **Abstract**

*The possibility of using a heat pump as a part of on-farm drying plant is considered taking drying of corn grain as an example. The methodology for kinetic calculations of a drying plant with a batch fluidized bed for granular materials is developed. These calculations are based on the use of an analytical solution for the problem of mass conductivity and taking into account the time-related changes in drying agent parameters over the layer height. To determine the concentration dependence of the mass-conductivity coefficient, a zonal method has been used.*

**Keywords:** heat pump; dryer; kinetic calculation.

---

## **1. Introduction**

To increase the efficiency of using a heat pump in a farm, it can be used for heating a farmhouse in winter, and for household needs in summer, for example, for drying seed grains. The drying of corn grains in a farm is discussed in the paper. The objectives of this work are: 1) analysis of the efficiency of using a heat pump in grain dryer, 2) developing an engineering method for the kinetic calculations of a periodically operating fluid bed dryer based on the analytical method of kinetic calculations, 3) obtaining the data on the mass conductivity of corn grains.

## **2. Farm heat pump dryer (HPD)**

The moisture content of corn harvested from the field is in many cases higher than that required by storage conditions, so it is removed by thermal drying. For this purpose, a farmer heat pump plant with a fluidized bed of periodic operation can be used in a farm specializing in the production of seed-quality grains. A thermodynamic analysis was performed for the operation of such an installation in which the source of low-potential heat is the ground and the drying agent is atmospheric air heated by a heat pump to a temperature of 60°C. The R600a was taken as the refrigerant and its thermodynamic parameters were taken from literature.<sup>[1]</sup> As the result of analysis, it was found that 1) the energy conversion coefficient is  $\Psi = 2.98$ ; 2) the energy saving for heating the drying agent is 66.4% due to the use of the heat pump, 3) for a fluidized-bed HPD at drying corn with a mass load of 75 kg, the total electric energy costs for the process (for heat pump and for air purge through the dryer) are ~ 16 kW, which is acceptable for operation of the dryer in the farm. Thus, the performed analysis and calculations show using HPD for drying corn seeds on a farm is fully justified.

## **3. Kinetic calculation of a batch fluidized bed dryer (FBD)**

The level of development the theory of drying, the mathematical modeling methods, the availability of effective computational programs, the widespread distribution of personal computers allow to use successfully the mathematical methods for the kinetic calculations of dryers - analytical<sup>[2, 3]</sup> and numerical ones.<sup>[4, 5]</sup> Such methods of kinetic calculations of continuous dryers for disperse materials has been developed. The operation of a batch dryer differs by the nonstationarity of the process, and it must be taken into account in the design calculation. In this paper, we present a method that takes into account the nonstationarity of the process. At the development stage the general kinetic problem was decomposed into two levels: microkinetic and macrokinetic. At the microkinetic level, the drying kinetics of single corn kernels were considered, and the influence of technological factors on the process was taken into account at the macrokinetic level. When formulating the microkinetic model, it was assumed that the grain is isotropic and assumes a shape of a

sphere with a radius R which volume is equal to the grain volume. The zonal method of calculation was used: the entire range of the moisture content of the material during the drying process was divided into a number of concentration zones, for each of which was given the necessary values of the mass conductivity coefficient and of other characteristics of the process. The drying duration in these zones was calculated by the analytical solution of the mass-conductivity problem in a regular mode<sup>[6]</sup>

$$\tau_i = \frac{R^2}{\mu_i^2 \cdot k_i} \cdot \ln \frac{B_i}{\bar{E}_i}, \quad (1)$$

where  $\mu_i$  is the first positive root of the characteristic equation for the solution of the problem at the i-th zone <sup>[6]</sup>;  $\bar{E} = (\bar{u}(\tau) - u_e) / (\bar{u}_{in} - u_e)$  represents the relative average volume moisture content of the grains;  $\bar{u}$  - average moisture content of grain, kgkg<sup>-1</sup>;  $B_i$  is the first preexponential factor of the solution of the mass-conductivity problem<sup>[6]</sup>. The grain temperature was calculated on the basis of the solution of the heat conduction problem.<sup>[6]</sup> This solution for the medium-volume temperature of a spherical body has the form<sup>[6]</sup>

$$\bar{\Theta} = \frac{\bar{t}(\tau) - t_a}{t_{in} - t_a} = \sum_{n=1}^{\infty} B_n \left[ \exp(-\mu_n^2 Fo) + \frac{R_V}{R} Ko Lu \frac{\mu_n^2}{Bi} \times \right. \\ \left. \times \sum_{m=1}^{\infty} B_m \frac{\mu_m^2}{\mu_m^2 - Lu \cdot \mu_m^2} \left[ \exp(-\mu_m^2 Fo \cdot Lu) - \exp(-\mu_n^2 \cdot Fo) \right] \right], \quad (2)$$

where  $\bar{t}$  - average temperature of grain, °C;  $B_n$  are coefficients that depend on the Biot number thermal;  $R_V$  is the ratio of the volume of the body to its surface (for a sphere  $R_V = 3$ );  $Fo$  - Fourier number caloric;  $Ko$  - Kossovitch number;  $Lu$  - Luikov number.

In describing the process at the macrokinetic level, it was assumed that in the FBD of a batch action, the solid phase is completely mixed, and the gas phase is ideally displaced. The moisture content and temperature of the drying agent in such a dryer vary both over layer height and in time. The kinetic calculation was carried out by the zonal method - based on the average values of the air parameters in the concentration zones ( $u_{in,i} \dots u_{f,i}$ ), which were found from the equations of material and heat balance. To take into account changes in air parameters over time, the successive approximations method was applied: first, the drying time  $\tau_i$  required to change the moisture content of the material from  $u_{in,i}$  to  $u_{f,i}$  was set, and then it was determined by calculation using equation (1). At the macrokinetic level, the following basic values were calculated: 1) the rate of fluidization beginning, at which the working air velocity was selected, and then the mass air flow in the

dryer ( $\text{kg s}^{-1}$ ) was determined; 2) the average in time  $\tau_i$  moisture content of the air at the outlet from the dryer  $\bar{d}_{fi}$  and then the average moisture content of the air in the layer on the time interval  $\tau_i$ :  $\bar{d}_{la,i}$ ; 3) the average in time  $\tau_i$  temperature of the air at the outlet from the dryer  $\bar{t}_{a,f,i}$ , and then - the average air temperature in the layer. The average values of the temperature and air moisture content in the layer were used to find the mass coefficient and the equilibrium moisture content of the material in the zones.

#### **4. Experimental research. Materials and Methods**

The experiments were performed to determine the equivalent diameter, density, mass conductivity and hygroscopic properties of corn grain of the following three varieties currently cultivated in Russia: Pioneer PR-8521, Pioneer PR-7709 FAO 160, Mysodur Amelior F-70. Equivalent diameter was determined by measuring the volume of a group of grains using a graduated cylinder, density - by measuring the volume and their mass. For the Pioneer PR7709 FAO 160 corn, the following has been determined:  $d_{eq} = 8.24 \text{ mm}$ ,  $\rho = 1065 \text{ kg m}^{-3}$ . The dependence  $k=f(u,t)$  was determined by the zonal method with the experimental drying curve taken in the absence of an external diffusion resistance.<sup>[6]</sup> Drying curves were obtained for 10 corn kernels of the same equivalent diameter  $d_{eq} = 2R$  - in a specially designed experimental setup with a triple replication of the tests, at five drying agent temperatures: 40, 50, 60, 70 and 80 °C, at air velocity  $5 \text{ ms}^{-1}$ . There is no external diffusion resistance at this air flow (its absence was judged by the fact that the change in the air velocity by half did not affect the drying curve). Corn grains were placed between the coils of the spring suspension, which was blown by the air stream in the transverse direction. The weight of the samples during drying was measured using the Techniport torsion balance PRLT with accuracy of 1 mg without removing grains from the drying chamber. The data obtained in the experiment on the coefficient of mass conductivity are shown in Fig. 1 for corn Pioneer PR-8521 (for other varieties the dependencies are similar). The data analysis allowed to draw the following conclusions: 1) the dependence of  $k$  on  $u$  for different varieties of corn is of the same character, the values of the mass coefficient for different varieties are close in magnitude; 2) the mass conductivity coefficient changes significantly with the moisture content of the material, it requires to take this change into account when drying; 3) the functions  $k=f(u,t)$  have the form characteristic for the seeds of other crops - such as canola, wheat, rye, barley, but greater in their values; 4) the rate of drying is limited by internal mass transfer.

Fig. 1 Dependencies  $k = f(u)$  for corn kernels of Pioneer PR-8521: 1 –  $t_a = 40\text{ }^\circ\text{C}$ ; 2 –  $50\text{ }^\circ\text{C}$ ; 3 –  $60\text{ }^\circ\text{C}$ ; 4 –  $70\text{ }^\circ\text{C}$ ; 5 –  $t_a = 80\text{ }^\circ\text{C}$  (points - experiment, lines - calculation).

## 5. Verifying the adequacy of the mathematical model

The adequacy of the model describing the microkinetic has been verified by comparing the experimental curve for drying the corn kernels located in a longitudinally blown monolayer at a low air velocity ( $1.8\text{ ms}^{-1}$ ) and the drying curve calculated for these conditions using the obtained data (note that the values of the mass coefficient were found from the drying curves, with an other air velocity  $\sim 5\text{ ms}^{-1}$ ). Figure 2 allows to compare the experimental and calculated drying curves, and it shows satisfactory match. The adequacy of the mathematical model describing the kinetics of corn grain drying in a batch fluidized bed

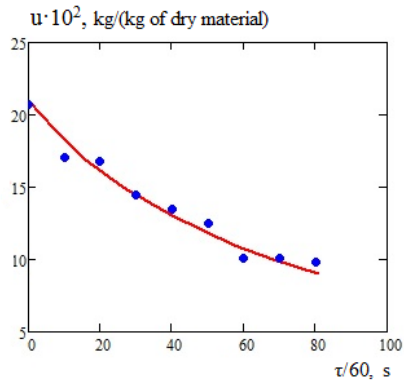

Fig. 2 Comparison of calculated (line) and experimental (points) drying curves for corn kernels of variety Pioneer PR-7709 FAO-16 ( $t_a = 50\text{ }^\circ\text{C}$ ,  $v = 1.8\text{ ms}^{-1}$ ).

dryer has also been verified by comparison of the calculated and experimental drying curves, the latter being obtained under laboratory conditions. The scheme of the laboratory dryer is shown in Fig. 3. In the experiment, a curve was obtained for drying corn grain in a layer (dryer diameter 150 mm, fixed bed height 190 mm), measuring the air velocity, temperature and moisture content of the air at the entrance to the material layer and at the outlet from it. Fig. 4 shows the comparison of the calculated and experimental drying

**Fig. 3** Scheme of laboratory installation: 1 - air temperature meter; 2 - drying chamber; 3 - corn; 4, 7 - gas distribution grids; 5 - air heating chamber; 6 - glass balls; 8 - gas blower; 9 - frequency converter, 10 - measuring diaphragm; 11 - pressure transmitter, 12 - secondary device, 13 - motor.

curves whereas Fig. 5 presents the comparison of calculated and experimental air temperatures at the outlet from the layer of drying material. As can be seen, the experimental data compare well with the calculated ones.

Fig. 5 Air temperature at the entrance to the material layer  $t_{a,in}$  (1) and at the outlet from the layer  $t_{a,t}$ : (2 - experiment, 3- calculations).

## 6. Conclusions

- 1) The feasibility of using HPD in a farmer dryer for corn seed is shown.
- 2) A zonal analytical method for engineering calculation of a periodically operating dryers with a fluidized bed of particulate material is developed.
- 3) Data on corn kernels required for calculations are obtained.
- 4) There is an internal diffusion kinetic regime when drying corn.
- 5) The adequacy of the mathematical model for drying kinetics to the real process is shown.

---

### **Abstract**

*Skimmed milk powders (SMP) were produced by ultrasonic atomizing-assisted spray drying (UASD). It was found that UASD can produce high quality SMP (with < 5% moisture content and < 2% insolubility) at lower inlet temperatures (~130°C). The particle size of the UASD-SMP was 10 times smaller (decreased from ~20 µm to 4 µm) than the traditionally spray-dried SMP and the color appeal of UASD-SMP was also better (L\* value increased by > 6 %). Overall, this research shown that UASD can be used to produce small particle size and high quality SMP.*

**Keywords:** *Skimmed milk powder; ultrasonic atomization; spray dryer; particle size distribution; color*

---

## **1. Introduction**

Atomizer is the key component of a spray dryer. It greatly affects the particle size and the quality of the final products. Rotary atomizer and pressure atomizer are the most commonly used atomizers in spray drying. Rotary atomizing produces droplets with a droplet size of 1-600 $\mu\text{m}$  whereas pressure atomizing generates droplets that ranged from 10-800 $\mu\text{m}$  [1-2]. After water evaporation process, these droplets are generally dried to >20 $\mu\text{m}$  dried particles [3]. Therefore, installation of a nano-micro sized atomizer in a spray dryer is expected to obtain the dried products with a smaller particle size.

Ultrasonic atomizing possesses many advantages. It produces small droplets, and is easy for absorption in human digestive system. Unlike the traditional atomizing methods that rely on high pressure or high-speed motion to smash liquid samples, ultrasonic atomizing utilized the low ultrasonic vibration energy as the driven force [4]. Besides, by adjustment of the amplitude of the vibration, the atomizing speed can be precisely controlled. Therefore, the droplets produced by ultrasonic atomizing are more regular, uniform and smaller than those droplets generated by traditional atomizing methods [5].

This research used fresh aqueous skimmed milk as the representative raw material. The relationships between the processing parameters (e.g. inlet temperature) and the product quality of ultrasound atomizing-assisted spray drying were systematically studied. The water content, solubility, color profile, protein content, particle size distribution, acidity, bulk density and microstructure of the final dried products were determined. These processing parameters and quality profiles were compared with those particles produced using a rotary atomizer-equipped spray dryer. The findings of this study contribute to the understanding and application of the atomizing-assisted spray drying.

## **2. Materials and Methods**

### **2.1. Materials**

Skimmed milk: Arla skimmed milk (1L, manufactured in Germany) was obtained from a Auchan supermarket in Wuxi. The skimmed milk contains 3.6g/100mL protein, 0g/100mL lipid, 5.1g/100mL carbohydrate, 50mg/100mL sodium and 120 mg/100mL calcium.

### **2.2. Methods**

#### *2.2.1. Experimental design and equipment*

The experimental design and related equipment is shown in Table 1 and Table 2, respectively. Regarding the experimental design, different inlet temperatures were used to analyse the effects of drying parameters on the quality of the ultrasound atomizing-assisted spray dried products.

**Table 1. Experimental design of this study**

Drying Methods	Inlet Temperature (°C )	Quality analyses
UASD	110、130、150、170、190	Water content、 color profile、 protein
RDS	130、150、170、190、210	content、 acidity、 bulk density、

UASD-Ultrasound atomizing-assisted spray drying, RDS-High-speed rotating dish spray drying

**Table 2. Equipment used in this study**

Equipment	Product model	Manufacture
High-speed rotating dish	QZR - 5	Linzhou Drying Equipment Co., Ltd,
Color meter	CR - 400	Canon Inc, Japan
Electronic balance	PL 203	Mettlet Toledo Co., Ltd, China
Mastersizer	2000	Malvern Inc, England
Scanning electro microscope	S-4800	Hitachi Co., Ltd, Japan
Lipid meter	SOX-406	Hanon Instruments Co., Ltd, China
Electric drying oven with	GZX-9140MBE	Boxunshiye Co., Ltd, China

### 2.2.2. Research platform of UASD

In this study, the ultrasonic atomizer was manufactured with 10 ultrasonic vibrators. The size of this ultrasonic atomizer is: 255mm length × 90mm width × 30mm height. The oscillating frequency of the ultrasonic atomizer was 1.7MHz with a maximum atomizing capacity of 0.5kg/h. The droplet size obtained by ultrasonic atomizing process was within the range of 2-10µm. The temperature of the feed solutions was controlled by a combined temperature controller and feed-recycling system. The temperature controller was manufactured by Thermo Electron Co., Ltd (HAAKE DC10-K10, Germany), which works in the temperature range of 10-100°C. The ultrasonic atomizing system is connected with a high-speed rotating dish spray dryer. The size of this spray dryer is 1600mm length × 2200mm width × 2500mm height. The water evaporation capacity and the electrical heating powder of this spray dryer is 5kg/h and 16KW, respectively. At the working stage, the rotary atomizer that equipped in the spray dryer was removed, and a thermal resistant tube was used to link the spray dryer and the ultrasonic atomizing system. The tube was inserted in the drying chamber with a reveal part of ~200mm.

### 2.2.3. Determination of the drying parameters of UASD and RDS

In order to achieve a desirable atomizing effect, skimmed milk have to be diluted and stored at a suitable temperature. A high concentration and low temperature environment results in a low atomizing capacity. However, if the temperature of the skimmed milk exceeds the protection range of the ultrasonic atomizer, the atomizing system will automatically close and stop working. We have done preliminary experiments and optimized the atomizing conditions (data not shown). In this study, the skimmed milk used

for UASD was diluted by adding distill water at a milk to water ration of 1:2.5; The temperature of this diluted solution was controlled at 30-35°C. The skimmed milk that used for RDSO was directly dried without any treatment. Regarding the atomizing capacity, the centrifuge frequency of high speed rotating dish spray dryer was 300Hz with an atomizing capacity of 900mL/h; the oscillating frequency of the ultrasonic atomizer was 1.7MHz with an atomizing capacity of 100mL/h.

#### *2.2.4. Measurements of the quality profiles of the skimmed milk powders produced by UASD and RDSO*

**Water content:** water content of the SMP produced by the two drying methods was determined by an electric drying oven (Table 2) with forced convection according to a national standard method (GB/5009.3-2016) [6].

**Solubility:** solubility of the SMP produced by the two drying methods was determined according to a national standard method (GB / 5413.29 – 2010) [7].

**Color profiles:** color profiles of the SMP were measured by using a CR-400 color meter (Table 2). The L, a and b value represents the extent of white/black, red/green, yellow/blue color of the skimmed milk after drying, respectively.

**Acidity:** acidity of the SMP produced by the two drying methods was measured according to a national standard method (GB / 5009.239 - 2016) [8].

**Particle size:** particle size of the dried products was determined by using a master sizer (Table 2) [9]. Each measurement was performed for triplicates and the average data was reported.

**Microstructure:** Morphological characteristics of the SMP produced by the two drying methods was determined by using S-4800 scanning electro microscope (Table 2). The acceleration voltage was 1.0kv. The dried products were coated by a palladium-gold alloy coating instrument (manufactured by Bal-Tec. Inc). The scanning electro microscope images of SMP samples were captured within a range of 600 – 2400 magnifications.

### **3. Results and Discussion**

#### **3.1. Water content of the dried SMP using UASD and RDSO as a function of different inlet temperatures**

As shown in Table 3, inlet temperature significantly affected water content of the SMP ( $p < 0.05$ ). Higher inlet temperatures resulted into a lower water content of the UASD-SMP and RDSO-SMP. At an inlet temperature of  $\geq 170^\circ\text{C}$ , no significant difference was observed for the water content of UASD-SMP and RDSO-SMP samples ( $p > 0.05$ ). When inlet temperature was  $\leq 150^\circ\text{C}$ , the water content of UASD-SMP was lower than that of RDSO-SMP. The water content of the RDSO-SMP was  $> 5\%$  at an inlet temperature of  $130^\circ\text{C}$ .

However, the water content of the UASD-SMP was below this national acceptable moisture content at an inlet temperature of 110°C. The findings of this section indicate that lower inlet temperature (of spray drying) was required to achieve an acceptable water content of SMP by applying UASD method. This was attributed to the small droplet size of ultrasonic atomizing, which allows the fast evaporation of water.

**Table 3. Water content of the skimmed milk powders obtained by UASD and RDS**

Inlet temperature (°C)	110	130	150	170	190	210
UASD-SMP	4.317	4.091 <sup>a</sup>	2.524 <sup>a</sup>	2.145 <sup>a</sup>	1.601 <sup>a</sup>	-
RDS-SMP	-	5.241 <sup>b</sup>	3.105 <sup>b</sup>	2.075 <sup>a</sup>	1.574 <sup>a</sup>	1.445

\*The data with different superscript at a same column is significantly different (p<0.05).

### 3.2. Solubility of the dried SMP using UASD and RDS as a function of different inlet temperature

At a certain extent, changes of solubility of SMP indicates the denaturation of proteins. Thus, low SMP solubility could be resulted by the denaturation of its protein component, negatively affecting its rehydration performance. Furthermore, different particle size of the dried powders also contributes to the varied solubilities of SMP.

As shown in Table 4. Solubility of the UASD-SMP decreased significantly with an increased inlet temperature (p<0.05). At an inlet temperature of ≤130°C, the solubility of UASD-SMP was 98.66-98.97% (meets the national standard of >97%); At an inlet temperature of >130°C, the solubility of UASD-SMP decreased sharply to 89.72-95.01%. Regarding the RDS-SMP, the dried powders possessed a solubility of >97% within the whole inlet temperature range of 110°C – 210°C. Overall, these findings indicated that solubility of the UASD-SMP was susceptible to inlet temperatures of spray drying. High inlet temperature(>130°C), small droplets size and tiny dried particles caused the denaturation of proteins component in SMP and significantly reduced its solubility (p<0.05).

**Table 4. Solubility of the skimmed milk powders obtained by UASD and RDS.**

Inlet temperature(°C)	110	130	150	170	190	210
UASD-SMP	98.66	98.97 <sup>a</sup>	95.01 <sup>a</sup>	90.79 <sup>a</sup>	89.72 <sup>a</sup>	-
RDS-SMP	-	98.95 <sup>a</sup>	97.82 <sup>b</sup>	97.83 <sup>b</sup>	97.71 <sup>b</sup>	97.96

\*The data with different superscript at a same column is significantly different (p<0.05).

### 3.3. Color profile of the dried SMP using UASD and RDS as a function of different inlet temperature

The color profiles of UASD-SMP and RDS-SMP are provided in Table 5. As shown in Table 5. Inlet temperature of the spray drying processes did not cause significant effects on the lightness color of SMP (p>0.05). However, the UASD-SMP was significantly lighter

than RDSD-SMP ( $p < 0.05$ ). Inlet temperature of the spray drying processes significantly affected the  $a^*$  value of SMP ( $p < 0.05$ ). High inlet temperature decreased the  $a^*$  value. At the same inlet temperatures,  $a^*$  value of the UASD-SMP was significantly lower than that of the RDSD-SMP. This means that the UASD-SMP samples were less red than RDSD-SMP. High inlet temperature increased the  $b^*$  value. At the same inlet temperatures,  $b^*$  value of the UASD-SMP was significantly higher than that of the RDSD-SMP, indicating a more yellowness color.

**Table 5. color value of the skimmed milk powders obtained by UASD and RDSD**

Inlet temperature(°C)	color value	110	130	150	170	190	210
UASD-SMP	$L^*$	98.31	97.47 <sup>a</sup>	97.81 <sup>a</sup>	97.55 <sup>a</sup>	97.42 <sup>a</sup>	-
	$a^*$	-2.65 <sup>a</sup>	-2.42 <sup>a</sup>	-2.53 <sup>a</sup>	-2.58 <sup>a</sup>	-3.02 <sup>a</sup>	-
	$b^*$	11.28	11.61 <sup>a</sup>	12.08 <sup>a</sup>	13.03 <sup>a</sup>	14.66 <sup>a</sup>	-
RDSD-SMP	$L^*$	-	95.25 <sup>b</sup>	95.62 <sup>b</sup>	96.23 <sup>b</sup>	96.55 <sup>b</sup>	95.36
	$a^*$	-	-2.22 <sup>b</sup>	-2.02 <sup>b</sup>	-2.38 <sup>b</sup>	-2.71 <sup>b</sup>	-3.22
	$b^*$	-	10.05 <sup>b</sup>	9.68 <sup>b</sup>	10.21 <sup>b</sup>	10.65 <sup>b</sup>	12.51

\*The data with different superscript at a same column is significantly different ( $p < 0.05$ ).

### 3.4. Acidity of the dried SMP using UASD and RDSD as a function of different inlet temperature

Acidity of the UASD-SMP and RDSD-SMP samples is presented in Table 6. The acidity of both UASD-SMP and RDSD-SMP were lower than the national standard value of 18°T. UASD-SMP was more acidic than RDSD-SMP, indicating the less oxidation occurred during the drying process. This might be due to the shorter water evaporation period and lower inlet drying temperature of the UASD process.

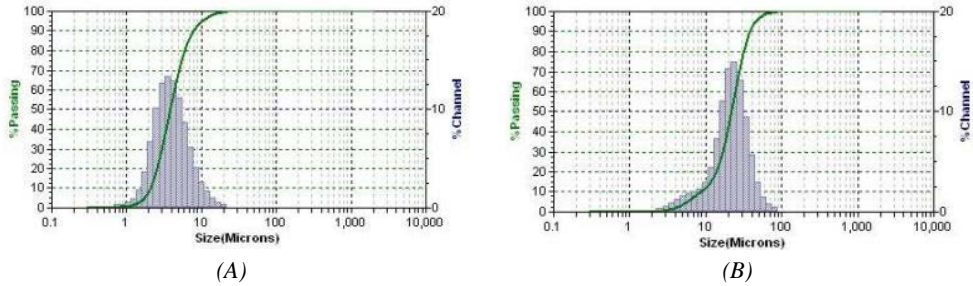

**Table 6. Acidity of the skimmed milk powders obtained by UASD and RDSD**

Drying Methods	Acidity (°T)
UASD (inlet temperature of 130°C)	15.91 <sup>a</sup>
RDSD(inlet temperature of 170°C)	16.89 <sup>b</sup>

\*The data with different superscript at a same column is significantly different ( $p < 0.05$ ).

### 3.5. Particle size of the dried SMP using UASD and RDSD

The average particle size and particle size distribution of the UASD-SMP and RDSD-SMP samples is presented in Fig. 1. The particle size of UASD-SMP was >5 times smaller than that of RDSD-SMP samples. This is due to the differences between the droplets produced by ultrasonic atomizing and high-speed rotary atomizing. The ultrasonic atomized droplet size was in a range of 2-10  $\mu\text{m}$ , and hence the surface area to contact the drying medium was enlarged enormously. This not only resulted into a fast water evaporation period, but also significantly reduced the particle size of SMP ( $p < 0.05$ ).

**Fig.1 Particle size distribution of (A) UASD-SMP obtained at 130°C inlet temperature and (B) RDS-D-SMP obtained at 150°C inlet temperature**

### 3.6. Morphological characteristics of the dried SMP using UASD and RDS

The morphology of SMP samples were monitored by scanning electro microscopy (Fig.2). The particles obtained through UASD were much smaller than those produced by RDS, which was also confirmed by the laser diffraction measurements as mentioned in section 3.5. The UASD particles were irregular, shrunk and compacted; the microstructure of RDS particles was spherical, uniformly distributed and loosely organized with a few broken skins. These differences in microstructure of SMP might explain the lower solubility of UASD-SMP, e.g. the uniformity of UASD-SMP was lower than that of RDS-SMP, the structure of UASD-SMP was more compact than RDS-SMP.

RDS-SMP ( $\times 2400$  magnification)

UASD-SMP ( $\times 2400$  magnification)

**Fig. 2 Scanning electro microscopy images of the dried SMP using UASD and RDS**

## 4. Conclusions

This research systemically compared and studied the quality aspect of SMP obtained by a novel drying method. The innovative UASD is expected to produce high quality and small particle size SMP. UASD required as low as 110°C inlet temperature to obtain dried SMP (<5% water content), which was almost 50°C lower than the inlet temperatures used for the traditional spray drying. Furthermore, the particle size of the UASD-SMP ( $\sim 4\mu\text{m}$ ) was >5 times smaller than that of the RDS-SMP. The color appeal of the UASD-SMP was >6% lighter than that of the RDS-SMP. These findings indicated that UASD is a promising

drying method to produce high quality powders for food and pharmaceutical industries. However, there are still a few scientific issues have not been solved for the USD method. E.g. the atomizing capacity of high-solid content solutions is relatively low; the final dried products is difficult to collect though the gas-solid separator that designed for the traditional spray drying. Therefore, further research on USD is recommended to be carried out in the drying field.

### **Abstract**

*Agitated thin film dryers (ATFD) has been considered as an effective technology for drying viscous liquid foods, pastes or pureed foods. In this study, a lab-scale ATFD was developed and applied for drying of juices from spinach leaves at varying temperature (60 – 90 °C), feed rate (0.3 – 0.5 kg/h) and blade rotation speed (300 – 600 RPM) combinations. Juice suspensions were successfully dried into powder with a moisture content ranging from 0.049 to 0.114 kg/kg total. Increasing the wall temperature and feed rate were found to improve the specific evaporation rate and evaporation rate of the ATFD, respectively. The blade rotation speed had limited effect on the water removal rate, while it played a crucial role in powder formation.*

**Keywords:** *Food solution; Spinach juice; Thin film drying; Scraped surface; Vacuum conductive drying.*

## **1. Introduction**

Drying is a commonly used technology to preserve food products. Various types of dryers have been developed that are tailored to specific feed properties and product requirements [1]. The most commonly applied drying technologies to liquid feeds can be categorized into two types, i.e. convective and conductive drying. Spray drying is one of the most commonly applied convective drying methods, where energy for evaporation is supplied by hot air to the product that is dispersed in micron-sized droplets [2]. Drum and agitated thin film drying are conductive drying methods, where energy for evaporation is supplied by steam condensation and transferred via a wall to the product that is applied at the other side. Whereas drum drying is more readily applied and effective for drying of viscous liquid foods, pastes or pureed foods, agitated thin film drying is not yet widely applied [1, 3]. Comparing to spray drying, drum drying is more efficient as it consumes on average 40% less energy due to a.o. lower energy loss via the exhaust gas [2, 4]. A major drawback of atmospheric drum drying is however that the product is exposed to the boiling temperature (100 °C), which can lead to undesired damage to heat sensitive foods [1, 3]. Operation of drum drying processes under reduced pressure could be an attractive alternative as well, but capital costs of vacuum drum dryers are relatively large. Agitated thin film drying (ATFD) is therefore identified as a promising alternative conductive drying method.

Only very few studies investigated ATFD. Pawar et al. [1, 5] mathematically studied the heat transfer and mass transfer during ATFD and proposed a stage-wised penetration theory model, by assuming ideal mixing between the bow wave and the thin film. However, the model was validated with ATFE instead of ATFD experiments. Because during ATFD the feed will transform from a viscous liquid into a paste and subsequently into a powder, this may be expected to have large influence on the mass and heat transfer during operation [6]. Hitherto, to the best of our knowledge no experimental studies have systematically investigated product transformation during ATFD drying and its consequence on the drying behaviour. It may be expected that the product properties will have large influence on the drying behaviour in an ATFD.

The aim of this study was therefore to obtain better understanding of drying behaviour of foods during ATFD drying and how this is influenced by process. Suspensions prepared from spinach leaves were selected as model system to investigate the influence of drying parameters, i.e. heating temperatures, feeding rates and rotation speeds.

## **2. Materials and Methods**

### **2.1. Material**

Spinach suspensions for ATFD experiments were prepared starting from fresh spinach leaves, which were purchased from the local supermarket. The fresh spinach leaves were

juiced by an Angelia AG-7500 Juicer (Angel Co. Ltd, Republic of Korea). After juicing, the squeezed juice and fibre residues were collected separately. The obtained insoluble fibre residues were dried by a hot air oven (Binder, Tuttlingen, Germany) at 60 °C for 20 hours. The dried fibres were milled by the Rotor Mill Pulverisette-14 (FRITSH International, USA) at 6000 RPM with a 0.2 mm sieve. The drying and milling of fibres was necessary because the fibre particles had to be small enough to avoid blockage of the feeding pump. Subsequently, the milled fibres were added back into the squeezed juice to obtain a spinach suspension with approximately again 2% w/w fibers. In addition, around 5 drops of Antifoam B aqueous silicone emulsion (Sigma-Aldrich<sup>®</sup>, Zwijndrecht, Netherlands) was added into 1 litre juice to prevent excessive foaming.

## **2.2. Lab-scale Agitated Thin Film Drying**

A lab-scale agitated thin film dryer was custom build for the experiments. The ATFD chamber was made from transparent glass to facilitate observation of the used heat exchange area. The ATFD chamber was equipped with a Liebig condenser and a dropping funnel (L.G.S. B.V, Ubbena, Netherlands) to condense and quantify the vapour release. The entire system was operated under reduced pressure (50 mbar) using a vacuum pump (type, country). Experiments were performed to determine the (specific) evaporation rates of the spinach suspensions at different drying conditions. The spinach suspension was preheated to 33 °C and then supplied to the system with a flow rate ranging from 0.3 kg/h to 0.5 kg/h. The drying temperatures of the heating chamber ranged from 70 to 90 °C. The condenser was operated with cooling water of 2 °C. The amount of condensed water was measured and used to obtain the evaporation rate. The specific evaporation rate was calculated by dividing the evaporation rate by the used heat exchange area.

## **2.3. Analysis of the moisture content and water activity**

Powders were collected at the bottom of the lab-scale ATFD for analysis of the moisture content and water activity. To determine the moisture content, around 1.5 g of the powder was dried in a hot air oven (Binder, Tuttlingen, Germany) at 105 °C for 16 hours. The water activity was measured by an AquaLab 4TE dew point water activity meter (METER Food, Munich, Germany). Measurements were carried out in duplicate.

## **3. Results and discussion**

The lab-scale ATFD setup was used to dry the prepared spinach suspensions at different drying conditions, which are reported in Table 1. The effect of the drying temperature on the evaporation rate and the specific evaporation rate was determined, as shown Fig. 1. Fig.

1 (A, B) showed that with the increase of drying temperature, the evaporation rate did not change significantly ( $p > 0.05$ ), while the specific evaporation rate significantly increased ( $p < 0.05$ ), based on one-way ANOVA analysis. This is because at higher drying temperature, the surface area used for drying decreased, as shown in Fig. 1 (C). The smaller surface area used for drying in this situation is related to the higher heat flux from the hot wall towards the sample at increased wall temperatures, which results in a higher specific evaporation rate. In this case the maximum feed rate can be increased, which benefits the capacity of the equipment.

**Fig. 1** (A) The evaporation rate and (B) the specific evaporation rate in the ATFD for different temperatures (Rotation speed = 600 RPM, Feed rate = 0.3 kg/h). The error bars represent the standard deviation of the experimental data ( $n = 3$ ). The same letters represent no significant difference at the 95% confidence interval. (C) The visual image of usage the ATFD chamber under different drying temperatures.

**Table 1** The fraction of the used heating exchange area, the moisture content and water activity of the powder at different drying conditions

No.	Drying conditions				Fraction of used heating area (-)*	Moisture content (kg/kg total)*	Water activity (a <sub>w</sub> )*
	Feed rates (kg/h)	Drying temperature (°C)	Rotation speed (RPM)	Vacuum (mbar)			
1	0.3	60	600	50	0.58 <sup>a</sup> ± 0.03	0.096 ± 0.009	0.55 ± 0.02
2	0.3	70	300	50	0.38 <sup>b</sup> ± 0.05	NaN**	NaN**
3	0.3	70	400	50	0.42 <sup>ab</sup> ± 0.11	0.087 ± 0.002	0.57 ± 0.02

9	0.5	90	600	50	0.34 <sup>bd</sup> ± 0.08	0.098 ± 0.071	0.56 ± 0.20

a-d : The same letters represent no significant difference at the 95% confidence level;

\* : Each value is expressed as mean ± SD;

\*\* : Not a number.

Fig. 2 and Fig. 3 shows the influence of the rotation speed and the feed rate on the evaporation rate and the specific evaporation rate. From Fig. 2, we can observe that both the evaporation rate and the specific evaporation rate did not change at different rotation speeds ( $p > 0.05$ ). This observation is opposite to simulations with the model proposed by Pawar et al. [1]. Pawar et al. [1] proposed that the heat transfer coefficient of the ATFD may be derived from the heat penetration theory and increases with the rotation speed. Therefore, the specific evaporation rate should increase as well. However, Pawar et al. [1] also experimentally observed that the water evaporation rate was independent of the speed of the blades, when they concentrated the 20% w/w ammonium sulphate solution in an ATFE. The differences between the experimental data and the model predictions are discussed later in more detail.

According to Fig. 3, we found that the effect of the feed rate is opposite to that of the temperature. The increased feed rate resulted in an increase in the evaporation rate ( $p < 0.05$ ) while it did not affect the specific evaporation rate ( $p > 0.05$ ), which can be explained by the increased usage of heat exchange area (Table 1).

Table 1 shows the moisture content and water activity ( $a_w$ ) of the dried spinach powder and the fraction of dissolved powder at different drying conditions. It can be seen that the moisture content of the powder ranges from 0.049 to 0.114 kg/kg total and the water activity of the powder ranges from 0.26 to 0.60. Although foods with  $a_w < 0.6$  may be considered as microbiologically stable, further drying in for example a fluidized bed would be recommended for vegetable powders to further decrease the water activity to  $a_w < 0.2$  [7]. It should be mentioned that during experiment No. 2, no powder was produced. Probably this was due to the low rotation speed, which did not provide enough shear stress to fracture the material. Therefore, even though the rotation speed does not affect the heat transfer (Fig. 2), it plays a crucial role to induce powder formation.

**Fig. 2 (A) The evaporation rate and (B) the specific evaporation rate in the ATFD for different rotation speeds (Temperature = 70 °C, Feed rate = 0.3 kg/h). The error bars represent the standard deviation of the experimental data (n = 3). The same letters represent no significant difference at the 95% confidence interval.**

**Fig. 3** (A) The evaporation rate and (B) the specific evaporation rate in the ATFD for different feed rates (Temperature = 90 °C, Rotation speed = 600 RPM). The error bars represent the standard deviation of the experimental data (n = 3). The same letters represent no significant difference at the 95% confidence interval.

#### 4. Conclusion

In this study suspensions prepared from spinach leaves were dried in a lab-scale agitated film dryer under different conditions. Obtained spinach powders were flowable, although the final moisture contents were relatively high. The drying behaviour was characterised and especially wall temperature appeared to determine the specific evaporation rate, which can benefit the dryer capacity. Surprisingly, blade rotation speed did not affect the drying rate, but appeared crucial to break up the material into small powder particles during the process.

### **Abstract**

*Drying conditions for convective driers are often based on empirical approaches in which the final product quality is evaluated post processing. Modern sensor technology and data processing enable second-by-second quality analyses but conventional systems do not utilize this possibility. An industrial convective drying chamber was modified with a camera system to investigate the product during the drying process. The obtained data was analyzed on color alternation (CIE-L\*a\*b\* color space and Browning Index), shrinkage and deformation. Both, shrinkage and deformation show minor dependence on drying conditons. The investigation shows the time depending optical parameter at different drying conditions. This might offer new "smart" drying programs with focus on improved product quality.*

**Keywords:** *color alternation; shrinkage; deformation; convective drying; smart drying*

## **1. Introduction**

Organic products are a growing market for European producers and commonly associated with a sustainable food chain. The production of organic processed food is mostly carried out by small and medium sized enterprises which are facing a double challenge regarding the consumer awareness for high quality products and legal standards. In recent years the organic sector has put significant effort in the development of clear definitions of gentle and quality oriented processing. Drying was identified as a preservation technology which operate inefficient with respect to raw material utilization, resulting product quality as well as energy efficiency. Consumers mostly don't know about the used amount of energy behind a dried food product or its quality standards during the drying process. This is a problem especially for organic foods which are expected to be produced sustainable and with high quality regardless to its magnitude of processing. European Community legislation only has explicit rules for agricultural production and additives used in processed food. There is a clear correlation between product quality and drying conditions and low temperature drying is commonly used for products which require gentle processing.

There has been a vast development of sensor technology in the last decade and several mass-produced optical analyzing tools are available at the market. However, industrial drying systems mostly do not utilize the possibilities which e.g. camera sensors offer. Drying of organic apples is mostly performed as batch processes by SMEs and drying conditions (mainly temperature) are empirically determined. As a result, the product quality is not monitored or controlled during processing and final product quality is first determined at the end of drying.

For the present investigation the potential of low temperature drying of organic apples was evaluated at different relative humidity with respect to color changes and product deformation during processing. A camera sensor was installed in an industrial drier which enabled determination of optical alternations of the product like color alternation, shrinkage and deformation in a continuous way without any interruption of the drying process. The results are used to suggest an improved control strategy.

## **2. Materials and Methods**

### **2.1 Product preparation**

Organic apples of the sort "Red Delicious" with the origin Italia were used for the experiments. The apples were obtained from a local organic supplier in Trondheim, Norway and stored in a refrigerator at 8°C until further processing. The apples were cut in slices of 5 mm thickness by using a cutter machine. The core and the apple skin wasn't removed so that slicing the apples was the only processing. The time between getting the apples out of the fridge, cutting and starting the experiment was always within 5 min.

## 2.2 Experimental setup

The experiments were executed in a convective drying chamber with a dimension of ca. 3m \* 1.5m \* 1m with a tray area of 50 m<sup>2</sup>. The drying chamber is equipped with an electric heater to set the drying temperature, a ventilator to set the air velocity and a heat pump to set the relative humidity. To avoid any interruptions or influences of the drying process due to measuring, a test rack was built and placed within the drying chamber at a representative point in the middle of the drier trays with all relevant measuring devices attached. The camera system (UI-5240CP-C-HQ Rev.2, company iDS Imaging Development Systems, Germany) contained a built-in heater to avoid influences of the image quality due to the surrounding temperatures in the drying chamber. The illumination was the LED-barlight (LHF300-M12-WHL, company Stemmer Imaging, Germany) with a color temperature of 6500K. The camera system was used to measure color alternations and deformations like shrinkage. To obtain also the sidelong deformation of the apple slices, a mirror was placed in a 45° angle next to the slices. In addition to the optical alternations there was also a pyrometer used for measuring the surface temperature of the apple slices and a scale (SB32000, company Mettler Toledo) to record the weight loss during the drying process. For each test series, four apple slices were analyzed by the camera system. The remaining space on the test rack was filled up with apple slices of the same thickness. The surface temperature of one representative apple slice was measured by the pyrometer. The process parameters of the test series are listed in Table 1 and are based on industrial low temperature drying conditions for organic apple producers. The drying temperature of 40 °C was used as reference case.

*Table 1: Overview of the investigated drying conditions for organic apples.*

Test series name	Humidity	Temperature	Air velocity
T20_RH25	25 %	20 °C	1,5 m/sec
T20_RH40	40 %	20 °C	1,5 m/sec
T20_RH60	60 %	20 °C	1,5 m/sec
T40_RH25	25 %	40 °C	1,5 m/sec

## 2.2 Optical analysis

For analyzing the optical alternations, an image was taken by the camera every 5 minutes and analyzed with a special application using the OpenCV libraries for image processing. An example is shown in Figure 1. The deformation of the apple slices was defined by the deviation of the actual slice area and the area of a corresponding circle whose diameter is the maximum width of the actual slice (yellow circle in Figure 1, left image). The ratio between these two areas gives a quantitative value about the deformation. A perfect round shaped apple slice e.g. would have the same area than its calculated minimum circle which results in a deformation of 1, proceeding deformation results in a value less than 1. The same principle was used to determine the deformation of the sidelong view but with using a minimum

rectangle (yellow rectangle in Figure 1, middle image). The shrinkage was defined by the ratio of the area of the actual apple slice and the area of the apple slice at the beginning of the drying process. The color alternation was measured by reading the color information of each pixel within the apple slices and averaging it (Figure 1, right image). The so obtained RGB values were transformed into the CIE-XYZ color space according the ISO Standard 13655 which is the base of the CIE-L\*a\*b\* color space and the Browning Index.

**Figure 1:** Measuring principle of the deformation top view (left), deformation sidelong (middle), color alternation (right)

The CIE-L\*a\*b\* color model was developed with the aim of linearizing the representation of colors with respect to human color perception and at the same time creating a more intuitive color system [1]. The dimensions in this color space are the luminosity L\* and the two-color components a\*, b\*, which specify the color hue and saturation along the green-red and blue-yellow axes, respectively. The CIE-L\*a\*b\* color space is often used in literature to describe the color of food.

The Browning Index is an indicator of the color change due oxidation of a freshly cut fruit or vegetable surface during storage or drying. The best known and most often quoted Browning Index is a form of excitation purity that follows the suggestion of Buera et al. (1985) [2] and is expressed as follows [3]:

$$BI = \frac{(x_{D65}-0,32)}{0,162} * 100 \quad (1)$$

(for Illuminant: D65 and Standard Observer 10°)

where x is the CIE Chromaticity value and calculated by the CIE-XYZ values

$$x = \frac{X}{(X + Y + Z)} \quad (2)$$

### 3. Results and discussion

Figure 2 shows the moisture ratio of the different test series over the drying time. The grey areas behind each test series shows the uncertainties of the data. The results shows that the

differences between the T20\_RH40 and T20\_RH25 test series is much less than compared to the T20\_RH60 test series. The same behavior was already measured in other publications for the drying of Temu Putih Herb, coriander leaves, okra and pistachio nuts [4]. The test series T40\_RH25 however shows a much quicker drying than the other test series what indicates that the drying temperature has much more influence on the drying kinetics than the relative humidity.

Figure 2: Moisture Ratio of organic apples at different drying conditions

The graph in Figure 3 shows that the CIE-L\* value is basically decreasing for all experiments over the whole drying process, what means that the apple slices became darker. Hereby the biggest rate of change happens within the first 2-3 hours, afterwards the change rate becomes insignificant. The values of the T20\_RH60 test series shows a continuous decrease of the CIE-L\* value whereas the other test series have a minimum after about 2 hours with a followed increase of the CIE-L\* value and a continuous decreasing afterwards.

Browning is one of the main quality parameters of dried apple slices and the consumer acceptance drops significant for products with increased brownish appearance. The browning Indices (BI) in Figure 4 shows, that the BI increases for all test series during the drying time. The biggest changing rate is taken place within the first 2-3 hours. All test series have a similar behavior where the browning index decreases after the first 2-3 hours and increases again afterwards. The T40\_RH25 test series is much more distinct in its curve progression than the other test series and has a higher browning index than the T20\_RH25 test series. This suggests, that a higher drying temperature and a higher relative temperature increases the browning index.

Figure 3: CIE-L\* values of organic apples at different drying conditions

Figure 4: Browning index of organic apples at different drying conditions

Browning is mostly a surface effect and all tests showed clearly that this effect occurs in the beginning of drying when naturally the product surface is dried. This gives an indication that the product quality with respect to browning could be improved by a low temperature and low humidity drying period in the beginning. Once the surface is dried and stabilized the drying temperature could then be increased so that the drying time is reduced. With the current system it is possible to program such a control algorithm in a way that the drying conditions are continuously adapted to the color change and browning of the product.

Figure 5 shows the shrinkage of the apple slices related to the area of the top frontal view over the Moisture Ratio. All test series shows an area shrinkage at the end of the drying process between ca. 25% and 35%. Hereby the shrinkage seems to be nearly linear to the moisture ratio for a certain time and converges then to an end value. The curve progress of all test series is similar what indicates, that the relative humidity has only a minor influence on the area shrinkage process of the apple slices.

The sidelong deformation results in Figure 6 doesn't start at 100% since the apples slices in the beginning of drying are not a perfect rectangle. All test series shows an increasing

deformation over the drying time. Thereby the test series with 20°C drying temperature shows a similar curve progression whereas the curve progression of the T40\_RH25 test series is taken place much faster. The magnitude of the deformation at the end of each test series is like all test series about 30% but varied very strong from apple slice to apple slice.

Figure 5: Top view shrinkage of organic apples at different drying conditions.

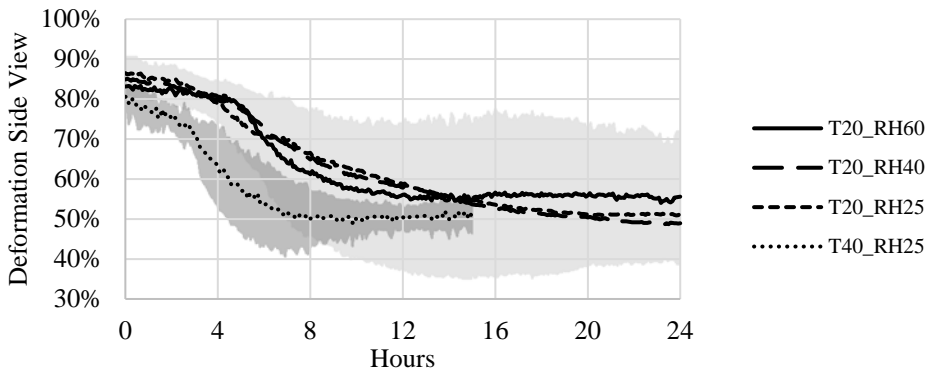

Figure 6: Side view deformation of organic apples at different drying conditions

The observations regarding deformation and shrinkage can be related to a certain mechanical stress in the product once the water is removed. Consequently, the deformation and shrinkage of the final product can most likely not be minimized by improved drying conditions. However, it can be considered to end the drying process with a higher final water content when the product is less shrunk or deformed. This would decrease the drying time and increase the amount market ready product.

#### 4. Conclusion

The application of a sophisticated, robust camera system in combination with image processing algorithm can measure optical alternations of the drying product like shrinkage, deformation and color alternation in very precise and continuous way. The browning of

organic apple slices showed a clear correlation to the humidity of the drying air, while the drying temperature only had secondary influence. The shrinkage and deformation of the product is mostly related to the moisture content of the product and the drying conditions seem not to influence the final shrinkage or deformation rate. Based on the achieved results an optimized control strategy for the industrial batch drier is suggested in which the product is first dried at low temperature and low humidity to reduce the browning effect, followed by short drying period at higher temperatures, which is finalized when the acceptable shrinkage and deformation is reached. This will result in a preservation process in which the drying conditions are continuously adjusted by the measured product changes. Such "Smart-Drying" systems require an advanced control system in which the process parameters like humidity and temperature are controlled by the actual optical conditions to improve the drying process with focus on product quality.

### **Abstract**

*This communication focuses on the development of an approach to improve the synthesis of  $[Ti_8O_{12}(H_2O)_2]Cl_8 \cdot HCl \cdot 7H_2O$  crystals which is one of the precursor for titanium dioxide  $TiO_2$  particles. This study provides a significant improvement in crystallization kinetics with a production rate increased by a factor nineteen by intensifying heat and mass transfers compared to the process in a close vessel. This enhancement was made possible by the development of a new reactor to control the heat and mass transfers involved. In parallel with the experimental set-up, a numerical model representative of the transfer phenomena was initiated. The first numerical results are encouraging and present a good agreement with the measurements.*

**Keywords:** Heat and mass transfer; Co-desorption, Modelling, Experiment

---

## 1. Introduction

Titanium dioxide  $\text{TiO}_2$  particles are widely used in various applications. Thanks to its high refractive index, the industrial production of  $\text{TiO}_2$  is mainly dedicated to produce pigments as whitening agent in paints [1]. This transition metal oxide is also well known for its n-type semi-conductivity leading to many applications such as gas sensor [2] or solar cell [3]. Additionally its bandgap close to 3.2 eV gives interesting properties related to its photoactivity such as photocatalysis, self cleaning, light induced superhydrophilicity, among others. Titanium dioxide can be synthesized from various precursors such as alkoxides or inorganic salts. Depending on the pH, single crystals of  $[\text{Ti}_8\text{O}_{12}(\text{H}_2\text{O})_{24}]\text{Cl}_8 \cdot \text{HCl} \cdot 7\text{H}_2\text{O}$  were demonstrated to selectively lead to different varieties of nanostructured titanium dioxide [4]. The crystals can be obtained by the hydrolysis of titanium oxychloride solution  $\text{TiOCl}_2 \cdot x\text{HCl} \cdot y\text{H}_2\text{O}$ , called aqueous solution of titanium tetrachloride. Due to the reactivity of the latter with water, it may be difficult to properly ensure the reproducibility of syntheses. Therefore a smart strategy is to use  $[\text{Ti}_8\text{O}_{12}(\text{H}_2\text{O})_{24}]\text{Cl}_8 \cdot \text{HCl} \cdot 7\text{H}_2\text{O}$  as reactant because of the known composition of the crystals and their solubility in polar solvents. With the adequate air temperature and air humidity conditions, the aqueous solution of titanium tetrachloride reacts to produce those crystals in releasing water and hydrochloric acid in the surrounding environment [5]. The formation process of  $[\text{Ti}_8\text{O}_{12}(\text{H}_2\text{O})_{24}]\text{Cl}_8 \cdot \text{HCl} \cdot 7\text{H}_2\text{O}$  is a complex process involving several species and several reaction kinetics. The aim here is to treat mass and heat problems in a highly reactive and deformable medium in order to get insight in the crystallization mechanisms and further optimize the process in order to accelerate the crystallisation. Figure 1 presents a simplified view of the different phenomena involved during the formation of  $[\text{Ti}_8\text{O}_{12}(\text{H}_2\text{O})_{24}]\text{Cl}_8 \cdot \text{HCl} \cdot 7\text{H}_2\text{O}$ . The commercial solution is initially composed of 3 species:  $\text{TiOCl}_2$ ,  $\text{H}_2\text{O}$  and  $\text{HCl}$  which react under particular ambient conditions of temperature and humidity to form  $[\text{Ti}_8\text{O}_{12}(\text{H}_2\text{O})_{24}]\text{Cl}_8 \cdot \text{HCl} \cdot 7\text{H}_2\text{O}$ . During the process,  $\text{TiOCl}_2$  and  $\text{H}_2\text{O}$  species are consumed while  $\text{HCl}$  and  $[\text{Ti}_8\text{O}_{12}(\text{H}_2\text{O})_{24}]\text{Cl}_8 \cdot \text{HCl} \cdot 7\text{H}_2\text{O}$  species are produced. At the solution/air interface,  $\text{H}_2\text{O}$  and  $\text{HCl}$ , are transferred to the ambient environment by evaporation. This evaporation causes on the one hand a variation in the volume of the mixture (shrinkage) and on the other hand a modification in the thermal and mass balance leading to temperature and concentration gradients within the mixture.

*Fig. 1 Schematic description of physical phenomena*

After a brief presentation of the titanium oxychloride solution, the static reactor, the laminar air flow reactor and the metrology used are described. A numerical model predicting the mass behavior of the solution during the first stage of process (before the crystallization kinetic) is presented. The experimental results obtained with the static and dynamic configurations are then discussed and show the capabilities to intensify the crystal production. The first numerical results are finally introduced.

## 2. Materials and Methods

### 2.1. Product description

At ambient temperature ( $T = 25^{\circ}\text{C}$ ), titanium oxychloride solution (Cristal) is a viscous, yellow liquid which is highly hygroscopic and very acidic (pH far below 1). The titanium oxychloride solution encloses  $[\text{TiOCl}_2(\text{H}_2\text{O})_2]$  species dissolved in aqueous hydrochloric solution with the following composition: 1.375HCl, 5H<sub>2</sub>O. This solution is composed (in percentage by weight) of 54.9 % of the initial species ( $\text{TiOCl}_2(\text{H}_2\text{O})_2$ ), 16.1 % of HCl and 29 % of water. Based on this composition, the solvent proportion is 64,2 % of water and 35.8 % of HCl. This formulation was validated by placing the commercial solution in an atmosphere containing 36 % wt HCl and verifying the mass balance. In classical conditions ( $T = 25^{\circ}\text{C}$  and  $\text{HR} \approx 50\%$ ), HCl-H<sub>2</sub>O co-desorption leads to the crystallisation of  $[\text{Ti}_8\text{O}_{12}(\text{H}_2\text{O})_{24}]\text{Cl}_8 \cdot \text{HCl} \cdot 7\text{H}_2\text{O}$ . This crystals formation requires a mass loss of 41.6 % wt : 15.2 % wt water and 26.4 % wt HCl.

### 2.2. Crystallization reactors

#### 2.2.1. Static reactor

The first syntheses were performed in a dessiccator containing a crystallizer filled with 2 mL of titanium oxychloride solution (solution height approx. 2 mm). A H<sub>2</sub>SO<sub>4</sub>/H<sub>2</sub>O mixture is deposited at the dessiccator base in order to set the relative humidity close to 55 % at ambient temperature. Mass variations and crystals formation are monitored by carrying out discontinuous successive *ex situ* measurements.

#### 2.2.2. Laminar air flow reactor

In order to intensify the massive exchanges and thus the production rate of crystals, a new experimental set-up was developed (Fig. 2). It consists in a rectangular PMMA duct (height: 11 cm, width: 17 cm) in which a PMMA crucible (10 cm x 10 cm) is placed. Air flow is blown parallel to the surface of the crucible containing the solution. This crucible which contained 22 mL of titanium oxychloride solution (solution height approx. 2.5 mm) is positioned on a weighing system that allows continuous mass monitoring. A heating system stuck below the crucible allowed us to control the solution temperature. The inlet air

conditions (temperature and relative humidity) are controlled by an upstream system equipped with a heat pump and a humidifier. Temperature sensors placed at upstream, downstream track air temperature variations. Other thermocouples are also stuck on heating element and positioned in the solution. A velocity sensor measures the air speed at the inlet of the duct. All these sensors are connected to a data acquisition system. In the same time, images of the solutions are recorded to track the shrinkage and the crystals formation.

Fig. 2 Laminar air flow reactors description

### 2.3. Numerical modeling

First, a numerical approach is initiated to predict the mass loss of the solution during the first step of the process (before the beginning of the crystallization). This model based on the mass conservation equations written for the solvents (HCl and H<sub>2</sub>O) and the solute [TiOCl<sub>2</sub>(H<sub>2</sub>O)<sub>2</sub>] should predict solvent concentrations as a function of the surrounding air conditions and/or the temperature of solution imposed by the heating system. The solution temperature is not computed but imposed based on experimental measurements.

The model assumptions are as follows: the initial solution (homogeneous) consists of 3 species [TiOCl<sub>2</sub>(H<sub>2</sub>O)<sub>2</sub>], H<sub>2</sub>O and HCl; the species transport only takes place by diffusion (Fick's diffusion); the species transfer is assumed to be one-dimensional; the shrinkage is assumed to be linear; water reacts with the solute and is consumed to form HCl species.

#### 2.3.1. Governing equations

The application of mass conservation principle leads to write the following equations:

$$\frac{\partial \rho_s}{\partial t} + \text{div}(\rho_s \vec{v}_s) = 0 \quad (1)$$

$$\frac{\partial \rho_i}{\partial t} + \text{div}(\rho_i \vec{v}_s) = -\text{div}(\vec{J}_i) + S_i \quad (2)$$

With  $\rho$  the mass density (kg m<sup>-3</sup>),  $J$  the mass flow (kg m<sup>-2</sup> s<sup>-1</sup>),  $S$  the mass source (kg m<sup>-3</sup> s<sup>-1</sup>) and  $v$  the shrinkage velocity (m s<sup>-1</sup>). The subscript  $i$  refers to HCl noted A or water noted W.

### 2.3.2. Boundaries conditions

At the interface between the solution and the crucible base, no mass transfers occur:

$$-\mathbf{n}(\vec{J}_1) = 0 \quad (4)$$

At the interface between the solution and the air flow, mass transfers depend on the difference of vapor densities between the product at the surface (surf) and the surrounding air (a):

$$-\mathbf{n}(\vec{J}_1) = h_m(\rho_{i,\text{surf}}^v - \rho_{i,a}^v) \quad (5)$$

With  $h_m$  the mass transfer coefficient ( $\text{m s}^{-1}$ ).

Water vapor and hydrochloric acid vapor are assumed to be ideal gas and the previous relation is expressed as a function of the partial pressure at the product surface and the partial vapor pressure of the ambient atmosphere. Considering that the initial complex does not affect the HCl/water mixture, it can be assumed that the partial vapor pressures of HCl/water mixture only depend on the temperature and concentration of HCl [6].

## 3. Results and discussion

### 3.1. Static syntheses

Various syntheses performed at room temperature and with a relative humidity set at 55 % present similar and repeatable behaviors. In figure 3, a first mass loss is observed during the first hours of drying caused by a significant release of solvents (HCl and water). This first stage goes on until the mass loss reaches about 15 % ( $\approx 15$  h). At this stage, the first crystalline seeds appear and the crystallization kinetic accelerates. Co-desorption is then slowed down as long as the crystals grow and agglomerate. At the end of the process, the mass loss corresponds to about 41 %wt of the initial mass which matches with the predicted value by chemical equations. Under these conditions, about 25 days are required to form the crystals with a production rate per unit surface of about  $630 \text{ g}/(\text{week} \cdot \text{m}^2)$ .

Fig. 3 Mass loss and crystals formation during static syntheses

### 3.2. Dynamic syntheses

In a second step, syntheses were performed using the laminar airflow reactor. First experiments are carried out without direct heating (Fig. 4). The air temperature ( $T_a$ ) is set to 28 °C and relative humidity ( $HR_a$ ) varies between 45 % and 55 %. The air velocity ( $v_a$ ) is set to about 0.45 m s<sup>-1</sup>.

**Fig. 4** Dynamic synthesis without direct heating, images of the crucible before (left) and after (right) crystallization, evolution of the mass loss, temperature and relative humidity with time (middle)

In these conditions, the first stage which corresponds to a mass loss ( $\Delta m$ ) of 15 % is completed in about 8 h. The stationary phase is reached after 110 h (> 4 days). At the end of process, the mass loss corresponds to about 35 % wt and not 41 % as expected. This result can be explained by a crystallization at the surface which prevents the mass diffusion (HCl and water) from the medium toward the surface. The production rate of crystals is about 2.2 kg/(week.m<sup>2</sup>) being more than 3 times the static production rate.

In order to intensify the mass transfer and thus reduce the synthesis time experiments are carried out with a direct heating (Fig. 5). The air temperature ( $T_a$ ) is set to 27 °C and relative humidity ( $HR_a$ ) varies between 50 % and 60 %. The air velocity ( $v_a$ ) is set to 0.45 m s<sup>-1</sup>.

**Fig. 5** Dynamic synthesis with direct heating, images of the crucible before (left) and after (right) crystallization, evolution of the mass loss, temperature and relative humidity with time (middle)

The solution temperature ( $T_i$ ) varies from 27°C to 32°C during the first two hours due to switching on of the heating element (heating element temperature about 42°C). The first stage which corresponds to a mass loss of 15 % is completed within about 2 h. The stationary phase is reached after 24 h. At the end of process, the mass loss corresponds to about 34 % wt which is very similar to the value obtained in the previous case (without heating element). In this condition, the production rate of crystals is about 12 kg/(week.m<sup>2</sup>), i.e., 19 times the production rate achieved in static mode.

### 3.3. Numerical results

The numerical model is tested for the dynamic configuration in the first hours of the synthesis process (before the beginning of the crystallization). The predicted mass losses are compared with the experimental ones for the tests performed without and with direct heating (Fig. 6). For these two configurations, the numerical results present a good agreement with the measurements. Experimentally, the solution density varies from 1.58 at the initial state to 1.5 when the mass loss reaches 20 %.

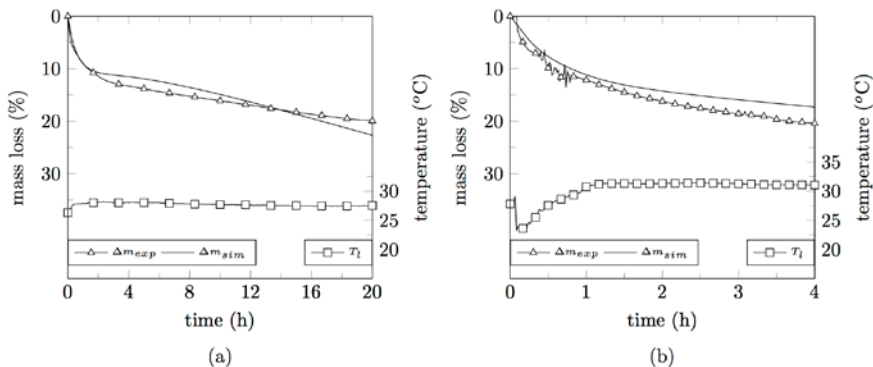

Fig. 6 Evolution of the temperature (open square), experimental (open triangle) and simulated (line) mass losses without (a) and with (b) direct heating, as a function of time

## 4. Conclusions

Under static conditions, the production of  $[Ti_8O_{12}(H_2O)_{24}]Cl_8.HCl.7H_2O$  crystals requires several weeks. In order to improve the production rate, a laminar air flow reactor with temperature and humidity controls was developed. With adequate conditions (air and solution temperature and air relative humidity), a significant improvement in the crystals production was obtained from 630 g/(week.m<sup>2</sup>) to 12 kg/(week.m<sup>2</sup>). These encouraging results could be improved in future by studying more extensively the temperature/humidity pair providing the best yield. In parallel, a numerical model describing mass transfers (before crystallization began) was initiated. The first numerical results correctly reflect experimental observations and encourage further development.

### **Abstract**

*Combining biotechnology and encapsulation by spray-drying is possible to obtain microorganisms-based products in powder format without losing viability. A methodology based on the improvement of the thermal stress resistance of selected strains of *Lactobacillus* sp. and subsequent culture stabilization by spray-drying by optimizing the process parameters and using thermal protectant materials has been developed. The results obtained showed that the final product kept the viability of the initial culture in addition to be a solid, powdery and ease-to-handle product.*

**Keywords:** *thermal resistance; spray-drying; probiotics; viability; fermentation; encapsulation.*

## 1. Introduction

Sectors such as food and agriculture are looking for products based on microorganisms (i.e. probiotics, biofertilizers) with the aim of conferring a beneficial physiological effect on the host; most of them are available in liquid form. The challenge of these sectors is to offer them in powder formats for decreasing costs and to facilitate their use and applications. Vacuum and freeze drying are two drying technologies used for this end. The main disadvantages of freeze-drying are the high energy input and long processing times [1]. Vacuum drying is faster and cheaper because it operates at a temperature above the freezing point. Other drying technology, convective drying, can cost from 4 to 8 times less than freeze drying. However, the quality of the obtained dried products can be much lower, with a drastic reduction in the volume and colour changes [2].

Spray drying is a widely used technology to dry liquids and it is used in different sectors of food industry ensuring microbiological stability avoiding risks of chemical and/or biological degradations and obtaining product with specific properties like instantaneous solubility [3]. Processing costs are six times lower than freeze drying [2,4], however, the high temperature can lead to cell damage. The enhancement of the thermal resistance of the cell culture can be one alternative [5]. The addition to the medium of ingredients that may induce osmotic shock may strengthen the cell membrane [6]. The preadaptation of cells to heat is another possible strategy. During thermal stress, proteins heat shock is produced. These proteins may help to repair misfolded proteins during spray drying [6]. The use of protectant materials during the spray drying process can also enhance the survival of the microorganisms [7,8] being carbohydrates, such as trehalose, glucose, maltodextrin, inulin, fructo-oligosaccharides or potato starch [5], the most commonly used in food industries [9].

This microencapsulation processes can increase the microorganisms survival, not only during the spraying process, but also providing extra protection against ambient conditions or gastrointestinal conditions, allowing probiotics to reach the gut in an adequate amount [10, 11].

The aim of this study was to obtain microorganisms-based products in a powder format without losing viability by combining biotechnology and spray-drying. For this purpose, this study has been focused on different aspects: process variables, including formulation of the feed (thermal protectants, and encapsulating materials) and different stress methods for the culture.

## 2. Materials and Methods

### 2.1. Materials

A probiotic strain of *Lactobacillus sp.* isolated in previous works from cured meat was used in this study. The reference culture medium was MRS Broth, purchased from VWR.

Osmotic stress was induced by different amounts of Sodium Chloride (Scharlau). Different protectant materials were used in the spray drying tests; Maltodextrin from Roquette, Trehalose, from Hayashibara, and modified starch, from Ingredion. All of them were food grade products.

## 2.2. Methods

### 2.2.1. Production of *Lactobacillus* sp. culture

For the screening of the spray drying conditions, a single batch of 20 L of *Lactobacillus* sp was produced using a stirring tank bioreactor (BIOSTAT C plus from Sartorius Stedim, Germany). The operating conditions were: Temperature: 37°C; Medium: MRS Broth 52 g·L<sup>-1</sup>. Dissolved Oxygen > 40% (controlled by cascade). When the culture reached the stationary phase, the culture was harvested using a high-speed refrigerated bench centrifuge (Sigma 6K15). After the harvesting, viable count of the product was done in order to know the concentration of the culture, measured in colony-forming units (CFU/mL).

### 2.2.2. Stabilization of the culture

The cultures of *Lactobacillus* sp. were stabilized by spray drying using a laboratory spray dryer (Büchi B-290, Switzerland). The operating conditions were: feed rate: 3-6 ml·min<sup>-1</sup>; inlet temperatures: 105-115 °C. Outlet temperatures between 51 and 71°C. The tests were performed with different carriers: thermal protectant materials and encapsulating materials (Table 1).

Table 1. Concentration of the thermal protectant materials

Samples	Trehalose (%)(m/m)	Maltodextrin (%) (m/m)	Starch (%) (m/m)
1-3	30,20	---	---
4-7	7,50	23,26	---
8-11	7,50	15,53	7,76
12-42	4,28	9,15	4,57

### 2.2.3. Preadaptation of *Lactobacillus* cultures to spray drying to enhance thermal resistance.

Shake flask cultures were performed to study the effect of the culture conditions in the final viability of the spray dried products. Two effects were studied (thermal and osmotic stress) and Surface Response Methodology (SRM) was used for the design of a 3-level factorial experimental design in 9-runs with triplicates. The following variables were selected as response: the concentration of the cultures (CFU/mL), the concentration of the microencapsulated microorganism (CFU/g) and the viability of the product after spray drying was calculated as follow:

$$Viability (\%) = \frac{\log(Total\ CFU_{spray\ drying})}{\log(Total\ CFU_{culture})} \quad (1)$$

The cultures were grown in 500 mL shake flask with 150 mL of MRS broth. The initial optical density of the cultures, measured at 600 nm, was adjusted to 0.1. The cultures were maintained at 37°C and 150 rpm. Different levels of thermal and osmotic stress were applied to the cultures according to the following experimental design.

To induce osmotic stress, when the cultures reached an optical density of 0,4-0,5, they were centrifugated and resuspended to 150 mL of MRS or MRS broth supplemented with Sodium Chloride (according to Table 2). To induce thermal stress, when the cultures reached an optical density of 0,8-1,0, the flasks were introduced in a water bath at the specified temperature (according to Table 2). The cultures were spray-dried once they reached stationary phase (30 hours of process).

**Table 2. Experimental Design.**

	<b>Thermal Stress (°C)</b>	<b>Osmotic Stress (M)</b>
R-1	49	--
R-2	42	0,3
R-3	49	0,6

R-5	42	0,6
R-6	42	--
R-7	49	0,3
R-8	--	--
R-9	--	0,6

### 3. Results

#### 3.1. Effect of the inlet temperature

First of all, several tests of *Lactobacillus* sp. culture were carried out with the aim to know the effect of the inlet temperature in the microorganisms viability. In these tests, trehalose was used as material for thermal protection.

**Table 3. Effect of the inlet temperature on the microorganisms viability**

<b>Sample</b>	<b>Tin (°C)</b>	<b>Tout (°C)</b>	<b>Viability (%)</b>
1	105	55	79,6%
2	110	68	75,6%
3	115	71	80,7%

As expected, low inlet temperatures give, in general terms, high viability. Opposite to what it might appear, inlet temperature do not have a direct effect on the survival of microorganisms. The reason is that the viability does not depend only on the initial temperature, but also on the residence time and, in general, the temperature profile of the process, from the feed to the final dried product. In this situation, the outlet temperature has

a remarkable importance. The residence time depends on several variables of the process, feed composition and concentration, and also de design of the spray dryer equipment.

### Effect of the feed composition

Table 4 shows the feed composition and the results of viability. Trials 12 to 15 were performed using the same carriers but with a lower concentration, as shown in Table 1.

Fig. 1 shows the effect of the feed composition and the inlet temperature, on the microorganisms viability. It can be seen that the effect of the feed composition, specially its concentration, are the relevant aspects to increase the viability in the final product.

Best results of viability were achieved for an inlet temperature of 115°C combined with the trehalose/maltodextrin/starch as protectants. As shown in Fig. 2, the feed composition (Carriers) is the most relevant parameter on the microorganisms viability in the final product. The effect of the feed composition is bigger than the temperature due to its high estadistical significance. The selection of the carrier is relevant, but its concentration in the feed is even more relevant. This effect is due to that a lower concentration implies lower outlet temperatures and therefore, higher viability. However, lower carrier concentration in the feed leads to bigger costs, so this parameter needs to be optimized for industrial processes.

**Table 4. Effect of the thermal protectants and wall materials on the microorganisms viability**

Sample	Feed Composition	Inlet T (°C) ( $\pm 2^\circ\text{C}$ )	Viability (%)
1	Trehalose	105	79,6%
2	Trehalose	110	75,6%
3	Trehalose	115	80,7%
4	Trehalose/maltodextrin	100	81,5%
5	Trehalose/maltodextrin	105	80,3%
6	Trehalose/maltodextrin	110	79,3%
7	Trehalose/maltodextrin	115	77,0%
8	Trehalose/maltodextrin/Starch	100	77,1%
9	Trehalose/maltodextrin/Starch	105	78,8%
10	Trehalose/maltodextrin/Starch	110	81,6%
11	Trehalose/maltodextrin/Starch	115	75,0%
12	Trehalose/maltodextrin/Starch	100	78,3%
13	Trehalose/maltodextrin/Starch	105	82,4%
14	Trehalose/maltodextrin/Starch	110	87,3%
15	Trehalose/maltodextrin/Starch	115	87,9%

Fig. 1 Principal effects for viability (%)

A: Trehalose (Sample 1-3)

B:Trehalose/maltodextrin (Sample 4-7)

Fig. 2 Pareto Diagram for CFU/g

C: Trehalose/maltodextrin/Starch (sample 8-11)

D: Trehalose/Maltodextrin/Starch (Sample 12-15)

Trehalose with maltodextrin seems to produce slightly better results than the combination of three carriers, but the addition of starch improves the encapsulation effect on the particles. The encapsulation of the microorganisms, lead to improved protection, longer shelf life, and lower damage during gastrointestinal tract in case of probiotics.

### 3.2. Preadaptation of *Lactobacillus* cultures to spray drying to enhance thermal resistance.

The average results of the response variables selected for the experimental design on Table 2 are shown in Table 5. Taking into consideration the previous results of viability, mass yield, and the effect of the inlet temperature; this last was fixed at 105°C for the rest of the study. As it can be shown, the variations in the fermentative process did not affect significantly the viable count of the culture. However, they had an effect in the viable count of the microencapsulated product and therefore in the final viability.

Table 5. Preadaptation of *Lactobacillus* cultures to spray drying to enhance thermal resistance

	Thermal Stress (°C) ( $\pm 2^\circ\text{C}$ ).	Osmotic Stress (M) ( $\pm 0,01\text{M}$ )	CFU/mL	CFU/g	Viability (%)
R-1	49	--	$2,66 \cdot 10^9$	$2,67 \cdot 10^8$	88,57%
R-2	42	0,3	$4,27 \cdot 10^9$	$2,12 \cdot 10^9$	95,11%
R-3	49	0,6	$2,16 \cdot 10^9$	$1,00 \cdot 10^9$	94,61%
R-4	--	0,3	$3,42 \cdot 10^9$	$2,97 \cdot 10^8$	88,40%
R-5	42	0,6	$2,63 \cdot 10^9$	$1,40 \cdot 10^9$	95,24%
R-6	42	--	$2,23 \cdot 10^9$	$2,75 \cdot 10^8$	89,59%
R-7	49	0,3	$5,85 \cdot 10^9$	$1,25 \cdot 10^8$	84,07%
R-8	--	--	$3,58 \cdot 10^9$	$3,08 \cdot 10^8$	88,63%
R-9	--	0,6	$2,64 \cdot 10^9$	$1,45 \cdot 10^9$	94,89%

**Fig. 3** Pareto chart of standardized effects for sprayed product viable count, Log (CFU/g)

**Fig. 4** Pareto chart of standardized effects for sprayed product viability (%)

According to Fig. 3, Osmotic stress has a significant effect in the final viability (%) as well in the final concentration of the microorganisms (CFU/g). The optimal conditions for maximizing the final viable count and viability are shown in Fig. 5, Fig. 6, Fig. 7 and Fig. 8.

**Fig. 5** Estimated surface response for sprayed product viable count, Log (CFU/g)

**Fig. 6** Contours for estimated response surface for sprayed product viable count, Log (CFU/g)

**Fig. 7** Estimated surface response for sprayed product viability

**Fig. 8** Contours for estimated response surface for sprayed product viability

For the final viability of the product, the estimated surface response shows that the optimal value for the viability, which can reach 97,264% could be achieved by applying osmotic stress of 0,6M and a thermal shock at 43,28°C.

## 4. Conclusions

Thermal processing of microorganisms for their stabilization and encapsulation can be done by Spray drying without losing viability. Combining biotechnology and encapsulation by spray-drying is possible to obtain microorganisms-based products in powder format keeping their viability.

Feed composition has a highlighted effect on viability. Some carriers as trehalose can be included as thermal protectants, improving microorganisms resistance against temperature. Other carriers, can be included with the objective of improving process yields, or giving added valuable properties to the final product, as encapsulating materials.

The concentration of carriers of the feed has also a remarkable effect, because lower concentrations lead to lower temperatures during the process. However, it is directly related to processes costs, so it must be optimized for industrial processes.

In addition, modifications in the fermentative process of the microorganism, as a preadaptation of the cells to spray drying may increase even more the final viability of the product. According to the results of the present study, the final viability of the product may increase from 79,6 % to 82,4% by the appropriate selection of protective materials, and from 82,4% to 95,2% by the preadaptation of the microorganism during its fermentation.

### **Abstract**

*In order to develop an alternative spray drying technology, a high drying rate in a smaller volume must be achieved. In this paper, results of CFD study are presented, carried out to investigate the possibility of spray drying in a novel design vortex chamber. The model is validated against experimental data, that makes a good agreement with an average error of 7% with only air and 24% with water spray. Results of temperature fields and droplet impact positions are discussed. The computations demonstrate that vortex chamber spray dryer can be an attractive solution for drying technology.*

**Keywords:** CFD; spray drying; vortex chamber; atomization.

---

## 1. Introduction

Spray drying is a widely used process for converting liquid feed into dry powder [1]. However, the technology has only little improved over time. This comes with an inherent weakness; conventional spray dryers need great volumetric flow rates of air and thus high capital costs [2]. Additionally, low inlet temperatures and small gas-solid slip velocities lead to low drying rates. In order to develop an alternative spray drying technology, high inlet temperatures whilst maintaining a small residence time must be accomplished [3]. Therefore, a new technology for spray drying called vortex chamber spray dryer (VC) is investigated here. Additionally, high-G fluidization in VC, leads to intensification of interfacial heat, mass and momentum transfer [4, 5].

The high temperatures and turbulent multiphase flow in spray drying, make it difficult to design and optimize the dryer. For this purpose, Computational Fluid Dynamics (CFD) modeling has emerged as a vital tool in understanding the flow fields and gas-particle dynamics [6, 7]. In this research, a CFD model is developed to investigate air flow patterns and droplet trajectories for spray drying in a novel multi-zone VC dryer. The predicted results are compared against available experimental data. An overall drying performance is evaluated based on temperature profiles, particle's moisture content, impact positions and product quality obtained at the outlets.

## 2. Methodology

### 2.1. CFD methodology

The simulations have been performed in the commercial CFD package FLUENT 16.0. The flow in a spray dryer is a dispersed multiphase flow, therefore, the Eulerian-Lagrangian approach was used. A three dimensional steady state model with k-epsilon turbulence model is used to simulate the gas phase. A two way coupling is applied to consider the heat, mass and momentum exchange between the continuous and discrete phase. The discrete phase turbulence is modeled using stochastic tracking model. The details of the CFD methodology and the governing Navier-Stokes, turbulence and discrete phase equations can be found in the literature and FLUENT user guide [8-10]. In order to simplify the computations, the droplet-droplet interactions, agglomeration and coalesce is not considered. Also, only the evaporation model is used for droplet drying i.e. droplets are not porous and contains only surface moisture.

### 2.2. Geometry and boundary conditions

The VC geometry simulated in this study is shown in Figure 1. presenting the inlets and outlets (due to confidentiality reasons the exact dimensions are not presented). Such setup of VC offers two separate temperature zones: axial hot zone in the cylinder and relatively cold zone in VC. Hot air enters the dryer through a honey comb flow distributor hence diminishing

small turbulences in the cylinder. The VC is made up of six wheels, each wheel consisting of 36 inlet slots through which air enters the chamber tangentially, creating a high-G vortex flow. Droplets are injected, counter flow to hot air using a pressure nozzle. The position of the atomizer is depicted in Fig.1.

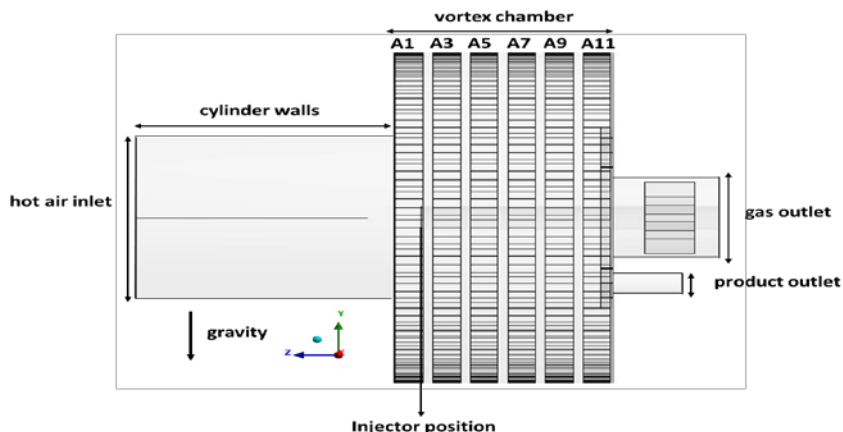

Figure 1. Geometry of vortex chamber spray dryer

The hot air inlet temperature is 350 °C and mass flow rate is 682 kg/hr while cold air average temperature to VC is 132 °C and mass flow rate of 615 kg/hr. The outlets are set to pressure of 5000 Pascal. The chamber walls are treated as adiabatic i.e. no heat loss to the environment is considered. A spray feed rate of 23 kg/hr is sprayed at a temperature of 65 °C with an injection velocity of 70 m/s. Droplet size distribution is modeled using Rosin-Rammler method. A spread parameter of 2.05 as reported by Kievet was used [11]. The maximum and minimum droplet size is set to 90 and 20 microns respectively while the mean droplet size of 52 microns [12] is used. Furthermore, a restitution coefficient of 0.2 is applied on VC walls.

### 3. Results and discussion

This section presents the predicted results of the CFD model. The model is validated against the available experimental data. Furthermore, an overall drying performance is evaluated based on particle impact positions and product obtained at outlets.

#### 3.1. Grid independency study

For the grid independency study, three grid sizes; 1.5M, 3M and 5.5M elements were used. By comparing temperature profiles at 3 different locations, an average error of less than 1% was found between the coarsest and finest mesh. Since, the difference was not significant, the grid of 1.5M elements is applied for further research.

### 3.2. Validation of CFD model against experimental data

The experimental data used for the model validation is obtained from the work of Thomas et al. [13]. It should be pointed out that, during experiments, it was not possible to operate the VC in steady-state, due to the clogging of the nozzle. The thermocouples, V1 and V4 are located in the outer region of VC at top and bottom respectively, V6 and V8 are located in the middle transition region of VC at left and right respectively while the thermocouples V12 and V13 are located in the central core of the VC. The thermocouples are positioned on each wheel in the axial direction.

**Figure 2. Comparison of results for V1 and V4 probes a) only air (left) b) with water spray (right)**

The Figure 2a shows a comparison of predicted temperature profiles against experimental data for probes V1 and V4. The model makes a good agreement with an average error of 2% and 9% for V1 and V4, respectively. It can be seen that model slightly over estimates the temperature. The error can be caused by no heat loss assumption in the model whereas in the experiments heat loss can occur. Figure 2b, gives comparison with water spray. A relatively bigger error; 30% and 60% is seen for V1 and V4 respectively. Much lower temperatures; 50-80 °C for wheels A1 and A3 are observed in the experiments. However, these can be due to water impinging and evaporating on the thermocouple. Another reason could be that in the model spray penetrates into the hot cylinder where major evaporation takes place, and thus predicted results with only air and with spray do not show significant difference.

The Figure 3a shows the comparison of predicted air temperature against experimental data for thermocouples V12 and V13. The predicted results correspond well with the experimental data with an average error 1% and 7% for V12 and V13 respectively. Moreover, low temperature values in experimental measurements suggests, stronger radial mixing of hot air with the rotating cold air. Figure 3b, shows the comparison with spray. The experimental measurements show a strong asymmetry between V12 and V13. The dissymmetry might be induced by the product outlet being, too close to the gas outlets causing the spray to instantly deflect back on one side giving much lower temperatures for V13. The effect is less pronounced in the predicted results. An average error of 6% and 20% is obtained for V12 and V13 probes, respectively.

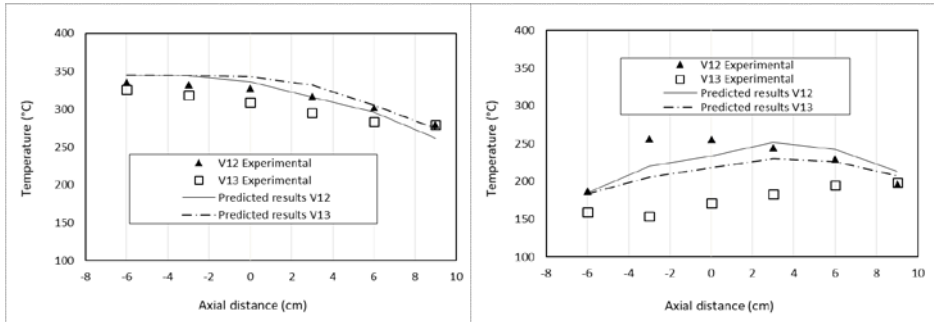

Figure 3. Comparison of results for probes V12 and V13 a) only air (left) b) with water spray (right)

Figure 4a, shows the comparison of predicted results for thermocouples V6 and V8. An opposing trend with an under prediction of temperature is seen for the middle-transition region. An average error of 11% for V6 and 13% for V8 is seen. The results imply a similar trend to that observed for the core region i.e. a stronger radial mixing of hot air with rotating cold air, that gives higher temperatures in the middle region of VC in the experiments.

Figure 4b, shows the predicted results against experimental measurements with water spray. The results shows a good agreement between numerical and experimental data with average error of 12% and 20% for V8 and V6 respectively. Plots show a similar trend of low temperature at the front two wheels where the biggest discrepancies are seen. This can again be explained with water droplets, which in experiments, do not penetrate into the hot cylinder but instead moves to the front of VC (A1 and A3 wheels).

Figure 4. Comparison of results at probes V6 and V8 a) only air (left) b) with water spray (right)

### 3.3. Influence of multi component spray injection

In this section, the discussion has been extended by using 56 kg/hr of feed with 40% solid content and feed density of 1080 kg/m<sup>3</sup>. A performance analysis of VC dryer is drawn based on particles impact positions, separation efficiency and mass of product recovered at the outlets. Figure 5, presents the temperature profiles on two axial planes for air flow only. A small reflux of cold air, from VC to cylinder can be seen on both planes. The reflux is caused

mainly by two reasons; low pressure in the cylinder and the influence of product outlet's back pressure. Such recirculating zones can be problematic, since it can lead to product deposition on cylinder walls. Furthermore, two temperature regions are visible in the dryer: a hot zone in the cylinder and around the nozzle and cold zone on the outer region of the VC.

*Figure 5. Temperature patterns on two axial planes, only air*

Figure 6, illustrates the temperature patterns with spray (40% solid content). It can be seen that temperature profiles are asymmetric. The reason for this is mainly, the strong back pressure caused by the product outlet, forcing the droplets to instantly deflect back. Moreover, it can be seen that significant evaporation takes place in the hot zone while in the VC temperature drop is mostly near wheels-A1 and A3.

*Figure 6. Temperature patterns on two axial planes, with water spray*

### 3.3.1. Particle trajectories

In order to design and optimize a dryer, it is of prime interest to predict the trajectories of different sizes particles. Figure 7, reveals the particle trajectories for different particle size ranges, as a function of water mass fraction. These figures indicate that particles below 45  $\mu\text{m}$  are instantly deflected back and leave via gas outlets. The particle sizes between 45-80  $\mu\text{m}$ , are very uniformly distributed over VC. These particles mostly leave via product outlet. A mean particle size of 30 and 40  $\mu\text{m}$  and a mean residence time of 0.48 and 1 seconds is found at gas and product outlet, respectively. Particles bigger than 80  $\mu\text{m}$  are mostly impinging the honey comb air inlet or cylinder walls and only a few return to VC. Thus, it can be concluded that a maximum of 80  $\mu\text{m}$  particle size, can be successfully dried without any risk of deposition on the walls. Moreover, all particles impinging VC walls are dried with zero moisture content.

**Figure 7. Particle trajectories as a function of water mass fraction**

Table 2, shows an overall drying performance as discussed by Huang et al [14]. Some of the particles are trapped in circulating zones and do not escape. These are removed from calculations after 10 seconds.

**Table 1. Overall drying performance of vortex chamber spray dryer**

	Percentage (%)	Deposit rate (kg/hr)
Gas outlets	56	15
Product outlet	18	4.5
Cylinder walls	3.5	0.7
Hot air inlet	12.5	0.8
Incomplete	10	1.4
Gas outlet temperature ( $^{\circ}\text{C}$ )		155
Energetic Specific Consumption (KJ/Kg.H <sub>2</sub> O)		10,000

## 4. Conclusions

A three-dimensional CFD model for spray drying in a VC was developed. A good agreement was made with the experimental data, depicting an overall average error; 7% and 24% with only air and with water spray respectively. The results depict small recirculation zones of cold air in cylinder, causing asymmetric spray patterns. It was found that a large proportion of particles leave via the gas outlets. In order to have an efficient VC dryer, separation of smaller particles from air is necessary. Based on the CFD research, it can be concluded that redesign of current VC configuration is necessary in order to harvest its full potential.

## 5. Acknowledgements

This research is conducted within RVO-Vortex chamber II Project-TEEI115007, in collaboration with ISPT (Drying and Dewatering cluster), Royal FrieslandCampina, Université Catholique de Louvain, Unilever and Energy Research Centre of the Netherlands (ECN). Authors would like to express their gratitude to RVO for the financial support and to all project members for the fruitful discussions during the meetings. Furthermore, authors would like to convey their special thanks to Prof. Juray De Wilde, Mr. Axel de Broqueville and Mr. Thomas Tourneur (*Université Catholique de Louvain*) for providing the geometry, operating conditions and experimental data.

### **Abstract**

*Solar conduction dryer (SCD) is a unique technology that uses conduction, convection and radiation mechanism of heat transfer making it one of the most efficient drying system. The SCD is one of the most effective piece of equipment's designed indigenously and it has tremendous potential to capitalize in erstwhile nations of tropical and torrid region where there is abundance of solar insolation. SCD, the most cost-effective dryer which runs on no electricity has already made inroads in the global market. In the present study, CFD studies were carried out for a given geometry and the corresponding boundary conditions.*

**Keywords:** Solar Energy; Solar Conduction Dryer; CFD modeling.

---

## **1. Introduction**

Drying is a complex operation involving transient transfer of heat and mass along with several rate processes, such as physical or chemical transformations, which, in turn, may cause changes in product quality as well as the mechanisms of heat and mass transfer. Physical changes that may occur includes: shrinkage, puffing, crystallization, glass transitions and so on [1]. As it is well known, drying is the most energy intensive operation of the industrial processes [2]. Energy efficiency in drying ranges from a low value of under 5 % for the chemical process industries to 35 % for the papermaking operations [1]. Thus, there is strong contention among the researchers around the globe to develop a simplified and low-cost approach that can minimise or nullify the energy requirement through combination of efficient design and optimized process variables.

Keeping these aspects in mind, several researchers have developed different type of solar dryers in last couple of decades to dry food materials as per the local need and indigenous technology. These dryers were based on the heat transfer mechanism of radiation and natural/ forced convection. They can be categorised in three types, such as, integral (direct), distributed (indirect) and mixed mode. In direct type of solar drying, the sun rays are directly incident on material while in indirect type, the air would absorb the heat and transfer it to the material. In mixed mode, the combinatorial heat transfer mechanism plays a crucial role in drying [3]. Thus, based on the above categorization, the following are some of the popular solar dryers in vogue, i.e. Natural convection cabinet dryer, Forced convection indirect dryer, Green house dryer, Solar tunnel dryer.

As described above, these dryers are working on the principle of one or maximum two heat transfer mechanisms. Solar conduction dryer is the first technology in the world that uses all the three modes of heat transfer, viz., conduction, convection and radiation making it one of the most efficient systems [4]. SCD works without the need for electricity and most importantly at zero operating cost, following the three principles of 'A's, i.e. availability, affordability and accessibility [5]. It costs 3-5 times less than the next competing solar dryer and has payback period of 100 days against cost of electricity saving. SCD is recognized by UNEP-Bayer Ag (Germany) as top four global sustainable technologies and by University of Texas-Austin as global leading social venture. US-AID has included SCD in its Feed the future (FTF) program.

Computational fluid dynamics (CFD) is a highly powerful tool to predict the performance and can help us to optimize the dryer geometry under given operating conditions without actually performing too many experiments. Various solar based designs like (a) solar air heater [6-9]; (b) drying systems such as direct, indirect, mixed [10-12] were simulated using computational fluid dynamics CFD modelling helps us to get the detailed inside look

in the flow field development, temperature distribution [13], humidity profiling and drying time [14].

The objective of the proposed work is not to understand the existing models and compare them, but to make use of these models with certain additional features and incorporate those state equations for all the three modes of heat transfer, which is the major highlight and selling point of the award-winning technology of Solar Conduction Dryer (SCD). Based on the experimental insights and the foregoing literature, CFD model was developed. Here, the results of CFD models based on combinatorial heat transfer mechanism were compared with the experimental findings. Certain alterations to the existing design were possible to be thought about and they were brought fore as an addendum to the design of the existing/commercial SCD.

## 2. Materials and Methods

### 2.1. Drying Equipment

*Fig. 1 Solar Conduction Dryer.*

The Solar conduction dryer (SCD) is a solar dryer (Figure 1) developed at advanced drying laboratory of Institute of Chemical Technology (formerly UDCT) Mumbai, India. This equipment utilizes solar power in the form of conductive, convective as well as radiation way of heat transfer for drying. The structure of SCD comprises of four drying chambers constructed from hollow sections of stainless steel. The dryer has four drying trays, covering a surface area of 1.04 m<sup>2</sup> each. Transparent plastic (Polycarbonate Multiwall Sheet) was used to cover the trays. The trays were coated with black colour special food grade coating, where the products to be dried are placed. The trays were insulated properly so as to minimize the heat losses to the surrounding. A low height air vent to create air current is provided at the middle of the dryer in the horizontal direction which also separates the drying chambers in two portions (parts), as shown in Figure 1. Each portion contains two drying trays. Atmospheric air enters from the front of the trays and it carries away the moisture of the sample through the canopy by means of natural convection. The

movement of the tray is by sliding them in and out through a designed channel for loading purpose.

## 2.2. Model (Governing equations for CFD)

Mass continuity, momentum, energy and radiation equations were solved to simulate the flow and temperature distribution in the unit. The solar load model available in FLUENT consists of a combination of a solar ray tracing algorithm and a radiation model called surface to surface (S2S). The solar ray tracing algorithm works as the source of the solar heat and the S2S radiation model accounts for the internally scattered energy. The sources for this energy are the surfaces exposed to the solar rays and thus soaked with solar heat energy. Equations are not being reproduced here, as the same could be obtained from Ansys.

## 3. Results and Discussion

SCD was simulated at measured solar radiation flux of  $1000 \text{ W/m}^2$ . A full-scale 3D simulation of SCD resulted in a symmetric flow pattern. Experimental data also suggested symmetric profile in thermal measurements across the two parts. Hence, half section of the SCD was simulated under the given conditions. Figure 3 shows the flow pattern of air as predicted by the CFD model. It can be seen that the flow is mostly straight without any lateral components. Small circulation zone was observed at the centre of dryer (region where the flow from both the inlets meet and then flows upwards towards the outlet). Here, the flow is predominantly laminar in nature.

### 3.1. Flow pattern in solar conduction dryer

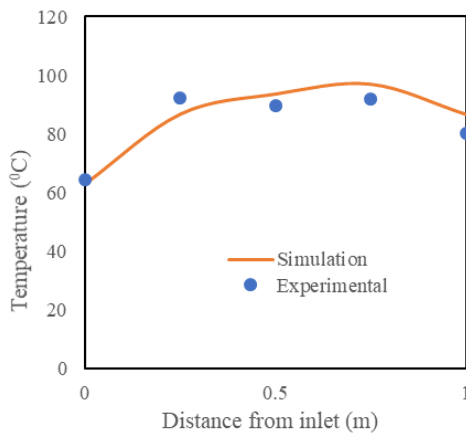

Fig. 2 Flow pattern of air from inlet to centre of dryer.

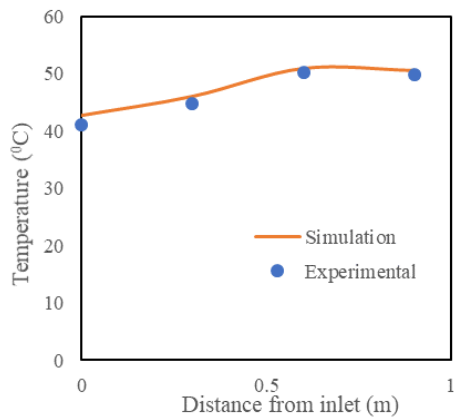

### 3.2. Comparison between experimental and simulated temperature of bottom plate and top plate of SCD

The thermal measurement of the bottom plate (Figure 3) indicates sharp rise in the temperature. The temperature remains constant in the dryer section. In the central part, a small dip in the temperature was observed, probably due to the negligible presence of air (hot) adjacent to the bottom plate. As the air gets heated from inlet to dryer section and as soon as it comes at the chimney section, it swirls off through it because of low density. This is very important observation, as it indicates the temperature variation in the dryer in tune with the entry and exit effect of the air. This temperature drop was very well captured in simulation results. Figure 4 compares the predicted temperatures with measured data. It can be deduced that the simulation results are in good agreement with the experimental data.

*Fig. 3 Comparison of experimental and simulation temperature (Bottom plate).*

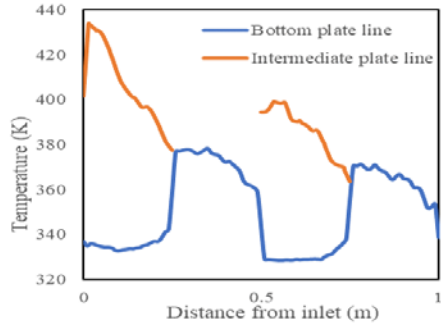

*Fig. 4 Comparison of experimental and simulation temperature (Top plate).*

### 3.3. Proposed design of modified solar conduction dryer (Design 1)

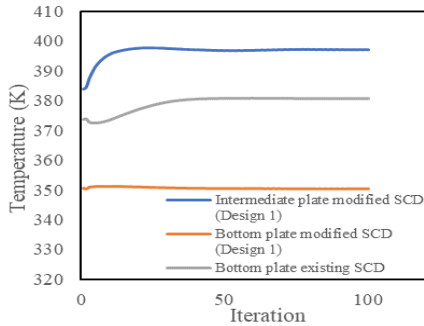

As per the patented design of solar conduction dryer, there is a loading space gap between the polycarbonate sheet (top plate) and the black coated aluminium plate (bottom plate). The gap is around more than 10 cm between these two. In order to maximize the utilization of energy and material loading capacity, we can alter the interiors of existing SCD. The modified design (Design 1) will contain an array of plates placed in a staggered manner between the top plate and the bottom plate. The array of plates is designed in such a way that the solar energy reach to the bottom plate. The plates were arranged as shown in Figure 5. Simulations were done described in results and discussion for the staggered plates arrangement. Simulations were performed till the steady results are obtained. These results are as shown in Figures 6-8.

**Fig. 5** Intermediate plate structure in modified SCD (Design 1).

**Fig. 6** Temperature profile of intermediate and bottom plate in modified SCD (Design 1).

**Fig. 7** Area weighted average temperature of bottom plate and intermediate plate in existing and modified SCD (Design 1).

**Fig. 8** Area weighted average temperature at outlet in existing and modified SCD (Design 1).

### 3.4. Comparison between existing and groove bottom plate SCD (Design 2)

It was found in the literature that the grooved or corrugated absorber plate creates maximum heat transfer area. There are so many type of grooved plates. So, the idea was that the use of that concept in our case. From the figures 11 and 12, it was found that, there is considerable difference of area weighted average temperature of bottom plate and the outlet air temperature. The use of groove absorber in the place of flat absorber provides a large surface area for heat transfer to the air stream. The convective heat transfer from bottom plate to air increases in this case but the loss is largely compensated by the increased heat transfer to the flowing air [15].

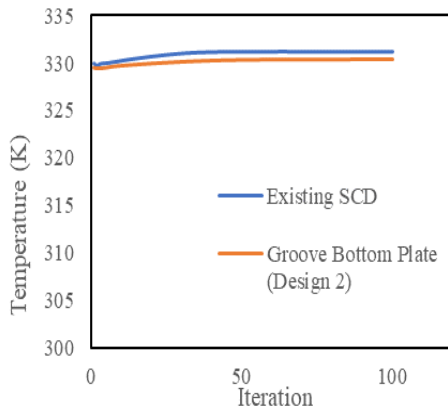

## 4. Conclusions

The CFD model has been successfully developed to predict the temperature of top and bottom plate. The model predictions are in good agreement with the measured data in

summer as well as winter environmental conditions. CFD simulations of modified solar conduction dryer was also carried out and it gives higher performance. Modified SCD is superior than the existing SCD in terms of outlet air velocity, outlet air temperature, intermediate plate temperature and material handling capacity. The material handling capacity can be increased by as high as 50 %. SCD contained groove bottom plate simulations were also done and it was found that there was increase in the outlet air temperature compared to existing SCD.

## Post-harvest treatment of algerian broad beans using two different solar drying methods

**Chouicha, S.; Boubekri, A. \*; Berbeuh, M. H.; Mennouche, D.; Frihi, I.; Rzezga, A.**

Université Kasdi Merbah Ouargla, Laboratoire de développement des Energies Nouvelles et Renouvelables dans les Zones Arides et sahariennes, Faculté des Sciences Appliquées, Ouargla 30000 Algeria

\*E-mail of the corresponding author: [boubekri.abdelghani@univ-ouargla.dz](mailto:boubekri.abdelghani@univ-ouargla.dz)

---

### **Abstract**

*This work was carried up in the objective to valorize the broad beans, largely harvested in Algeria, by solar drying means. In the present research paper, an experimental study was conducted on solar drying of broad beans by two different methods. Experimental trials were performed on a direct and an indirect laboratory scale solar dryers at Ouargla university in the southern of Algeria. Selected samples were dried at 50°C, 55°C, 60°C and 65°C. In both two applied cases, drying curves were obtained and compared. Among twelve consulted drying models the Page model was correlated with satisfaction to describe the solar drying of broad beans using a non linear regression analysis method. Operating and thermal performances of the two used drying systems were checked by the energy effeceincy and economic calculation. Obtained results showed that the direct solar drying ensures good preservation of the final product with a drying time of 5 hours.*

**Keywords:** solar drying ; convective drying ; broad bean ; quality

---

## **1. Introduction**

Faba bean (*Vicia faba* L.) is one of the oldest crops and ranks the sixth in production among the different legumes grown in the world after soybean, peanut, beans, peas, and chickpeas. Faba bean is popular legume food with high yield capacity and high nutritional value. It is widely used in the Mediterranean region as source of protein in both human and animal nutrition. It is a popular breakfast food and also used as vegetable green or fresh canned. In Algeria, faba bean is one of the most important pulse crop cultivated due to the richness of seed protein content. Also, The most important organic components of faba bean seeds are proteins 20-41% of seed dry matter, carbohydrates (51-68% ), 12% fiber, 1.2-4% lipids vitamins and minerals [1]. Due to its chemical composition, faba bean is a suitable food for diabetics and may help prevent heart disease and reduce levels of blood glucose vitamins and minerals [2]. The major producer countries include China, Indonesia, India, Turkey, Egypt, Spain, France and Algeria. Broad beans is grown on 12,000 ha areas in Algeria, with a production of 60,787 tons in 2013 [3]. Due to their seasonal and perishable nature, broad beans must be subjected to some form of preservation such as canning, freezing, or cold storage in order to make them available for later consumption [4]. Drying is practiced to enhance the storage life, to minimize losses during storage, and to reduce transportation costs of agricultural products [5]. Solar drying of agricultural products is one of the most important potential applications in the Algerian Sahara. Farmers and citizens dry crops particularly menthe, tomato, abricots, and broad beans. Traditional open sun drying is practiced on a large scale in Ouargla regions where the agriculture suffers from high product losses due to inadequate drying, fungal growth, encroachment of insects, birds and rodents, etc. The problems associated with open-air drying can be solved through the use of a solar dryer which can reduce crop losses and improve the quality of dried product significantly compared to traditional drying method. Solar dryers used in agriculture for food and crop drying are used for industrial drying processes. They can be proved to be a very useful device from the energy conservation point of view. Such a process not only saves energy but also saves a lot of time, occupies less area, improves quality of the product, makes the process more efficient, and also protects the environment [6]. A research group in the laboratory of renewable energy in aride zones (LENREZA) at Ouargla University, Algeria, worked in this field of solar drying. Two types of solar dryer: indirect hybrid solar dryer and direct active solar dryer have been constructed and tested in Ouargla climatic conditions. In the direct solar dryer the product to be dried receives energy from both direct exposure to solar radiation; also the product being dried is protected from rain, insects, and dust. They found the product to have high-quality in terms of flavor, color, and texture. In all cases, the use of a direct convective solar dryer considerably reduces drying time in comparison to open-sun drying. The Passive solar dryers have the advantage of cheap, easy construction from locally available materials and

do not require any other energy during operation. Their major drawbacks are the decrease drying rates, important drying time and the very high internal temperature with the likelihood of overheating the product [7, 8]. Various drying techniques are employed to dry different food products. Each technique has its own advantages and limitations. Choosing the right drying techniques is thus important in the process of drying of the perishable products. To reduce its dependence on solar radiation for operation and to improve the quality of drying many studies on drying of fruits and vegetables using solar dryers with different sizes and designs exist in literature [9]. We can refer to some works such as on drying of potato [10], green pepper, green bean and squash [11], apricot [12], pistachio, and other products. However, studies on drying of broad beans are scarce. Therefore, the analyze of chemical composition and improving of production were experimentally investigated [13-16]. No information is available on the drying behavior of broad beans in the open literature. Therefore the main objectives of this study are to investigate the valorization by drying of broad beans for both direct and indirect solar drying conditions, and to study the thin layer drying modeling of broad beans.

## **2. Materials and Methods**

Fresh local broad beans (*Faba vicia l*) were bought at local market in Ouargla, Algeria. They were singled out one by one using a visual criterion like color, size, absence of physical damage and uniform maturation degree. Dry pods were removed manually by visual inspection. The broad beans pods were then shelled manually.

### **2.1. Description of the Drying System**

Two different solar driers were used in this study (Fig. 1 a, b). They are both laboratory scale prototypes, suitable for the agroalimentary products, designed and assembled by the energy conversion research unit at LENREZA laboratory, University of Ouargla, Algeria. The direct forced convective dryer (fig. 1a) consists mainly of a drying room and a chimney. The indirect forced convective drier system (fig. 1b) is composed of solar collector with simple circulation inclined by 31°C (Ouargla city altitude, Algeria). Air circulation and air exit are aspired by a fan (trade mark KFA-30 A; at a speed of 1400 rotation /mn).

### **2.2 Moisture Measurements**

Moisture was determined with a kern moisture analyzer operating at the following conditions: sample weight (45g), analysis temperature (105°C). The device stops automatically once weight of dehydrated sample is constant. Moisture content is expressed as a percentage value. Three measurements were taken, and the mean value of relative moisture is 2.2 % ± 0.1 in dried base. During the experiments, broad beans were dried to the final moisture content of 0.13 kg water / kg dry matter [17]

Fig. 1 Schematic diagrams of an indirect active hybrid solar–electrical dryer and a direct solar dryer.

### 2.3 Experimental Procedure and Measures

Prior to each experiment, the product samples were weighed with a precision of 0.01 g then reweighed at equal time intervals. So the check in was done each 60 minutes. The desired final moisture content were defined as the standard moisture ensuring a suitable storage of the vegetable product wich is about 0.13 kg water/kg dry matter [4]. The experiment is stopped when the desired final water content is reached.

### 3. Mathematical Modeling of Drying Kinetics

Experimental results of moisture ratio versus drying time were adapted to the theoretical semi models most significant, largely widespread in the process of drying. The report/ratio of moisture (MR) and the drying rate of broad beans during the experiments of drying were calculated using the following equations:[18,19]

$$MR = \frac{X - X_e}{X_0 - X_e} \quad (1)$$

$$\frac{dX}{dt} = \frac{X_{t+\Delta t} - X_t}{\Delta t} \quad (2)$$

#### 3.1. Data Analysis

The coefficient of determination ( $R^2$ ), reduced chi-square ( $\chi^2$ ), and root mean square error (RMSE) were used in this study to evaluate the goodness of fit. To get the best fit of the experimental data, the coefficient of determination  $R^2$  should be higher and the  $\chi^2$  lower.

## 4. Results and Discussion

### 4.1. Drying behavior as influenced by the dryer type

Fig. 2 Moisture content evolution versus time

Figure 2 presents the variation in the moisture content as a function of time in the types of driers direct and indirect, it is clear that the moisture content decrease continuously with drying time, the type of solar dryer affected drying time and product quality. The drying time taken to reduce moisture content from  $2.2 \pm 0.1$  kg water/kg dm to final moisture of  $0.13 \pm 0.1$  kg water/kg dm was 5h for the direct solar dryer and 8h for the indirect one. Obtained experimental results proved the importance of the direct process in the

valorization of the product compared to the indirect one. In reference to available literature, it is also evident that both the two tested methods are more efficient than the sun drying method traditionally adopted by farmers.

## 4.2 Suitable Model for Describing Drying Process

### 4.2.1 Models and Statistical Criteria

By using of Curve-Expert software, it was noted that the values of the three used statistical criteria (standard error (S), coeff. Correlation (r), and Chi Square) appear very similar, making it difficult to distinguish between 12 models. According to the calculation results we saw that for the Page model, the minimum value of the standard error  $S=0.000819$ , the correlation coefficient R corresponds to a large value  $R=0.999848$ , with a minimum value of Chi square = 0.010008 so the empirical page model describes solar drying of broad beans

### 4.2.2 Expression of the Page Model Parameters as a function of Temperature

The following results were obtained by curve fitting using the curve-Expert1.3 software for each parameter. The empirical relation found between the parameters of the equation of page model and temperature are developed and are plotted in Fig3.

Fig 3. Evolution of K and n parameters with temperature

Finally the expressions adopted for the general equation according to the Page model with the parameters depending from time and temperature of the drying air, are given below.

$$XR(t) = \exp. (-k t^n) \quad (6)$$

$$n(T) = 2.916086 + 0.775023 * \cos(0.267699T - 4.114475) \quad (7)$$

$$K(T) = 0.091139 + 0.002939T + 2.369690e-005T \quad (8)$$

## 5. Conclusion

In this study, post harvest treatment of broad beans, by hot air direct and indirect solar drying means, is presented. Based on the experimental results reported herein, the following conclusions can be made. Solar drying has allowed us to minimize post-harvest losses, and preserve the final quality of the dried product, especially when the search aims the

conservation for a long term. Experimental results showed that broad beans dried in direct solar drier had shorter drying time than other dried in indirect convective solar dryer. The semi theoretical models, namely, Page model was used to describe the drying kinetics of broad beans with a satisfactory correlation. An empirical equation, with temperature dependent parameters, was successfully adopted. The most adaptable solar dryer for drying of the broad beans is the direct solar dryer. Although this adaptation depends on techno-economic parameters and social considerations. The criteria for energy consumption and profit on the cost led to place the direct solar dryer as more efficient and more profitable economically.

### **Abstract**

*Wurster granulation with external product classification can be used for stable continuous coating or layering processes. It has been ascertained from recent population balance simulations that the ratio of the spray rate to the nuclei feed rate can be used to control the thickness of the sprayed product layer. However, thermal conditions are not considered by population balances regarding the particle size as distributed property. For this reason, heat and mass transfer is investigated in the present contribution by modelling of several subprocesses. The results can be used to discuss the cause of fluidized bed destabilization due to over-wetting.*

**Keywords:** *continuous operation; Wurster fluidized bed; spray granulation; spray limits; heat and mass transfer.*

## 1. Introduction

The continuous Wurster spray granulation with external product classification is suitable for particle growth processes such as coating and layering with constant product specifications (size, layer or porosity distribution) and product yields. As ascertained by recent results and from former studies [1], higher spray rates and lower feed rate are needed to achieve larger layer thicknesses. Thereby the spray rate is limited by thermal conditions, fluidization gas saturation, drying kinetic and agglomeration tendency which might lead to process instability due to over-wetting. For this reason it is aimed in this contribution to describe the heat and mass transfer of the Wurster-granulator by diverse models, to determine spray limits and to discuss the cause of process destabilization.

## 2. Process configuration and modelling

The present contribution bases on a former case study of Hampel [1] describing the here discussed process with a two-zone population balance model whose simulated product size distributions has been validated by lab scale experiments for a certain range of process parameters. The heat and mass transfer of this Wurster granulation process should be investigated with several model approaches such as an ideal two-component particle growth model, steady state particle circulation in Wurster-chamber, pneumatic transport and spray deposition in Wurster-tube (spray zone denoted with  $\alpha$ ) as well as drying and heating outside the Wurster tube (drying zone denoted with  $1-\alpha$ ).

### 2.1. Reference case – Experimental design and modelling

The experimental design of the continuous Wurster spray granulation in Hampel's investigations [1] consists of a conical fluidized bed apparatus which is interconnected to a straight-duct air classifier as illustrated in Fig. 1a). Particles are raised through the Wurster-tube due to high gas velocities and are sprayed with a solid-containing liquid. Above the Wurster-tube particles fall back into the drying zone. The particle circulation has been described, e.g. by Börner et al. [2]:

$$\tau_{1-\alpha} = \tau_{\alpha} \frac{1-\alpha}{\alpha}, \quad (1)$$

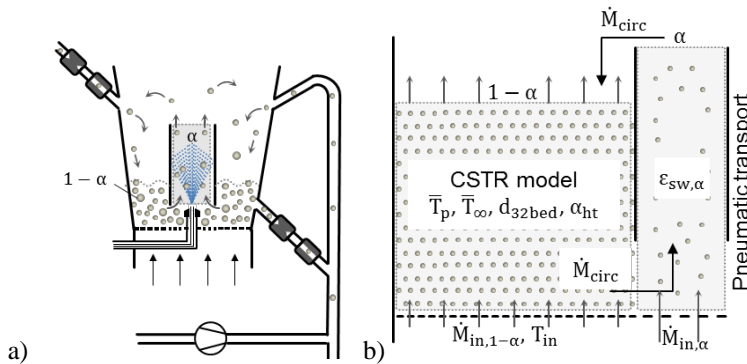

wherein  $\tau_{\alpha}$  and  $\tau_{1-\alpha}$  represent the residence time (s) of the spray zone and the drying zone, respectively. Further,  $\alpha$  is defined as the volume fraction ( $\text{m}^3/\text{m}^3$ ) of spray zone related to the total volume of the disperse system (spray zone and drying zone).

## 2.2. Heat and mass transfer modelling

The heat and mass model is illustrated in Fig. 1b) and assumes basically the following aspects. Particles circulate through spray and drying zone with constant residence times. The interior of Wurster-tube is seen as spray zone and the drying zone is assumed as a homogeneous fluidized bed describing the outer region of the Wurster-tube. Stationary pneumatic transport and moistening of particles takes place in the spray zone, wherein swarm sinking is also considered. The temperature of the particles leaving the spray zone is assumed to be the wet bulb temperature. Finally, evaporation of sprayed water content (drying period) and particle heating (heating period) occur in the drying zone until the particles re-enter the spray zone.

**Fig. 1 a) Wurster spray granulation chamber with an interconnected straight-duct air classifier [1], b) Two-zone heat and mass transfer model.**

Furthermore, a simplified two-component particle growth model is used in order to approximate the stationary size distribution of fluidized bed particles. This model contains several assumptions such as: mono-sized feed and product, mono-shaped disperse system of solid spheres, constant feed and spray rate, evenly distributed particle growth rate, non-distributed residence time due to permanent classifying with an ideal separation performance and steady state conditions. As a conclusion, a two-component single particle model consisting of a spherical core and a spherical layer with a well-defined core diameter and coating layer thickness can be derived. The number density distribution regarding the size of the fluidized bed particles turns out to be a uniform distribution. Hence, the Sauter diameter  $d_{32,bed}$  and an average effective particle density  $\bar{\rho}_{p,eff}$  among the population can be obtained analytically which are both needed for the description of heat and mass transfer.

2.2.1. Pneumatic transport in spray zone

The residence time in the spray zone is a parameter which is required for the two-zone population balance of the abovementioned reference case. The spray zone residence time is approached in this contribution based on the assumption of stationary pneumatic transport with constant solid volume fraction:

$$\tau_{\alpha} = \frac{L_{wt}}{u_{g,\alpha}/\epsilon_{sw,\alpha} - k_{sw}u_s(d_{32,bed})} \text{ and } k_{sw} = (1 - \epsilon_{sw,\alpha})^{5,5(Ar)^{-0,06}} \quad (2a) \text{ and } (2b)$$

Eq. 2a takes into account the Wurster-tube length  $L_{wt}$  (m), the spray zone gas velocity  $u_{g,\alpha}$  (m/s) and the solid volume fraction in spray zone  $\epsilon_{sw,\alpha}$  ( $m^3/m^3$ ) which can be estimated by CFD-DEM simulations. Further Eq. 2a includes the swarm sinking correction  $k_{sw}$  (-) and the terminal sinking velocity  $u_s$  (m/s) of a single sphere. The swarm sinking factor  $k_{sw}$  can be calculated with Eq. 2b suggested by Richardson and Zaki [3].

2.2.2. Fluidization gas cooling, particle drying and particle heating in drying zone

The fluidization gas cooling is depicted schematically in Fig. 2a). Fig. 2b) shows the drying period and the heating period of a single particle with retention time  $t_{1-\alpha}$  (s) in the drying zone.

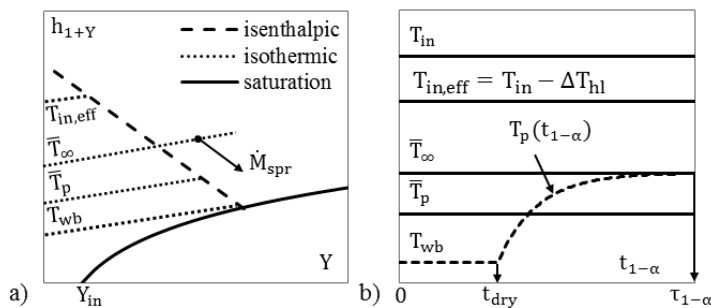

Fig. 2 a) Schematic Mollier-diagram illustrating the temperature range inside the Wurster-granulator, b) Single particle temperature evolution versus retention time in the drying zone.

The average gas temperature  $\bar{T}_{\infty}$  ( $^{\circ}C$ ) in the drying zone is calculated with incoming gas temperature  $T_{in}$  ( $^{\circ}C$ ) below the distributor plate, with the temperature drop  $\Delta T_{hl}$  ( $^{\circ}C$ ) due to heat losses at the gas distributor plate, the solid content of spray solution  $x_s$  (kg/kg), with the evaporation energy  $\Delta h_{eva}$  ( $J/kg$ ) of deposited spray solvent and others:

$$\bar{T}_{\infty} = T_{in} - \Delta T_{hl} - \frac{(\dot{M}_{spr}(1-x_s) - \dot{M}_{in,\alpha} \frac{\varphi_{\alpha} Y_{sat}(T_{in}, Y_{in})}{1+Y_{in}}) \Delta h_{eva}^{\circ}(T_{wb})}{\dot{M}_{in,1-\alpha} c_{p,fl}} \quad (3)$$

Particles, leaving the spray zone and entering the drying zone, have been cooled down to the wet bulb temperature. The particle temperature evolution in the drying zone is divided into two segments: the drying period as first segment and the heating period as second segment. The time interval of 0 to the required drying time  $t_{dry}$  defines the drying period. Within the drying period, the particle temperature  $T_p$  remains at the wet bulb temperature  $T_{wb}$ . The heating period starts directly after complete evaporation of coating humidity where the particle temperature is still at the wet bulb temperature. The particle temperature rises subsequently and approaches the average surrounding temperature of the fluidization gas  $\bar{T}_{\infty}$  with increasing drying zone retention time. Finally the particles enter the spray zone at the total residence time  $\tau_{1-\alpha}$  in the drying zone. The particle temperature curve of the heating period is obtained from the energy balance of a single particle:

$$T_p = \bar{T}_{\infty} - (\bar{T}_{\infty} - T_{wb}) \exp(-St'(t_{1-\alpha} - t_{dry})). \quad (4)$$

The particle heating kinetic is represented by the modified Stanton number  $St'$  (1/s) which is defined with  $St' = 6\alpha_{ht}/(d_{32,bed}\bar{\rho}_p,effc_p)$  and the heat transfer coefficient  $\alpha_{ht}$  (W/m<sup>2</sup>/K) can be determined with Gnielinski's approach [4]. The drying time is approximated by an energy balance assuming constant drying rate. In order to estimate the average particle temperature  $\bar{T}_p$  in the drying zone, the time function of the particle temperature (Eq. 4) has been integrated with retention time  $t_{1-\alpha}$  and divided by the total residence time in drying zone  $\tau_{1-\alpha}$ :

$$\bar{T}_p = T_{wb} \frac{t_{dry}}{\tau_{1-\alpha}} + \bar{T}_{\infty} \left(1 - \frac{t_{dry}}{\tau_{1-\alpha}}\right) - (\bar{T}_{\infty} - T_{wb})k_{ht} \quad (5)$$

$$k_{ht} = \frac{1 - e^{-St'(\tau_{1-\alpha} - t_{dry})}}{St'\tau_{1-\alpha}}. \quad (6)$$

Thereby  $k_{ht}$  is introduced as a coefficient of heating kinetic including the influence of the modified Stanton number on the average particle temperature.

### 2.3. Parameter setting

The parameter values of the material properties, mass flow and inlet temperature of the fluidization gas as well as the bed mass are chosen according to the reference case [1] and are listed in Table 1. Therein are also given further parameters which are the swarm solid volume fraction  $\varepsilon_{sw,\alpha}$  and the relative air humidity  $\varphi_{\alpha}$  in the spray zone. Both parameters are adapted to measured fluidized bed temperature. Beside this, a heat loss temperature difference  $\Delta T_{hl}$  has been determined from measurements determining the temperature below and above the distributor plate.

Table 1. Model parameters

$d_f$	$d_{pr}$	$\rho_{f,eff}$	$\rho_{c,eff}$	$\dot{M}_{in}$	$x_s$	$T_{in}$	$M_{bed}$	$\epsilon_{sw,\alpha}$	$\Phi_\alpha$	$\Delta T_{hl}$
mm	mm	$\frac{kg}{m^3}$	$\frac{kg}{m^3}$	$\frac{kg}{h}$	$\frac{kg}{kg}$	°C	kg	$\frac{m^3}{m^3}$	-	K
0.3	0.4	1380	806	70	0.32	70	1	0.02	0.35	5.7

In the present contribution, model results based on Table 1 and three different spray rates (0.8 kg/h, 1.1 kg/h and 1.3 kg/h) are investigated.

### 3. Results and Discussion

Several spray rate independent parameters of the Wurster granulation can be obtained from the presented the heat and mass transfer model, see in Table 2. These include the Sauter diameter of the bed particles  $d_{32,bed}$ , the swarm correction factor  $k_{sw}$ , the single particle sinking velocity  $u_s$ , the superficial gas velocity in spray zone  $u_{g,\alpha}$  as well as the residence time in spray zone  $\tau_\alpha$  and drying zone  $\tau_{1-\alpha}$ . It can be seen that the swarm effect can not be neglected with a factor 0.93. The sinking velocity is smaller than the spray zone gas velocity which is a requirement for stable circulation in the Wurster-granulator. The spray zone residence time is much lower than the drying zone residence time.

The drying time  $t_{dry}$ , the heat transfer coefficient  $\alpha_{ht}$ , the modified Stanton number  $St'$ , the heating kinetic factor  $k_{ht}$ , the average gas temperature  $\bar{T}_\infty$  and the average particle temperature  $\bar{T}_p$  are calculated for three different spray rates  $\dot{M}_{spr}$ , respectively (see Table 3). The drying time increases linearly with spray rate and it is negligibly small compared to the residence time in the drying zone. The low drying time is caused by the high heat and mass transfer conditions of the fluidized bed. The particle heating coefficient is small. Thus the contribution of the particle heating kinetic to the average particle temperature can be neglected. Hence, the average particle temperature hardly differs from the average gas temperature in the drying zone due to the low drying times and the low particle heating kinetic coefficients.

Table 2. Spray rate independent model results

$d_{32,bed}$	$k_{sw}$	$u_s$	$u_{g,\alpha}$	$\tau_\alpha$	$\tau_{1-\alpha}$
mm	-	m/s	m/s	s	s
0.35	0.93	1.79	2.02	0.508	27.949

Table 3. Spray rate dependent model results

$\dot{M}_{spr}$ $\frac{kg}{h}$	$t_{dry}$ s	$\alpha_{ht}$ $\frac{W}{mK}$	$St'$ 1/s	$k_{ht}$ %	$\bar{T}_{\infty}$ °C	$\bar{T}_p$ °C
0.8	0.018	503.6	3.19	1.234	43.30	43.06
1.1	0.027	506.7	3.21	1.226	31.77	31.67
1.3	0.034	509.0	3.22	1.221	24.29	24.08

The model results of the spray rate of 0.8 kg/h are compared with the measured fluidized bed temperature of a Wurster batch granulation process spraying a solution with 32 wt-% sodium benzoate solution on MCC-particles.

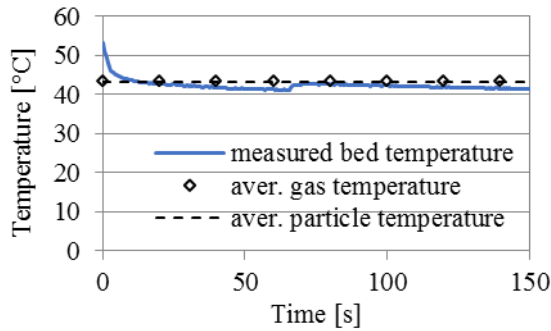

Fig. 3 Model-based average gas and average particle temperature adapted to measured fluidized bed temperature.

Additionally, several batch processes spraying pure water have been conducted for different bed masses (0.5 kg, 1 kg, 1.5 kg, and 2 kg) and different fluidization gas temperatures (70°C, 80°C and 90°C). Thereby the spray rate has been increased until destabilization of the fluidized bed took place.

#### 4. Conclusions

Although the drying kinetic in the drying zone is ascertained as large, process destabilization due to over-wetting takes place far below the point of saturation. For this reason, it is presumed that the enhancement of agglomeration tendency with the larger spray rates cause the destabilization. Agglomerated particles might not be raised through the Wurster-tube for the reason that the sinking velocity is strongly increased. Hence agglomerates accumulate at the bottom of the fluidized bed, block the particle circulation and finally destabilize the fluidization.

### **Abstract**

*Drying is one of the most energy intensive unit operations. It easily accounts for up to 15% of all industrial energy consumption. In the most drying processes heat is required to evaporate moisture which is later removed with a flow of air. The hot, humid air leaving the dryer is often considered as a waste stream, and a large fraction of energy is lost. The aim of the theoretical and experimental concept study presented here was to evaluate a method of reclaiming energy from low temperature waste streams and converting it to useful in industry saturated steam of temperature from 120 to 150 °C. Chemical heat pump concept based on the dilution and concentration of phosphoric acid was used to test the method in the laboratory. Heat of dilution and energy needed for water evaporation from the acid solution were experimentally measured. The cycle of successive processes of dilution and concentration has been experimentally confirmed. Theoretical model of the chemical heat pump was tested and coefficient of performance measured. Energy balance of the drying system and efficiency increase of the dryer supported with chemical heat pump were calculated.*

**Keywords:** *Efficiency of drying; energy recovery; chemical heat pump*

---

## 1. Introduction

Drying is very intensive unit operation which, on the global scale, can accounts for up to 15% of all energy used in the industry [1](Chua et al. 2001). In many cases a large fraction of energy applied for drying is wasted with low temperature streams leaving the process [2](Ogura et al. 2005). Any energy recovery system in the drying can reduce significantly process energy consumption. Applications of heat pump technology offers energy saving potential along with temperature and humidity control. Drying assisted with heat pumps exploiting consecutive compression, condensation, expansion and evaporation of working fluid, is an object of research since eighties of last century. Dryers with heat pumps ensure economical process and at the same time product's quality especially agriculture and food products. In the recent years chemical heat pumps have gained more interest as offering higher temperatures and possibility to store energy in chemical substances.

Chemical heat pumps (CHP) are using reversible exothermal and endothermal chemical reactions to transfer energy, increase the temperature of working fluids and sometimes to store energy by chemical substances [3](Kawasaki et al. 1999). Selection of these chemical substances is important to absorb and release heat energy [4](Kato et al. 1996). Numerous chemical substances can be used in CHP to create a cycle of chemical reactions. The following substances have been proposed as working fluids: water systems: hydroxide/oxide, salt hydrate/salt or salt hydrate, ammonia systems: ammoniate/ammoniate or salt, amine complex with salt, sulfur dioxide systems: sulphite/oxide, phryrosulphate, carbon dioxide systems: carbonate/oxide, barium oxide/barium carbonate, hydrogen systems: hydride or metal, hydrogenation/ dehydrogenation [5](Wongsuwan et al. 2001).

Unlike the "classical" vapor compression heat pumps CHP enable to achieve significantly higher temperatures of heated medium which is crucial for the potential application, e.g., for production of saturated steam usually applied as a heating medium in majority of industrial processes. Despite the presented advantages, currently, there are no installations using CHP for low-grade waste heat recovery available on the market.

CHP absorbs energy via endothermic and release energy via exothermic in the form of chemical. CHP systems utilize the reversible chemical reaction to change the temperature level of the thermal energy, which stored by chemical substances [3](Kawasaki et al. 1999). These chemical substances are important in absorb and release heat energy [4](Kato et al. 1996). Various chemical substance can be use in CHP for chemical reaction, for examples, water system (hydroxide/oxide, salt hydrate/salt or salt hydrate), ammonia system (ammoniate/ammoniate or salt, amine complex with salt), sulfur dioxide system (sulphite/oxide, phryrosulphate), carbon dioxide system (carbonate/oxide, barium oxide/barium carbonate), hydrogen system (hydride or metal, hydrogenation/ dehydrogenation), etc. has been proposed as working medium [5](Wongsuwan et al. 2001).

One of promising chemical systems for CHP is water solution of phosphoric acid where waste heat of low temperature level is accumulated in endothermic and released in exothermic dilution of phosphoric acid [6]( Ducheyne 2017). The results of dilution heat laboratory measurement will be presented.

The distant aim of the project is to apply CHP system to saturated steam production needed for drying using abundant waste heat available from cooling electricity generator.

## 2. CHP concept

The basic configuration of CHP is shown on Fig.1. In general CHP consists of a generator, a reactor, condenser and an evaporator. Waste heat, in most cases at the same temperature, is provided to the generator  $Q_G$  and the evaporator  $Q_E$  while upgraded heat is delivered by reactor  $Q_R$ . Part of the heat at low temperature is removed from the condenser  $Q_C$ . Usually to increase efficiency of CHP cycle internal heat exchanger transferring heat between solutions is added [7](Horuz and Kurt 2010).

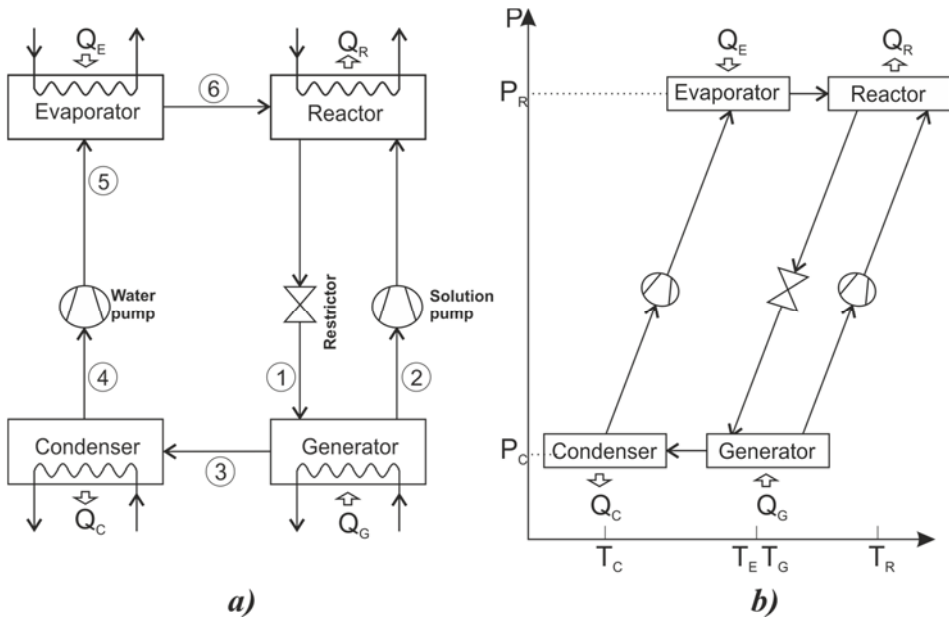

Fig. 1 Chemical heat pump: a) CHP schematic, b) CHP the pressure vs. temperature diagram.

In the presented CHP concept two component working fluid is used. Primary fluid absorbs secondary fluid producing upgraded heat while waste heat is consumed in an endothermic evaporation of secondary fluid. In the study solution of phosphoric acid will be primary while water secondary fluid.

The solution leaving the generator at high concentration will be referred as strong solution, while solution returning from the reactor to generator at lower concentration of phosphoric acid will be referred as a weak solution.

The CHP presented in Fig 1a operate with the cycle depicted in Fig. 1b The weak solution 1 is entering the generator where part of the secondary fluid is evaporated and strong solution 2 is produced. Strong solution is returned to the reactor, while vapour 3 removed from solution is condensed, pumped and heated. Water or water vapour enters the reactor where it is mixed with strong solution 2'. The heat of dilution increase the temperature of cooling water. Weak solution is returned to the generator. The CHP operate at two pressure levels, lower which is saturation pressure at the condenser temperature and upper level which is saturation pressure at the evaporator temperature. As Fig. 1b present there are three temperature levels of CHP: a generator, a condenser and reactor. In most cases the evaporator and generator are using the same heat source so their operation temperatures are the same.

The performance of CHP can be increased with heat exchanger transferring energy from weak solution to strong solution, or modifying path of the stream providing waste heat. Every industrial application is different and CHP system should be well fitted to the real needs. To do so an exact process model, based on validated experimental data of heat consumption and production, should be developed.

### 3. Materials and Methods

#### 3.1. Materials

The 85% by weight phosphoric acid was purchased from Sigma-Aldrich and used without further purification. Demineralized water was used in all dilution experiments.

#### 3.2. Apparatus and calculation of results

Measurements of the heat of dilution were conducted using a diathermic reaction calorimeter (Fig. 2) equipped with PTFE measuring cell **1** with a capacity of: 50 cm<sup>3</sup> and an automatic injection system **8**. Temperature was measured using a thermocouple type K **5** of diameter of 0.5 mm. The control and acquisition of data from the measurement system was carried out using the LabView software.

Heat of dilution of phosphoric acid was calculated using the following heat balance:

$$\Delta H_{dil} = r_u \cdot \Delta T_{cor1} \quad (1)$$

Where:  $\Delta H_{dil}$  - heat generated during dilution of phosphoric acid, J;  $r_u$  - heat capacity of the system ;  $\Delta T_{cor1}$  - rectified temperature increase determined by graphical method for the process of acid dilution.

Heat capacity of the system was determined by measuring Joule heat provided to the system by heating coil.

$$r_u = \frac{U \cdot i \cdot t}{\Delta T_{cor2}} \quad (2)$$

Where:  $U$  - potential difference applied to the heating coil, V;  $i$  - electric current passing through the heating coil, A;  $t$  - heating time, sec;  $\Delta T_{cor2}$  - rectified temperature increase determined by graphical method for the electric heating process of the system.

*Fig.2 Scheme of the calorimeter*

- 1 – PTFE measuring cell, 2 - insulation inserts, 3 – bomb calorimeter, 4 – magnetic stirrer, 5 – thermocouple, 6 – stainless steel needle, 7 – cover, 8 – syringe, 9 – autosampler controlled by a microprocessor, 10 – stepping motor for autosampler drive, 11 – reaction mixture, 12 - heating coil

### 3.3. Methodology

A sample of acid was placed in a PTFE measuring cell of the reaction calorimeter. Deionized water was injected with autosampler, and the injection time was 0.2 sec. The mass of the

water used for the dilution of the acid was determined by the difference of the weight of the syringe with water before and after the measurement, with a weighing accuracy of  $\Delta m = \pm 0.0001\text{g}$ . Temperature measurement with a sampling rate of 0.01/ sec lasted 10 minutes. Then, for the obtained reaction mixture, the thermal capacity of the system was measured using a heating coil. The electrical parameters of the process for all measurements were set at  $U = 5\text{V}$  and  $i = 1.2\text{ A}$ , the heating time of the system was 15 sec. The obtained dependences  $T = f(t)$  were used to determine the values:  $\Delta T_{\text{cor1}}$ ,  $\Delta T_{\text{cor2}}$  by graphical method. After taking into account the accuracy of the mass measurement and the characteristics of the instruments used, the method error was determined to be  $\pm 3\%$ .

#### 4. Results and discussion

The heat of dilution has been determined over the molar concentration range from 57.8 to 11.8 *m* (85%-53% by weight) at ambient pressure. The heat of dilution between molality of initial  $m_1$  and final  $m_2$  molality are given in the Table 1.

*Table 1. Experimental data for phosphoric acid heat of dilution measurement*

Run	$m_1$ mol/kg	$m_2$ mol/kg	$\Delta T_{\text{cor1}}$ K	$n_{\text{H}_2\text{O}}/n_{\text{H}_3\text{PO}_4}$ -	$\Delta H_{\text{dil}}$ kJ/mol
1	57.827	29.916	12.206	1.855	3.842

Plot of heat of dilution versus molar ratio of solvent and solute is given in Fig. 3. The heat of dilution of aqueous phosphoric acid solutions, presented in Fig3, show a large curvature for molar ratio less than 3.

Our results are in a good agreement with the values of dilution heat obtained by other workers for low concentration phosphoric acid. [8, 9]( Wakefield 1972, Millero 1978).

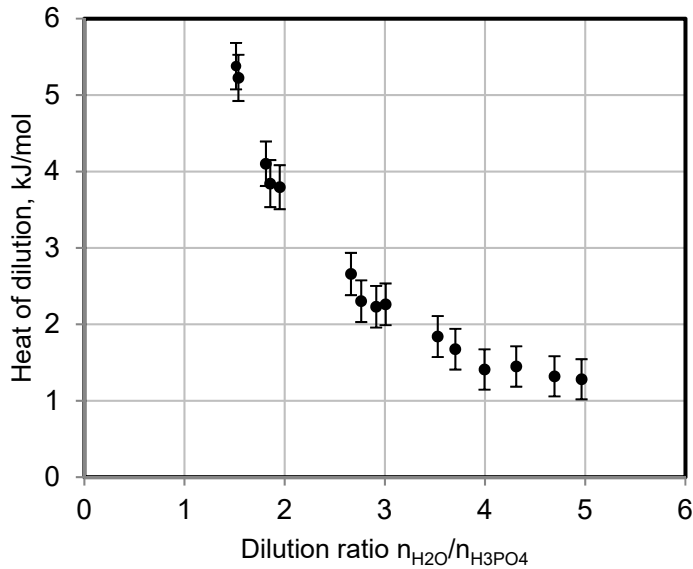

Fig.3 Phosphoric acid heat of dilution vs water /acid molar ratio.

## 5. Conclusions

Heat pump technology can improve heat efficiency of many drying processes. Low temperature systems are intensively studied and already implemented in the industry. Chemical heat pumps offers prospect to generate heat flux at elevated temperature.

Heat of dilution for phosphoric acid of high concentration was experimentally measured at isobaric conditions. Thermal effect of dilution strongly depends on acid concentration.

Laboratory experiments proved that phosphoric acid and water can be used as a efficient working system in CHP. Heat of dilution important for energy recovery in heat pump reactor, enable to produce technologically useful heat flux from waste heat source.

### **Abstract**

*In this research, a Coulomb force assisted heat pump (CF-HP) dryer was invented for the purpose of improving the drying characteristics and product quality of biomaterials. As compared to heat pump drying alone, the assistance of Coulomb force in heat pump dryer enhanced the drying rates and effective moisture diffusivity of lemon slices up to 26%, which eventually shortened the total drying time to 40%. This saved the total energy consumption of HP drying by 31.5%. High retention of vitamin C and TPC were also found in CF-HP dried slices due to mild drying temperature and fast drying rate.*

**Keywords:** *Coulomb force; Heat pump drying; Drying rate; Vitamin C; Total Phenolic Content (TPC).*

---

## **1. Introduction**

Heat pump (HP) drying is one of the advanced drying methods that have been used for drying of many agriculture products. It is known as an energy efficient drying method which can produce good product quality as drying is conducted at mild temperature and low relative humidity<sup>[1,2]</sup>. However, mild temperature drying limits the moisture diffusion in the drying materials, which in turn lengthened the total drying time. Hybrid drying involving heat pump combined with other methods such as ultrasound, radio frequency / microwave heating, infrared heating and solar heating also been studied by researchers with the purpose to stimulate the moisture diffusivity and thus drying rate of the drying materials during heat pump drying<sup>[3]</sup>. Nevertheless, most of the hybrid drying methods like are lack of practical application for drying of heat sensitive biomaterials<sup>[4]</sup>.

In this research, an electricity-assisted (Coulomb force) heat pump (CF-HP) drying is proposed as an alternative drying method for the drying of biomaterials such as lemon slices. In CF-HP drying, a high voltage wire mesh is incorporated in the heat pump dryer in order to enhance the removal rate of bound moisture, which in turn counteracts the long drying time required due to mild temperature drying. Owing to the bipolar property of moisture content inside the lemon slices, a positive net force (Coulomb force) can be induced when the lemon slices are placed near to the high voltage, but low frequency mesh. The generated force stimulates the moisture diffusion in the lemon slices which consequently dried by convective air flow produced by heat pump dryer. As there is no heating involved in drying process, the desired properties of the dried lemon slices can be preserved. Hence, CF-HP drying is envisaged to be a successor of heat pump drying in terms of high drying rate and moisture diffusivity, short total drying time, low energy consumption and good quality of dried products.

## **2. Materials and Methods**

### **2.1 Sample preparation**

Fresh Eureka lemons were sliced crosswise into circular slices. The average thickness of slices was measured as  $3.0 \pm 0.5 \times 10^{-3}$  m and the initial weight of each slice was recorded as  $8.20 \pm 0.05 \times 10^{-3}$  kg. The average surface area of the slices was calculated as  $2.38 \times 10^{-3}$  m<sup>2</sup>. The lemon slices were dried until equilibrium moisture content (EMC) achieved.

### **2.2 Drying methods**

#### *2.2.1 Heat pump drying*

A laboratory scale heat pump dryer is designed and fabricated by I-Lab Sdn. Bhd., Selangor, Malaysia. The heat pump (HP) dryer consists of a drying chamber of dimensions

0.8 m × 0.6 m × 0.6 m and a heat pump system. Mild temperature dehumidifier air produced by the heat pump system is used as a drying medium and force circulation of convective air is produced by a blower. The dryer was operated at drying temperature of 22°C and 34% relative humidity (RH) when the auxiliary heater was turned off whereas the drying temperature was 31°C and 24% RH when the auxiliary heater was on. The average air velocity in the chamber was maintained at 1.1 ms<sup>-1</sup>.

### 2.2.2 Coulomb force assisted heat pump drying

For Coulomb force assisted heat pump (CF-HP) drying, a high voltage system was incorporated inside the heat pump drying chamber, as shown in Fig. 1. The high voltage source which determined to be  $1.5 \times 10^4$  V and 50Hz, was generated by using a transformer. The output of transformer was connected to the wire mesh, where the string meshes and lemon slices were being loaded on. The effective distance between the lemon slices and wire mesh was determined to be  $3 \times 10^{-3}$  m. The drying condition of the hybrid heat pump drying was similar to heat pump drying in section 2.2.1. CF-HT-HP drying is the CF-HP drying with auxiliary heater being switched on.

Fig. 1 Simplified diagram of the Coulomb force assisted heat pump (CF-HP) dryer

### 2.2.3 Oven drying

Lemon slices were dried in a laboratory scale hot air convection oven (Memmert, UFB500) at three different temperatures which were 40°C, 50°C, and 60°C, at the corresponding relative humidity (RH) of 33.4%, 20.2% and 12.6%, respectively. The average air velocity inside the chamber was determined as 0.6 ms<sup>-1</sup>. Oven dried lemon slices were used as reference samples which meant for the quality comparison with samples dried by heat pump and Coulomb force assisted heat pump drying methods.

## 2.2.4 Freeze drying

Lemon slices were pre-frozen in a deep freezer (ARDO-CV382 Upright Freezer) at  $-40^{\circ}\text{C}$  for 24 hours, before freeze dried in a laboratory scale freeze dryer (Labconco) at  $-40^{\circ}\text{C}$  and 13.3 Pa. The total drying time for freeze drying of lemon slices was set at 48 hours to obtain the optimum vitamin C and TPC retention in freeze dried lemon slices<sup>[5]</sup>. The freeze dried slices were used as control sample for the determination of vitamin C and TPC in the dried slices subjected to different drying methods.

## 2.3 Energy consumption

Total energy consumption for heat pump and Coulomb force assisted heat pump drying was measured by the power meter (D02A,  $\pm 1\text{W}$ ).

## 2.4 Drying rate and moisture diffusivity

The initial moisture content ( $M_0$ ), moisture content at a given drying time  $t$  ( $M_t$ ), equilibrium moisture content ( $M_{eq}$ ), moisture ratio ( $MR_t$ ) and drying rate ( $R$ ) of the lemon slices were calculated by equations (1) – (5) whereas the moisture diffusivity ( $D_{eff}$ ) of the samples was determined using Fick's second model (equation (6)), by assuming the lemon slices to be of the shape of slab.

$$M_0 = \frac{W_0 - W_d}{W_d} \quad (1); \quad M_t = \frac{W_t - W_d}{W_d} \quad (2); \quad M_{eq} = \frac{W_{eq} - W_d}{W_d} \quad (3); \quad MR_t = \frac{M_t - M_{eq}}{M_0 - M_{eq}} \quad (4)$$

$$R = \frac{W_d}{A_s} \left| \frac{F_{t+1} - F_t}{t_{t+1} - t_t} \right| \quad (5); \quad MR = \frac{8}{\pi^2} \left[ \sum_{n=0}^{99} \frac{1}{(2n+1)^2} \exp\left(-\frac{(2n+1)^2 \pi^2 D_{eff} t}{l^2}\right) \right] \quad (6)$$

Where  $W_0$ ,  $W_t$ ,  $W_d$ , and  $W_{eq}$ , refer to initial weight of the sample (kg), weight of the sample in the middle of drying process at time  $t$  (kg), bone dry weight of the sample (kg), and equilibrium weight of the sample (kg), respectively.  $A_s$  is denoted as the surface area of the samples ( $\text{m}^2$ ),  $F_t$  is the free moisture content of the sample at time  $t$  (kg  $\text{H}_2\text{O}$  / kg dry material).  $l$ ,  $t$  and  $n$  are the sample's thickness (m), drying time (s) and a positive integer, respectively.

## 2.5 Quality analysis

### 2.5.1 Vitamin C

Dried lemon slices were cut into small pieces of equivalent size and subjected to extraction process at  $4^{\circ}\text{C}$  for 24 hours using 0.05 L of metaphosphoric acid-acetic acid ( $\text{HPO}_3\text{-CH}_3\text{COOH}$ ) as extracting solvent. After removal of solid slices by vacuum filtration, the supernatants were titrated into  $5 \times 10^{-3}$  L of indophenol standard solution (IS). The amount

of supernatants,  $V_s$  used to decolourize the IS solution was recorded. Equation (7) was used to determine the vitamin C (kg Ascorbic acid / kg dry weight) in dried lemon slices which derived based on the standard curve obtained using Ascorbic Acid as standard solution<sup>[6]</sup>.

$$\text{Vitamin C} = \frac{0.31V}{V_s W_d} \quad (7)$$

Where  $V$  is the volume of the extracting solution used (L)

### 2.5.2 Total phenolic content (TPC)

Similar to vitamin C analysis, dried lemon slices were cut into small pieces of equivalent size and subjected to extraction process at 4°C for 24 hours using 0.05 L of solvent which made up of acetone, distilled water and hydrochloric acid in volume percentage of 75%, 22% and 3%, respectively. After removal of solid slices by vacuum filtration,  $1 \times 10^{-3}$  L of supernatant was titrated into  $5 \times 10^{-3}$  L of 0.2N Folin-Ciocalteu reagent and held for 3 minutes. Then,  $4 \times 10^{-3}$  L of 7.5% sodium carbonate solution ( $\text{Na}_2\text{CO}_3$ ) was added into the mixture and incubated in dark at room temperature for 30 minutes to allow colour development. Subsequently, the extract was adjusted with 0.04 L of distilled water and the absorbance ( $A$ ) of the extract was measured at  $7.65 \times 10^{-7}$  m in a single beam spectrophotometer (JENWAY 6320D). Equation (8) was used to determine the TPC (kg Gallic acid / kg dry weight) in dried lemon slices which derived based on the standard curve obtained using Gallic acid as standard solution<sup>[7]</sup>.

$$\text{TPC} = \frac{AD_f V}{9.02W_d} \quad (8)$$

Where  $D_f$  is dilution factor.

## 3. Results and Discussion

### 3.1 Drying rate, effective moisture diffusivity and total drying time

*Table 1. Average drying rate, effective moisture diffusivity and total drying time of heat pump and Coulomb force assisted heat pump dried lemon slices*

Drying Method	Average Drying	Average	Reduction of Total Drying Time (%)
	Rate (R) ( $\times 10^{-5}$ kg $\text{H}_2\text{O}$ / $\text{m}^2 \cdot \text{s}$ )	Effective Diffusivity ( $D_{\text{eff}}$ ) ( $\times 10^{-11}$ $\text{m}^2 \cdot \text{s}^{-1}$ )	
HP	5.33	2.95	–
CF-HP	5.83	3.25	31.6
CF-HT-HP	6.67	3.73	39.9

**Table 2. Power and total energy consumption of heat pump and Coulomb force assisted heat pump drying methods**

Drying Method	Power (W)	Total Energy Consumption ( $\times 10^8$ J)
HP	1723.07	9.20
CF-HP	1726.62	6.30
CF-HT-HP	3150.11	10.11

As shown in Table 1, the highest average drying rate was found for CF-HT-HP drying, followed by CF-HP and HP drying of lemon slices. As compare to heat pump drying alone, the average drying rate and effective moisture diffusivity of Coulomb force assisted heat pump drying were found to improved up to 25.1% and 26.4%, respectively. The induced Coulomb force in lemon slices during hybrid heat pump drying decreased external mass transfer resistance rendered by the high electric field, which consequently intensified the drying rate and enhanced the moisture diffusivity from core to product surface. This reduced the total drying time of 31.6% and 39.9% for CF-HP and CF-HT-HP drying, respectively. In terms of energy consumption, CF-HP drying is more efficient in energy saving as it required the least energy, which is only 68.5% and 62.3% of the total amount of energy required by HP and CF-HT-HP drying, respectively as indicated in Table 2.

### 3.5 Vitamin C content of dried lemon slices

**Fig. 2. Comparison of vitamin C in lemon slices for different drying methods. Vitamin C contents with different superscript letters indicate a significant difference at  $p < 0.05$ .**

Based on Fig. 2, except for freeze dried samples, CF-HP dried lemon slices showed the highest amount of vitamin C among all samples. The vitamin C content of CF-HP dried slices is significantly higher than oven dried slices due to mild temperature drying condition

and high drying rate. Similar to this, the amount of vitamin C in heat pump and CF-HT-HP dried samples were found to be 2.5% to 93.2% higher than oven dried samples. This indicates drying of lemon slices at mild temperature could minimize the deterioration of vitamin C during the drying process. In addition, integration of Coulomb force in heat pump drying (CF-HP) enhanced the drying rate and shortened the total drying time required as compared to HP drying which led to a better vitamin C retention in dried lemon slices. Due to increased drying temperature, the used of auxiliary heater in CF-HT-HP drying reduced the vitamin C content in lemon slices as compared to those dried with CF-HP and HP method, resulted in lower vitamin C content similar with those found in lemon slices dried at 40°C. Lowest amount of vitamin C in 50°C and 60°C oven dried lemon slices could be due to combination of thermal and oxidative degradations of vitamin C. However, freeze dried lemon slices preserved the highest vitamin C among of all as drying at high vacuum could mitigate oxidative degradation of vitamin C<sup>[6]</sup>. Commercial dried products which commonly dried by solar or hot air drying method are found to retain low amount of vitamin C attributed to thermal degradation and oxidative destruction of vitamin C due to prolong drying time<sup>[7]</sup>.

### 3.6 TPC content of dried lemon slices

**Fig. 3. Comparison of total phenolics content (TPC) in lemon slices for different drying methods. TPC with different superscript letters indicate a significant difference at  $p < 0.05$ .**

In contrast to the retention of vitamin C, oven dried slices at elevated temperature (50°C and 60°C) retained the highest amount of TPC as shown in Fig 3. According to Vega-Galvez et al., high retention of TPC in fruits dried at elevated temperature could be due to the conversion of phenolic molecules from other forms of phenolic compounds, which led to greater amount detected<sup>[8]</sup>. Furthermore, high drying rate and short drying time of the

lemon slices at elevated temperature also prevents the degradation of TPC attributed to volatilization, oxidation and heat destruction process. The effect of drying rate and drying time on the TPC of dried slices was further shown by the heat pump and hybrid heat pump dried slices. Among of them, the TPC in CF-HP and CF-HT-HP dried slices were insignificantly different, but they were significantly higher than the TPC of HP dried slices although drying was conducted at mild temperature. Similar to the results of vitamin C analysis, TPC in commercial dried lemon slices was the lowest among of all due to low drying rate and prolong drying time of open sun drying or solar drying.

#### **4. Conclusion**

Coulomb force assisted heat pump drying intensified the drying rates, enhanced the moisture diffusivity and consequently reduced the total energy consumption and drying time of lemon slices as compared to conventional heat pump drying method. In terms of product quality, it appears that CF-HP drying is a highly recommended drying method for the preservation of antioxidants.

### Abstract

*Jaboticaba (Plinia cauliflora) is a Brazilian fruit with a high content of anthocyanins compounds. Peel corresponds to 30 % of the fruit weight and it is considered a residue since just the pulp is used. The aim of this work was to analyze the convective drying process of the jaboticaba peels. Moisture content of dried peels showed a range of 7.17 to 13.26 (% w.b.). The results also reported that jaboticaba peels have high anthocyanins content (fresh:  $1162.99 \pm 41.35$  mg/100g d.b) and it was possible to maintain these compounds even after the drying process (1052 to 1270 mg/100g d.b).*

**Keywords:** jaboticaba; peel; drying; residue; anthocyanins.

---

## 1. Introduction

Jaboticaba (*Plinia cauliflora*) is a Brazilian fruit, with color dark blue purple characteristic of the peel[1]. This seasonal fruit grow in the tree trunk and it can be found in Midwest and Southeast regions of the country at September to February. The peel corresponds about 30 % of the total fruit weight and is rich in anthocyanins and phenolics compounds that are natural antioxidants presented in fruits, vegetables and plants[2]. Anthocyanins provides color to the fruit and can be used as natural colorant in food, cosmetic and pharmaceutical products, however the temperature, light and oxygen influence on stability of this compounds[2]. They are considered natural antioxidants and can to provide health benefits when associated with human diet by reducing cardio vascular risk factors, abdominal aortic atherosclerosis[3]. Besides that, the peels are generally discarded as waste and only the pulp of fruit is used.

The high moisture content presents in jaboticaba peel require a treatment to storage. To conserve fruit and vegetables, facilitate the storage and the transportation, drying is an important unit operation that involves heat and mass transfer[4], considered one of the oldest methods of food preservation[5]. Without water, the microorganisms presents in the dried material can not to multiply[6]. Convection is possibly the most common mode of drying particulate or sheet-form or pasty solids. Heat is supplied by heated air or gas flowing over the surface of the solid. The surface of the material is exposed to air flow and the moisture content is removed by convection[7].

The aim of this work was to analyze the convective drying process of the jaboticaba peel and to determine the influence of air temperature (50 to 80 °C) and the air velocity (1 to 2 m/s) on the anthocyanins compounds.

## 2. Materials and Methods

Fresh jaboticaba (*Plinia cauliflora*) fruits were collected from a private farm located in São José do Cedro, Santa Catarina, Brazil (26° 27' 18'' S, 53° 29' 39'' W), in late September 2017. The peels were separated of the pulp and washed with running water. Subsequently, the peels were sanitized in a solution of sodium hypochlorite and stored in sealed opaque bags at - 18 °C until use. The moisture content of the samples was determined in triplicate using an oven at 105 °C for 24 h.

### 2.1 Extraction procedure and Anthocyanins compounds

The peels were milled using a analytic mixer (GEHAKA, A 11), after 1 g milled peels were added to 50 mL of an acidified ethanol solution (50 % v/v, pH=1) in erlenmeyers. The maceration extraction was performed in duplicate using a shaker (NOVA ÉTICA, 109-1) at 150 rpm for 1 h. After extraction process, the extract was filtered with vacuum pump using filter paper twice to obtain a better separation between the solid and the liquid phase.

To quantify the anthocyanins content presents in jaboticaba peels was used a modify Fuleki and Francis[8] method. The extract absorbances were determined in triplicate using a UV/VIS spectrophotometer (EQUILAM, 755B) at 520 nm and calculated by Equation 1. Results were expressed as milligrams of cyaniding 3-glucoside equivalents per 100 g of sample, majority anthocyanins presents on jaboticaba peel.

$$Ant \left( \frac{mg}{100 g_{w.b.}} \right) = \frac{Abs \cdot V_1 \cdot 1000}{w \cdot 982} \quad (1)$$

where *Abs* is the absorbance,  $V_1$  is the volume of total extract in mL, *w* is the weight of the sample in grams, 1000 the correction factor to result be expressed in 100 grams of sample and 982 is the coefficient of extinction (982 to mg of cyaniding 3-glucoside).

## 2.2 Drying experiments

The drying experiments were carried out in a convective hot-air dryer (EcoEducativo) (Fig. 1). The experimental system involved a fixed bed dryer. The air flow coming from the blower (a) was monitored by an psychrometer (b) and was heated by an electrical heater system (c). Measurements of air velocity were performed by an anemometer (f). In order to monitor the mass of jaboticaba peel samples during the drying experiments a digital balance ( $\pm 0.01$  g) (e) was used, connected with a tray in the drying chamber. 20 g of jaboticaba peels were distributed uniformly as a thin layer into the stainless steel tray (137 mm in diameter and 7 mm of high) and dried.

*Fig. 1 Drying system.*

An experimental design was performed, where the independent variables were the inlet air temperature ( $T_{air}$ ) and air velocity ( $v_{air}$ ). The anthocyanins content was analyzed as dependents variable. Drying time were fixed in 2 h to observe the anthocyanins degradation with temperature and air velocity. The drying curves ( $(M-M_e)/(M_o-M_e)$  as a function of time)

were obtained. The equilibrium moisture content was assumed as the final moisture content when the drying rate was practically null, at each drying condition.

### 3. Results and discussion

Fig. 2 shows (A) fresh jaboticaba peels (B) dried jaboticaba peels (80 °C; 1 m/s). It can be verified the shrinkage of samples due the fast water removal from the intercellular spaces[9] of the peel. Table 1 shows the results of final moisture content and anthocyanins content for dried samples.

Fig. 2 Fresh jaboticaba peels (A) and dried jaboticaba peels (B).

Table 1. Results of moisture and athocyanins contents.

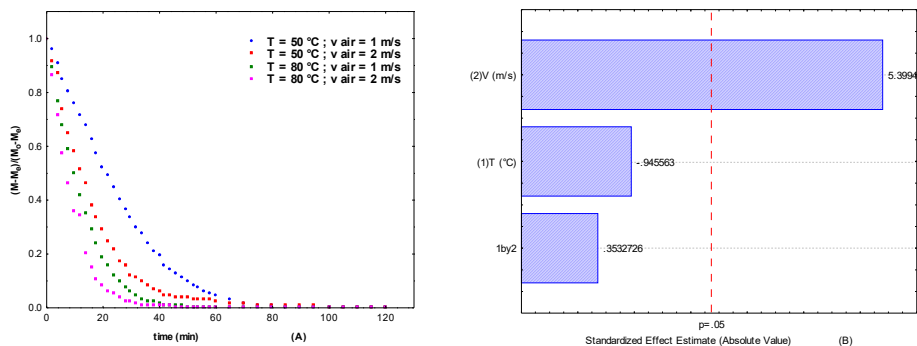

Runs	T (°C)	v <sub>air</sub> (m/s)	Moisture (w.b. %)*	Anthocyanins (mg/100g <sub>d.b.</sub> )*	Anthocyanins (mg/100g <sub>w.b.</sub> )
1	50	1	11.91 ± 0.26	1095.94 ± 10.82	965.34 ± 9.53

6	65	1,5	10.19 ± 0.89	1253.23 ± 39.19	1125.49 ± 35.20

\* avarage ± standard deviation

The fresh sample of jaboticaba peels showed a initial moisture content of  $76.74 \pm 0.71$  % (w.b.). The results for anthocyanins content was  $1162.99 \pm 41.35$  mg/100g (d.b.), which corresponds to  $267.71 \pm 6.88$  mg/100 g (w.b.). Garcia[10] reported results of anthocyanins content in jaboticaba peels between 310 and 315 mg/100g (w.b.).

Regarding the dried samples, the results of moisture content were in range of 7.17 and 13.26 % (w.b.). Flours in general must to have moisture content below 15 % [11] to inhibit the microbial growth, but there isn't a specific resolution to moisture content of jaboticaba peels. The anthocyanins contents were in the range of 1051.94 to 1269.88 mg/100 g (d.b.). Leite-Legatti et al. [12] reported 732.77 mg/100 g (w.b.) and Lima [13] found 1585 mg/100 g (w.b.) in freeze dried jaboticaba peels. Dried peels in present study showed anthocyanins content almost twice higher than Alves [14], that reported in theirs study that the anthocyanins content was 588 mg/100 g (d.b.) to samples dried at 60 °C. These differences could be due plant varieties, cultivation practices, environmental and geographical factors [13]. Higher results to anthocyanins compounds in some dried samples on the present study could be related with the formation of new antioxidants compounds. It was observed by Dewanto [15] for tomatoes. Freitas [16] also reported similar behavior with freeze dried butiá samples (pulp and peel), which showed an increase of anthocyanins compounds. Moreover, the moisture content in fresh samples can hamper the anthocyanins extraction. Also, the differences between anthocyanins for fresh and dried samples could be related with morphological changes in the structure of the cells during the drying process [17].

Typical drying curves obtained are illustrated in Fig. 3. Overall drying kinetic curves obtained for jaboticaba peels under different drying conditions showed the same behavior.

**Fig. 3 (A) Drying curves at 50 and 80 °C; (B) Pareto chart of standardized effects.**

As expected, an increase in air temperature and air velocity also significantly increased the drying kinetics and resulted in lower final moisture content. The presence of a constant-rate drying period to indicates that the moisture content is on the surface and the main heat transfer mechanism in this period is the convection. According to Geankoplis [6], the final moisture content decrease with the increase of the temperature. The difference of vapour pressure between the surface of the material and the hot air increase with the increasing of the temperature, decreasing the exposure time until the equilibrium. Moreover, higher temperatures increase the mass and heat transfer coefficients.

The results for the effects of operating variables on anthocyanins content obtained from statistical analysis are shown in the Pareto diagram (Fig. 3 (B)). It can be verified that only the effect of air velocity was significant for anthocyanins content at a confidence level of 95 % in the ranges studied. The results indicated that anthocyanins content can be maximized by increasing the air velocity from 1 to 2 m/s. It's inferred that in higher velocities there are the presence of vortices which help to increase the mass and heat transfer coefficients. These vortices are accentuated due the concave structure of the jaboticaba peel. The results indicated that the adequate drying condition is at 80 °C and 2 m/s, since it was the condition that showed lower drying time, and consequently represents a lower cost of the process.

#### **4. Conclusions**

The jaboticaba peel drying was analyzed in this study. The results showed that the samples had an inicial moisture content of 76.71 % (w.b.) and after the drying process the values were in range of 7.17 to 13.26 (% w.b.). Jaboticaba peels showed a high anthocyanins content, even after drying process. The drying process showed that the air temperature and air velocity had an influence on the increase of the drying rate and a reduction of the process time. The statistical analysis of the results showed that the air velocity was significant at a confidence level of 95 % for anthocyanins content. Jaboticaba peels are a residue that can be used as additive of flour in food industry since this material showed a high content of bioactive compounds.

### **Abstract**

*The pore structure is a decisive factor for the process efficiency and product quality of freeze dried products. In this work the two-dimensional ice crystal structure was investigated for maltodextrin solutions with different concentrations by a freeze drying microscope. The resulting drying kinetics was investigated for different pore structures. Additionally the three-dimensional pore structure of the freeze dried samples was measured by  $\mu$ -computed tomography and the pore size distribution was quantified by image analysis techniques. The two- and three-dimensional pore size distributions were compared and linked to the drying kinetics.*

**Keywords:** pore size distribution; freeze drying; maltodextrin solution; freeze drying microscope

---

## **1. Introduction**

Lyophilisation or freeze drying is commonly applied to stabilize (bio-)pharmaceutical substances and high value foods for long-term storage. During drying, the thickness of the dried layer is steadily increasing. Therefore, the mass transfer resistance becomes the dominating factor causing very long process times [1]. The mass transfer resistance is directly linked to the pore structure of the frozen solution. The pore structure is also important for the freeze drying of particulate matter as it determines the intra-particle mass transfer resistance and process efficiency. Furthermore, collapse phenomena are directly linked to the pore structure as the pore structure determines the maximum product temperature. The pore structure is determined by the freezing process prior to sublimation and is depending on cooling rate, nucleation temperature and solid content of the solution [2].

The pore structure is the decisive factor for the formation of the drying front of both particulate systems and frozen liquids. Therefore it is the aim of this work to investigate the influence of the process parameters cooling rate, annealing treatment and solid concentration on the pore size distribution of maltodextrin solutions as model systems.

Regarding the quantitative evaluation of pore size distribution it has to be distinguished between the evaluation of the frozen system and the dried system. In most cases it is assumed that no shrinkage occurs during freeze drying and the pore size of the frozen system is not different to the dried system. For frozen systems the ice crystal size distribution is mostly determined from sliced frozen samples by light microscopic techniques or Cryo-SEM [3]. In dried systems, mostly SEM and more recently  $\mu$ -computed tomography are used for the evaluation of pore structure of freeze dried products [4, 5]. The aim of this work is to compare the two-dimensional ice crystal structure as observed in a freeze drying microscope with the three-dimensional pore structure measured by  $\mu$ -computed tomography ( $\mu$ -CT) and to link the pore structure to the drying kinetics.

## **2. Materials and Methods**

Maltodextrin solution (DE 10-14 from medesign I.C. GmbH) was used as model substance. Solutions of maltodextrin were prepared by using bi-distilled water with the following concentrations: 5%, 10% and 20% (w/w).

### **2.1 Freeze drying microscope**

The controlled cooling of the solutions was carried out with the cryostage FDCS196 (Linkam Instruments, Tadworth, UK) coupled to an Olympus BX51 polarized light microscope (Olympus Microscopy, Essex, UK) equipped with a Pixelink PL-A662 camera (Pixelink, Rochester, USA). A quantity of 10  $\mu$ l of the sample was loaded into a 15 mm

diameter quartz glass crucible, which was placed on a silver block in the stage. The controlled temperature ranged between  $-196^{\circ}\text{C}$  to  $125^{\circ}\text{C}$ . The sample was enclosed by a spacer to achieve a uniform thickness of  $690\ \mu\text{m}$ . Thus the sample forms a cylindrical disk with a diameter of  $4.3\ \text{mm}$  and a height of  $690\ \mu\text{m}$ . Temperature was measured using a Pt100 temperature sensor from Linkam Instruments (accuracy  $\pm 0.1^{\circ}\text{C}$ ). By calibrating the 20x magnification lens (LMPlan Fl 20x/0.40) with a scale, the lengths and dimensions of the microscopic images were calculated using Linksys32 software.

## 2.2 Freezing and drying experiments and microscopic image analysis

After placing the liquid sample onto the quartz crucible, the stage was sealed and all samples were cooled to  $-50^{\circ}\text{C}$  at a defined cooling rate. Two different cooling rates were investigated:  $0.5\ \text{K/min}$  and  $20\ \text{K/min}$ . Furthermore two annealing treatments were investigated: In Treatment I the sample was heated to  $-10^{\circ}\text{C}$  for 90 min after freezing and cooled back to  $-50^{\circ}\text{C}$ . In treatment II the sample was heated to  $-5^{\circ}\text{C}$  after freezing for 180 min and cooled back to  $-50^{\circ}\text{C}$ . After reaching  $-50^{\circ}\text{C}$ , pictures were taken to evaluate the two-dimensional ice-crystal size distribution of the frozen samples. The subsequent drying step was carried out with a shelf temperature of  $-18^{\circ}\text{C}$  and a pressure of  $10\ \text{Pa}$  for all freezing protocols. During drying, a picture was taken every 10 s. As soon as primary drying was finished which was determined by the disappearance of the drying front, the silver block was heated to  $30^{\circ}\text{C}$  and the secondary drying was carried out overnight until a final water content of approx. 2% was achieved. The samples were then taken out of the cryostage and stored in a desiccator until further evaluation of the dry pore structure by  $\mu\text{-CT}$ .

For the evaluation of the ice crystal size, the software Linksys 32 was used. Three pictures of each sample were taken and 100 ice crystals were manually analysed per picture. The ice crystals were analysed by edging the ice crystals. From the ice crystal contour the equivalent diameter  $x_{pm}$  of a sphere with equal area of projection was obtained.

## 2.3 $\mu\text{-CT}$ measurements and image analysis

The samples that were evaluated for ice crystal size and drying kinetics, were taken for the  $\mu\text{-CT}$  analysis as well. Three-dimensional X-ray  $\mu\text{-CT}$  scans were performed using the XCT1600 system from Nordson Matrix Technologies GmbH (Feldkirchen, Germany). The cylindrical freeze-dried cakes from the freeze drying microscope were cut with a razor knife to prepare cuboid pieces (length and width about  $2\ \text{mm}$ ) out of the center of the dried solids. The imaging system was adjusted to operate at a tube voltage of  $60\ \text{kV}$  and current intensity of  $20\ \mu\text{A}$ . X-ray shadow images were acquired with a pixel resolution of  $1\ \mu\text{m}$  and 2000 projections with an exposure time of  $4487\ \text{ms}$ . The obtained images were reconstructed into a series of 2-D images using the CERA Xplorer software (Siemens

Healthcare GmbH, Erlangen). The resulting 3-D images consisted of more than 2000 slices encoded in 16-bit precision.

Image processing and analysis were done with MAVI Fraunhofer ITWM software (Fraunhofer Institute for Industrial Mathematics, Kaiserslautern). Fig. 2 shows part of the image analysis steps performed with MAVI. First, the original data set was cropped into three cubic sub-volumes of  $400 \times 400 \times 400$  voxels equivalent to  $400 \times 400 \times 400 \mu\text{m}^3$  (Fig. 2a). Afterwards, a global threshold was defined to separate pores and solid. The global threshold was adjusted to the water content in the solutions; i.e. 0.8 for the 20% solution, 0.9 for the 10% solution and 0.95 for the 5% solution. After transformation of the greyscale into binary images (Fig. 2b), a Euclidean distance transformation was carried out, which created a distance map by assigning each background voxel a grey value based on the distance to the closest foreground voxel (Fig. 2c). Thereby, local minima were identified. To avoid oversegmentation of pore structure, a h-minima transformation was then performed with a global  $h = 10$ . This value was chosen by comparison of the results with the two-dimensional ice-crystal structure (see section 3.1). Subsequently, the individual pores were segmented using the watershed segmentation method. All remaining regional minima served as water sources for the flooding. The lines where water from different basins met were identified as the watershed lines. Separated cells were produced from the logical difference between the watershed lines and the initial binary image (Fig. 2d). Finally, the object features tool of MAVI was used to obtain the volume of the individual pores. The equivalent pore diameter values were determined by calculating the diameters of spheres corresponding to the pore volumes. Therefore the equivalent diameter  $x_v$  of a sphere with the same volume was determined.

*Fig. 2. Illustration of all steps performed for the image analysis with MAVI: 3D image of cubic sub-volumes of  $400 \times 400 \times 400$  voxels (a), binarized image (b), distance map after Euclidean distance transform (c), watershed image (d)*

## 2.4 Evaluation of drying rate

After keeping the sample at  $-50^\circ\text{C}$  for 15 min the pressure was decreased by a rotary vane pump to 10 Pa. Then the samples were heated to  $-18^\circ\text{C}$  at a rate of 3 K/min. Due to the cylindrical geometry of the sample, the drying proceeded in radial direction. As the dried part of the sample appears much darker than the frozen part, the radial drying front could be

easily visualized. The distance between edge of the sample ( $R_0$ ) and the drying front over time  $r(t)$  was measured at three positions every minute. From the movement of the drying front  $\Delta r$  the drying rate was calculated.

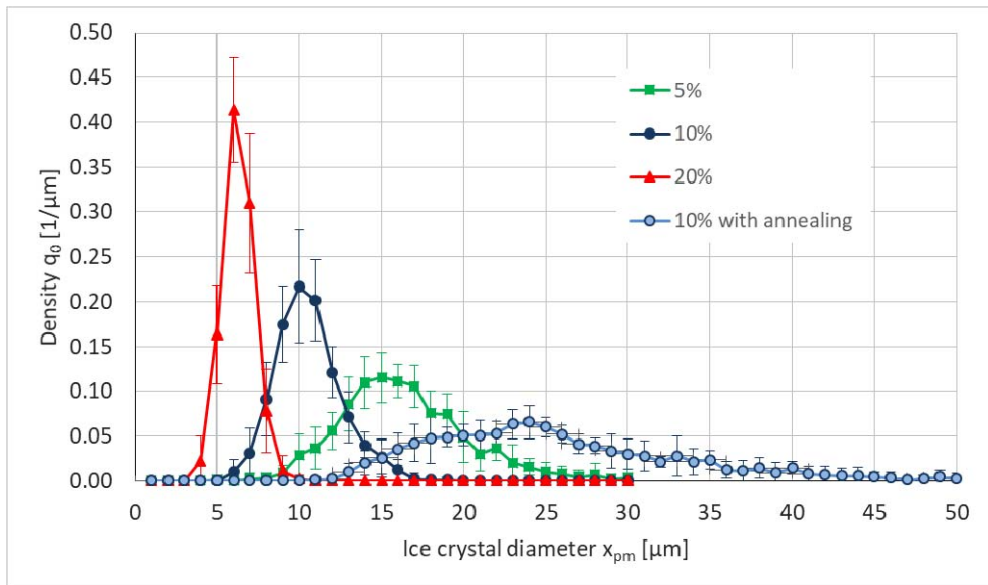

$$\dot{m} = \frac{\rho_{ice} 2\pi r h \varepsilon \Delta r}{\Delta t} \tag{1}$$

Here,  $\rho_{ice}$  is the density of ice at the sublimation temperature,  $r$  is the radius of the sublimation front,  $h$  the height of the sample (690  $\mu\text{m}$ ),  $\varepsilon$  the porosity and  $\Delta r/\Delta t$  the change in sublimation front distance.

### 3. Results

#### 3.1 2D ice crystal structure

At first, the two-dimensional ice-crystal size distribution was evaluated for the different freezing protocols and solid concentrations. Fig. 3 shows the two-dimensional ice crystal size distribution for three different solid concentrations with and without annealing treatment.

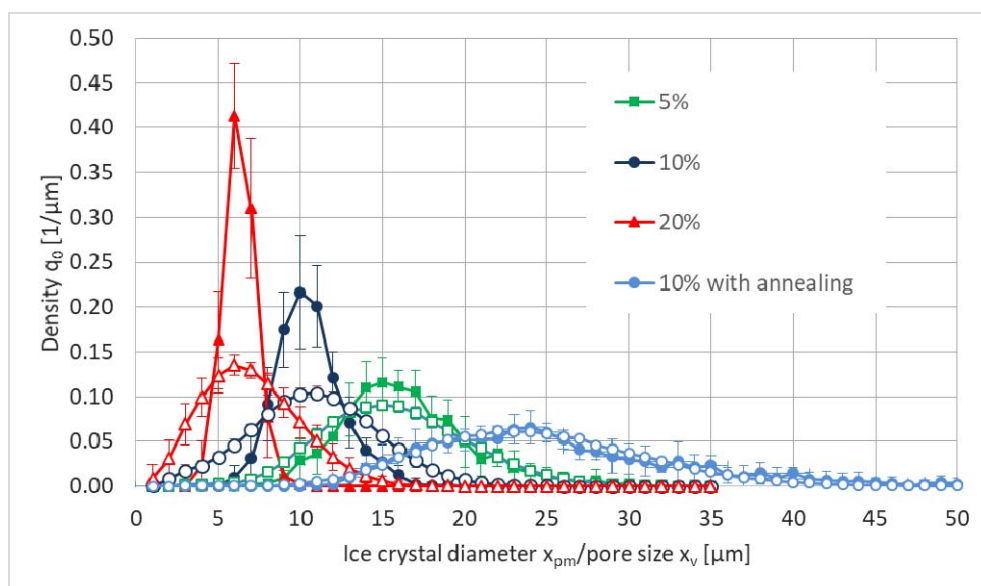

**Fig. 3. Ice crystal diameter for frozen maltodextrin solutions at -50°C for different solid contents. Freezing was carried out with a cooling rate of 20 K/min. For the 10% solution, the ice crystal size distribution for annealing treatment II (-5°C/180min) is also shown**

It was found that the freezing rate had no significant influence on ice crystal size distribution (data not shown), but an annealing treatment above  $T_g$  (annealing treatment II) led to a much broader and coarser ice crystal size whereas the annealing treatment I had no influence on ice crystal size (data not shown). Next to the annealing treatment, the solid concentration had the largest impact on ice crystal size. Fig. 3 shows that the lowest solid concentration (5%) leads to the largest ice crystal diameters and also to the broadest distribution.

### 3.2 3D pore structure

The cylindrical disks prepared in the freeze drying microscope were further dried until about a water content of 2%. From the dried samples, a  $\mu$ -CT image with a resolution of 1  $\mu\text{m}$  was taken in order to evaluate the three-dimensional pore structure. As indicated in section 2.3, a h-minima transformation was performed to avoid oversegmentation. The h value is therefore a free parameter. The parameter h was chosen such that the modes of the 2D and 3D distribution coincide. The comparison between 2D ice crystal diameter  $x_{pm}$  and 3D for the different freezing protocols and solid contents is shown in Fig. 4.

**Fig. 4. Comparison between 2D and 3D Structure. Density distribution of ice crystal sizes (filled symbols) in comparison to pore sizes of dried cake (empty symbols) for different solid contents (freezing rate 20 K/min) and annealing treatment**

Fig. 4 shows that the discrepancy between 2D ice crystal size and 3D pore size becomes smaller with increasing pore size. The reason could be that the resolution limit in the light microscope is higher than in the  $\mu$ -CT and therefore the larger sizes match better. As both

measurements refer to different equivalent diameters, another reason could be that the shape of the pores is dependent on size and that small pores are less spherical. This issue has to be investigated in more detail in future. At last we were interested in the effect of pore structure on drying kinetics. For that we investigated the relationship between mean ice crystal size (modal value) and maximum drying rate as well as drying time. This correlation is shown in Fig. 5. An exponential relationship was found showing the high importance of pore size on drying kinetics.

Fig. 5.: Correlation between mean ice crystal diameter and maximum drying rate and total drying time.

#### 4 Conclusions

The work shows the high importance of pore size distribution for the freeze drying process. It was shown that it is possible to evaluate the three-dimensional pore structure with  $\mu$ -computed tomography and image analysis and that the pore size is strongly dependent on the solid concentration and on an annealing treatment prior to drying. This means that it is possible to design the pore structure to meet the requirements of the freeze drying process. The work shows the applicability of the  $\mu$ -CT measurement of pore size distribution and shows that for small pore sizes there is a discrepancy between two- and three-dimensional pore size. This relationship has to be investigated further.

## 5 Nomenclature

$x_{pm}$	diameter of sphere with same mean area of projection	m
$x_v$	diameter of sphere with same volume	m
$h$	height	m
$R$	radius of sample	m
$r$	radius of sublimation front	m
$q_0$	density distribution	$\mu\text{m}^{-1}$

### Greek letters

$\varepsilon$	porosity	-
$\rho$	density	$\text{kgm}^{-3}$

### Subscripts

ice	ice
0	initial

---

### ***Abstract***

*This paper concerns hybrid drying of kale. Eight different schedules of drying were tested experimentally to find out the influence of microwave enhancement on the kinetics (drying rate and time), energy consumption of convective drying and quality of products. Different power of microwaves and modes of microwave application were tested. Quality of products was assessed through water activity and colour measurements, as well as retention of ascorbic acid. The results obtained in the studies allowed to state that intermittent application of high-power microwave pulses may lead to a meaningful reduction of drying time and high quality of the dry products.*

***Keywords:*** hybrid drying; intermittent drying; kale; ascorbic acid; colour

## 1. Introduction

Kale (*Brassica oleracea* L. var. *sabellica* L.) is a common vegetable consumed in many countries, mainly in soups and salads. It may be described as a green headless leafy cabbage with long petioles and large midribbed leaves. Kale is recognized as a valuable source of many vitamins and nutrients. Moreover, kale is an excellent dietary source of natural antioxidants. Beneficial properties of Brassica vegetables have been attributed to the presence of bioactive compounds such as phenolic compounds and ascorbic acid, associated with a reduced risk of cardiovascular diseases and several types of cancer.<sup>[1]</sup>

Refrigeration and freezing are the easiest methods of food preservation. Regrettably, chilling of the raw material maintains acceptable characteristics only for a few days. On the other hand, freezing may cause significant sensory quality degradation. Besides, both refrigeration and freezing require a lot of energy which may not be accessible, especially in undeveloped countries. Drying is another method of food preservation. It is easier and less demanding in terms of apparatus construction. Ultimately, natural sun drying may be realized without any apparatus just with the use of solar radiation. Usually however, food products are dried by forced convection (with hot air) using various dryer designs (cabinet, tunnel, chamber, drum etc.).<sup>[2]</sup>

Unluckily, food processing may have both beneficial and detrimental effects on the phytochemicals in vegetables.<sup>[3]</sup> Drying operation is usually accompanied by physical, biological and chemical changes, which influence the product quality, and finally the consumer choice. The main effect of drying is related with degradation of heat-sensitive phytochemicals, such as vitamins, antioxidants, minerals, pigments and other bioactive compounds.<sup>[4]</sup> For these reasons, new drying technologies are sought to minimize the detrimental influence of this processing method on the products quality. The aim of this research was to analyse the influence of intermittent application of microwaves during convective drying on process kinetics, energy consumption and quality of products. Different modes of microwave enhancement and a changeable power of radiation were tested experimentally to determine their influence on the analysed parameters.

## 2. Materials and Methods

Fresh kale (*Brassica oleracea* L. var. *sabellica* L.) was bought on a local market and stored for at least 24 h under refrigeration at 4°C. Before drying, 500 g of raw material was rinsed and cut into smaller pieces. Next, the samples were dried in a hybrid rotary dryer<sup>[5]</sup> in eight different schedules (Table 1).

*Table 1. Description of the drying schedules.*

No.	Code	Description	T (°C)	v (m/s)	P <sub>mw</sub> (W)
1	CV	convective drying			0
2	CVMW1				100
3	CVMW2				200
4	CVMW3	microwave-assisted conv. drying			300
5	CVMW5		50	2	500
6	IT1				100-300
7	IT2	hybrid intermittent drying			300-100
8	IT3				1000

All the CVMW programs were realized in stationary conditions – constant application of microwaves during convective drying. For the IT1 and IT2 programs, the microwaves were also applied continuously, but the MW power was reduced (from 300 to 100 W in IT1) or increased (from 100 to 300 W in IT2) by 10 W for every 10 % of the weight loss. In the IT5 program, convection drying was supported periodically (for every 15 minutes) by high-power microwave impulses (1000 W) lasting 5 min each one. The effectiveness of drying schedule was assessed on the basis of its kinetics, energy consumption and product quality. The kinetics of particular process was analysed through comparison of drying curves – the evolution of moisture ratio (MR) in time, and the average values of drying time (DT) and rate (DR). The moisture ratio (MR) was designated by the following equation:

$$MR = \frac{MC_t - MC_{eq}}{MC_i - MC_{eq}} \quad (1)$$

where  $MC_i$ ,  $MC_t$ , and  $MC_{eq}$  are the initial, instantaneous (for a given time of the process) and equilibrium moisture contents.

The initial moisture content ( $MC_i$ ) of the material was determined with a moisture analyser (XM120; Precisa, Switzerland; precision 0.01%). The equilibrium moisture content ( $MC_{eq}$ ) was assumed constant during the research and equalled 0.05. The moisture content at a given time of the process ( $MC_t$ ) was expressed as the ratio of moisture mass to the initial mass of the wet sample. Energy consumption was measured with a standard electricity meter (precision 0.01 kWh) and recalculated to the MJ per gram of evaporated moisture (EC).

The product quality was assessed on the basis of colour, water activity, and ascorbic acid measurements. The colour of the fresh or dry material was measured with the use of colorimeter (CR400; Konica Minolta, Japan; precision 0.01). On the basis of the obtained CIE Lab tristimulus colour coordinates ( $L^*$ ,  $a^*$ , and  $b^*$ ), a relative colour change parameter (dE) was determined by:

$$dE = (dL^{*2} + da^{*2} + db^{*2})^{0.5} \quad (2)$$

where  $dL^*$ ,  $da^*$  and  $db^*$  constitute differences between CIELab coordinates of fresh and dried samples.

Water activity ( $a_w$ ) was measured for both fresh and dried samples by using a laboratory meter (LabMaster-aw; Novasina, Switzerland; precision 0.001) at constant temperature of the chamber (25°C). Ascorbic acid content was determined by the modified method<sup>[6]</sup>, with the use of spectrophotometer (UV 5100; Hitachi, Japan; precision 0.01). The absorbance was measured at the wavelength of 734 nm, and next recalculated with the use of analytical curve. Next, the ascorbic acid loss (AL) was determined as:

$$AL = \left(1 - \frac{AC}{AC_0}\right) \cdot 100\% \quad (3)$$

where:  $AC_0$  and  $AC$  is the ascorbic acid content for fresh and processed sample, respectively.

### 3. Results and discussion

#### 3.1. Drying kinetics

In Figure 1, the evolution of moisture ratio (MR) and the average drying rate (DR) for particular drying processes are presented.

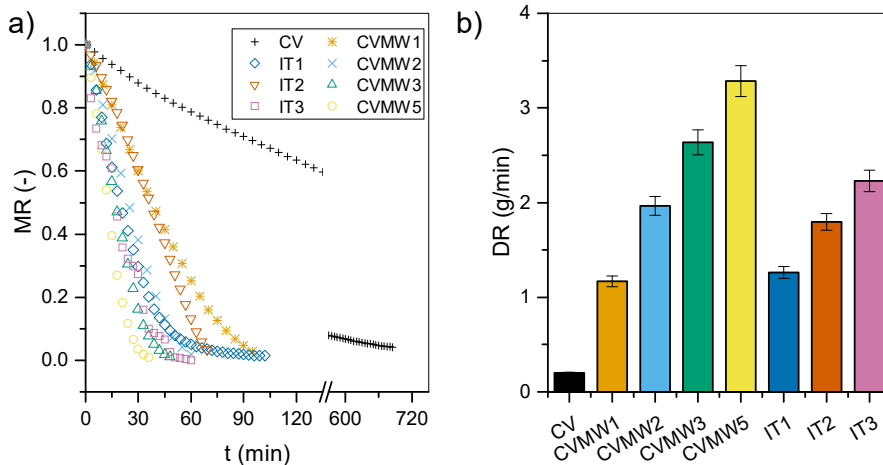

Fig. 1. a) evolution of the moisture ratio (MR) and b) average drying rate (DR) in particular drying processes.

Application of MW during stationary processes (CVMW1-5), visibly affected the kinetics of convective drying (Fig. 1a). The higher MW power the faster drying rate (Fig. 1b) and shorter drying process as a consequence (Fig. 2a). In case of intermittent processes (IT1-3) the DR diminished noticeably, but the drying time was still significantly shorter than for CV. A comparison of IT1 and IT2 allows to state that starting with a higher MW power at the beginning of intermittent drying is more efficient than gradually increasing of MW power. Both drying rate and drying time were better for the IT2 program, where MW power was reduced from 300 to 100 W by 10 W for every 10% of the weight loss. Application of pulsed high-power microwaves during IT3 program positively influenced the kinetics of CV. The drying rate was higher than in other nonstationary schedules and almost all stationary ones (Fig. 1b). It resulted in visibly shorter drying time (Fig. 2a).

Fig. 2. Average values of a) drying time (DT) and b) energy consumption (EC).

Figure 2b presents the average energy consumption for different drying schedules. One can see that application of microwaves during stationary (CVMW1-5) and nonstationary (IT1-3) processes affected the total energy consumption. The highest values of this parameter was observed for CV, whereas the lowest one for CVMW5. Such results stay in good agreement with other kinetic parameters (DR and DT). It also implies that microwaves effectively improved the drying process of kale. The ineffective interaction of microwaves causes a negligible decrease in drying time, which connected with a larger instantaneous consumption of electricity (than for a purely convective operation), results in an increase in the total energy consumption.

### 3.2. Quality of products

In Figure 3, the average values of water activity (aw) and ascorbic acid loss (AL) are presented, respectively.

Fig. 3. Average values of the: a) water activity ( $aw$ ) and b) ascorbic acid loss ( $AL$ ).

It is generally assumed that if the processed product is characterized by  $aw$  below 0.6 it can be acknowledged as stable in terms of microbiological safety.<sup>[7]</sup> All dry products obtained by different schemes were characterized by the  $aw$  below 0.4, which means that there is no microbial proliferation.<sup>[8]</sup> The analysis of the ascorbic acid loss (Fig. 3b) allows to state that all of the tested processes negatively affected retention of this valuable compound. The smallest leakage of ascorbic acid (below 10%) was observed for IT3, where high-power impulses of MW were applied. It may result from the relatively short duration of drying and a small increase in the sample temperature. During this process, microwaves were applied only for 5 minutes, and then a 15-minutes the so-called *relaxation period* was introduced. The main aim of application of the *relaxation period* was to ‘equalize’ the material after intensive microwave drying. During this period, the temperature of samples decreased and the humidity distribution becomes more aligned. It surely resulted in milder drying conditions in comparison to severe stationary microwave-assisted convective processes (CVMW). Nevertheless, the ascorbic acid content in products dried by hybrid methods was higher than for solely convective process (CV). A small retention of ascorbic acid surely results from significantly longer drying time. Only in case of CVMW1, where the weakest microwave enhancement was applied (100 W), the amount of ascorbic acid was similar to CV. Such result is quite unexpected and means that six-fold reduction in drying time did not affect the retention of the ascorbic acid present in dried products.

**Fig. 4. Average values of the relative colour change (dE).**

The last analysed parameter was colour of the dry products. Figure 4, shows the relative colour change (dE). It can be seen, that all drying procedures influenced significantly the colour of the obtained products. Change in colour is mainly attributed to chlorophyll and carotenoids degradation. Chlorophyll is highly susceptible to degradation during processing and storage, and depends on temperature, pH, time, enzyme, oxygen and light. Carotenoids have been proven to be more stable during thermal processing compared with chlorophylls, but may be isomerized and oxidized under the influence of heat, light and oxygen, and others.<sup>[9]</sup> As expected, the highest value of relative colour change (dE) was observed for CV, whereas the smallest values of this parameter were noticed for nonstationary processes, i.e. IT2 and IT3. It is a very positive effect because the reduction of MW radiation (in terms of both power and time) was aimed at this programs at the increase of the product quality. Interesting results were also observed for stationary schedules CVMW3 and CVMW5. Taking into account the progress of dE for CVMW1 and CVMW2, it was supposed to be higher for CVMW3 and CVMW5. Surprisingly, the value of dE decreased in these schedules which implies that colour of products depends on the drying time.

#### 4. Conclusions

The continuous application of microwave radiation positively influences the kinetics of convective drying. The higher power of microwaves causes faster drying, shorter duration of the process and lower energy consumption. Unfortunately, microwave-assisted convective drying may negatively affect the quality of products. It was found that application of low power microwaves (100 and 200 W) is not favourable in terms of colour and retention of ascorbic acid. The higher power of continuous microwave enhancement (300 and 500 W) allows preserving both colour and ascorbic acid to a greater degree.

Intermittent microwave-assisted drying can be an attractive alternative for both solely convective and stationary microwave-assisted convective processes. All kinetic and quality parameters attained values similar to those observed for stationary hybrid processes (CVMW). Additionally, it was found that the high-power microwave impulses very positively influence the retention of ascorbic acid.

### **Abstract**

*This study aimed to compare the agglomeration process of pea protein isolate (PPI) using water and aqueous gum Arabic solution as binder liquids. Drying air temperature and binder flow rate were set at 75 °C and 3.1 mL/min, respectively. Moisture content, mean particle size, wetting time and flowability were analyzed. Using water as binder liquid, the responses were (4.0 ± 0.4)%, 316.13 ± 16.73 μm, 10 s and free flow, respectively. Aqueous gum Arabic solution provided (2.9 ± 0.5)%, 462.67 ± 51.23 μm, 3 s and free flow as responses. Gum Arabic solution showed to be a more promising binder.*

**Keywords:** Agglomeration; Pulsed fluidized bed; Pea protein isolate; Wetting time; Flowability.

## **1. Introduction**

The food and pharmaceutical industries use fluid bed agglomeration to improve the physicochemical properties of powders, such as wettability, density, flowability and moisture content.<sup>[1,2]</sup> The improvement of these properties depends on the operating conditions, the properties of the raw material and the binder solution.<sup>[2]</sup>

Fluid bed agglomeration consists of atomizing a binder liquid in a fluidized bed of particles and is considered as successive humidification and drying operations.<sup>[3]</sup> First, the liquid is atomized into the particles generating liquid bridges; then hot air removes water by transforming the liquid bridges into solid bridges to form agglomerates.<sup>[4]</sup> This is a complex process because it depends not only on the characteristics of the particulate solid, but also on the operational parameters and properties of the binder solution.<sup>[5]</sup>

The pea exhibits high protein content, ranging from 23 to 33% depending on the species. In addition, it has a good nutritional value, being rich in essential amino acids, vitamins and minerals.<sup>[6,7]</sup> Pea protein isolate (PPI) has great potential as a substitute for soy protein in industrial processes. However, the powder produced by spray drying is cohesive rather than instantaneous, consisting of fine particles, limiting its use in the industrial process.<sup>[8]</sup>

The main factors to be considered in the fluidized bed agglomeration process are flow and concentration of the binder solution, atomization pressure, temperature and velocity of fluidization air and bed relative humidity.<sup>[5]</sup>

Thus, the objective of this work was to analyze the influence of binder solutions on the characteristics of agglomerated PPI in pulsed fluidized bed. At the end of the process, the improvement in the wetting time, flowability and particle size distribution of the agglomerated PPI were analyzed.

## **2. Materials and Methods**

### **2.1. Materials**

Samples containing 0.20 kg of a commercial PPI (CA Gramkow®, Brazil) were used as raw material for all the agglomeration experiments. The PPI contains 6.4% of moisture, above 80.0% of protein, 1.12% of fibers, 7.88% of lipids, 0.28% of carbohydrates and about 4.3% of others constituents. The particle size of raw PPI, measured by laser diffraction and represented by percentiles D10, D50 and D90, were 33.30, 81.0 and 181.92  $\mu\text{m}$ , respectively.

The binder solutions were water and aqueous gum Arabic solution, both at room temperature ( $\pm 27$  °C). The concentration of aqueous gum Arabic solution was 15% w/w; it was prepared by submitting gum Arabic (Nexira Brasil Comercial, Brazil) and distilled

water to magnetic stirring until complete dissolution of the binder, which was verified visually.

## 2.2. Equipment and process variables

Experiments were performed in a rotating pulsed fluidized bed (RPFb). Details of this equipment are described by Andreola et al.<sup>[9]</sup>

The following operational conditions were kept fixed: sample mass at 0.2 kg, nozzle height at 300 mm, pulsation frequency at 4 Hz, atomizing air pressure at 7.0 Psi and binder amount at 76 mL. The fluidizing air velocity, fluidizing air temperature and binder flow rate were set at 0,39 m/s, 75 °C and 3.1 mL/min, respectively. The operating conditions were selected based on preliminary experiments (data not shown) that were performed to obtain an agglomerated product in stable fluidization conditions. Experimental responses express the average of three replicates.

## 2.3. Moisture content, mean particle size and particle size distribution

The moisture content in the samples was determined by an infrared moisture analyzer (MB200, Ohaus Corporation, USA), that was previously calibrated according to the AOAC standard methodology.<sup>[10]</sup>

The mean particle diameters and particle size distributions of raw and agglomerated PPI were measured by Mastersize S (Malvern Instruments, Malvern, UK).

## 2.5. Wetting time and flowability

Wetting time was measured as the time required for 3 g of powder to disappear from the surface of water (80 mL at 27 °C) when the slider that separates the powder and liquid sections were removed.<sup>[11]</sup> The Hausner index (*HR*) was calculated from the bulk ( $\rho_b$ ) and tapped ( $\rho_t$ ) densities of the raw and agglomerated powder, as shown in Eq. (1).

$$HR = \frac{\rho_t}{\rho_b} \quad (1)$$

Classification of powder flowability based on the *HR* value is given in Table 1.<sup>[12]</sup>

**Table 1. Classification of powder flowability based on the Hausner index (*HR*)**

<b>HR</b>	<b>Flowability</b>
<1.2	Free
1.2-1.4	Intermediate
>1.4	Non-free

### **3. Results and discussion**

#### **3.1. Raw material and binders properties**

Commercial PPI shows density and mean diameter of  $1.2659 \pm 0.0035 \text{ g/cm}^3$  and  $81.00 \pm 0.61 \text{ }\mu\text{m}$ , respectively, and its fluidization behavior could be classified as pertaining to Geldart group A. Wetting time was over 300 s and *HR* was 1.3, classifying the flowability as intermediate. The large particle distribution is the main factor responsible for high wetting time and low flowability, because it provides more compacted bed, decreasing the porosity.<sup>[2,9,12]</sup>

Density, superficial tension and rheology of both liquid binders must be considered. Water presents density of  $1.00 \text{ g/cm}^3$ , superficial tension of  $7.2 \times 10^6 \text{ mN/m}$  and Newtonian behavior; while gum Arabic solution presents  $1.0522 \pm 0.0002$ ;  $47.35 \pm 0.69$  and pseudoplastic behavior, respectively.

#### **3.2. Process responses**

##### *3.2.1. Moisture content*

In agglomeration using water as liquid binder, moisture content reaches  $(4.0 \pm 0.4)\%$ , while with the use of gum Arabic solution, moisture content was  $(2.9 \pm 0.5)\%$ , after 24.5 min of atomization and 10 min of drying. For both cases, this parameter was at least 2% lower, getting at 3.5%, compared to the raw material.

Low moisture contents are important mainly for material storage. Temperature at  $75 \text{ }^\circ\text{C}$  is enough to promote water evaporation of the system, making the product drier. Binder flow rate at 3.1 mL/min also provide this type of product, whereas the binder wets the particles less and, when associated with temperature, its evaporation is more effective.<sup>[2,9]</sup>

Fig. 1. shows the relative humidity at bed exit. Although the same temperatures and flow rates were used for both conditions presented, the environment inside the bed remained moister, at least 20% higher, when the water was used as a binder. The fact that the gum Arabic solution has 15% solids, can produce this effect, since there is less water available.

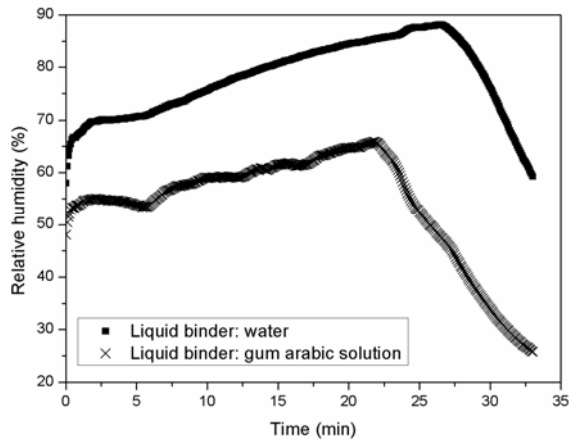

Fig. 1. Relative humidity at bed exit in relation to time.

3.2.2. Mean particle size and particle size distribution

Both liquid binders afforded agglomerated PPI with diameter larger than the initial size of raw PPI. To water as binder, particles increased 3.8 times, reaching  $316.1 \pm 16.7 \mu\text{m}$ , and when gum Arabic solution was used, the particle size reached  $462.7 \pm 51.3 \mu\text{m}$ , corresponding to a growth of 5.7 times. We also detected several particles with diameter higher than  $600 \mu\text{m}$ . The particle size distribution to raw and agglomerated PPI is presented in Fig. 2.

Fig. 2. Particle size distribution of raw and agglomerated PPI.

Agglomerated product also presented fines with diameter of less than  $50 \mu\text{m}$ , which represented approximately 19% and 24% to agglomeration process with water and gum

Arabic solution, respectively. These fines correspond to non-agglomerated particles and may originate from breaking of the agglomerates by friction within the moving bed.

### **3.3. Wetting time**

Compared with raw PPI, agglomerated PPI underwent faster wetting, even though the powders were not completely immersed into water. Agglomerated PPI achieved complete wetting in less than 10 s, to agglomeration with water, and 3 s, to gum Arabic solution which attests to its greater capacity to absorb moisture. It represents a decrease of 97% and 99% in wetting time, respectively.

The presence of fine particles allows for a more compact powder during storage, i. e., the smaller particles can penetrate into the spaces between the larger particles, so the product occupies less space.<sup>[11,13]</sup>

### **3.4. Flowability**

Agglomeration process with water furnished bed density ( $\rho_b$ ) of  $0.2579 \pm 0.0058 \text{ g/cm}^3$ , and compact bed density ( $\rho_t$ ) of  $0.2970 \pm 0.0070 \text{ g/cm}^3$ . Already for agglomeration for gum Arabic solution,  $\rho_b = 0.1640 \pm 0.0284 \text{ g/cm}^3$  and  $\rho_t = 0.1939 \pm 0.0284 \text{ g/cm}^3$ . The *HR* values obtained for agglomerated PPI were 1.15 and 1.18, classifying the product as free. Raw PPI consists of fine particles, which may confer the material a strong cohesive behavior, whereas agglomeration improves PPI flowability. Although the flowability of agglomerated PPI is not yet ideal, this product exhibited significantly better handling properties than raw PPI.

## **4. Conclusions**

The particle agglomeration of PPI occurs due to the pulverization of liquid binder on the surfaces of the particles, resulting in a wetted sticky surface and subsequent particle coalescence. On particle drying, the agglomerated structure consolidates, leading to particle enlargement.

Agglomeration of PPI using gum Arabic solution produced larger granules with high flowability and lower cohesiveness when compared to agglomeration with water and spray dried raw material. Additionally, size enlargement also resulted in an improvement of instant properties that was characterized by the higher wettability of the granules.

### **Abstract**

*Acacia gum is an important food emulsifier that presents poor instant properties which can be improved by fluidized bed agglomeration. This study investigated the influence of drying conditions on particle growth kinetics using an in-line particle size monitoring by spatial filter velocimetry. The drying conditions varied according to the binder flow rate and the fluidizing air temperature. The particle growth kinetics showed drying conditions dependence. At mild drying conditions the growth rate and the process yield were higher. The in-line particle size monitoring was useful to observe the influence of the drying conditions on the growth kinetics.*

**Keywords:** *fluidized bed agglomeration; acacia gum; particle growth kinetics; in-line monitoring.*

---

## **1. Introduction**

Acacia gum is a food additive that has several functions and it is mostly used as an emulsifier, for its effectiveness as a long time stabilizer on oil in water emulsions.<sup>[1]</sup> This gum can be used as a fiber food enricher and as a sucrose replacer, in food formulations, as it causes equivalent sensation in the mouth.<sup>[2,3]</sup> In addition, it stands out in the food additives market because it is natural, of vegetable origin and does not undergo chemical modifications.<sup>[4]</sup> The powdered acacia gum is a powder with fine particles, which is difficult to handle, and shows poor dispersion properties. However, the agglomeration process can improve its quality.<sup>[5]</sup>

The particles agglomeration process is used at the pharmaceutical and food industry to improve the characteristics of its powdered products and is often performed in fluidized beds since this equipment provides high rates of heat transfer.<sup>[6]</sup> Fluidized bed agglomeration process involves the particles fluidization by hot air flow and liquid binder atomization onto these particles. The hot air flow is also responsible for the binder evaporation, causing the particles drying and granules to consolidate. The fluidized bed agglomeration is a complex process, that can be influenced by several process parameters like the binder kind and flow, the fluidizing air temperature, and the binder atomization pressure.<sup>[7,8]</sup>

The agglomeration kinetics knowledge is important since the particle size growth is the goal of agglomeration processes. The spatial filter velocimetry (SFV) is an in-line particle size monitoring that provides the granule growth and breakage as a function of granulation time by the measurement of the particle chord lengths. This technique is a new method and has been used successfully in recent studies.<sup>[9,10,11]</sup> The SFV particle size monitoring can improve the knowledge about what favors particle size increase or its breakage providing important information to the granulation kinetics study.

There are not many experimental studies about food agglomeration kinetics. This work presents a study about powdered acacia gum agglomeration kinetics. The particle growth rate was monitored by in-line particle size monitoring using a spatial filter velocimetry probe for different drying conditions.

## **2. Materials and Methods**

### **2.1. Materials**

Spray dried acacia gum (Spraygum BB - Nexira Brasil Comercial) was used as raw material for the agglomeration experiments. The acacia gum wet basis moisture content ( $X_{w.b.}$ ) is less than 10.0%. The binder solution was distilled water at room temperature ( $\pm 27$  °C).

### **2.2. Characterization of raw and agglomerated acacia gum**

Characterization of raw and agglomerated acacia gum were done based on the median particle size ( $D50$ ), powder flow characteristics, wetting time ( $t_w$ ) and  $X_{w.b.}$ . The raw material

particle size was measured by *SFV* probe as described above and also by laser diffraction (Mastersizer 3000, MAZ3000 Malvern Instruments, Malvern, UK). Powder flow characteristics were determined by the Carr index (*ICarr*) values, as described by Turchiuli et al.<sup>[12]</sup> The  $t_w$ , was the time required for the complete wetting and immersion of 3.0 g of the sample in 70 ml of water at room temperature.<sup>[13]</sup>  $X_{w.b.}$  was measured for the raw material, at the end of the binder atomization and at the end of the drying using a halogen moisture analyzer (HR83, Mettler Toledo).

### 2.3. Equipment and agglomeration process

The agglomeration experiments were run in a lab-scale fluidized bed. The fluidized bed chamber had a conical base constructed from transparent acrylic Plexiglas®. The bed pressure drop, the air temperature, and the air relative humidity were monitored and recorded by a data acquisition system and processed in the LabVIEW 8.6™ software. Details of the equipment and the data acquisition system are described by Andreola et al.<sup>[14]</sup> However, in this study, the equipment was operated without air pulsation.

Three different agglomeration conditions were performed, in triplicate, to evaluate the influence of drying conditions on growth kinetics and particle growth rate of powdered acacia gum. The process parameters that varied were the binder flow rate ( $Q$ ) and fluidizing air temperature ( $T_{air}$ ) in the following way: condition 1 (E1), 1.5 mL/min and 85 °C; condition 2 (E2), 2.3 mL/min and 75 °C and condition 3 (E3), 3.0 and 65 °C. The sample mass, initial fluidizing air velocity, the volume of binder, atomization air pressure and atomization nozzle height were kept constant at 0.4 kg, 0.28 m/s, 80 mL, 6.7 psi and 0.35 m, respectively. The increase in fluidizing air velocity was necessary to maintain a stable fluidization, it was increased (step 0.03 m/s) every 5 min until 0.43 m/s.

The process time was different once the binder volume was fixed and the process was carried out until the agglomerated moisture content reached a lower or equal value than that one of the raw material. The E1 had not a drying period and E2 and E3 had an 8 minutes drying period time.

### 2.4. Process yield

The process yield (*Yld*, %) was determined based on the initial sample mass ( $m_{initial}$ ) and the final product ( $m_{final}$ ) by the Eq. 1. The  $m_{final}$  was obtained discounting particles larger than 850  $\mu\text{m}$ , separated by sieving, from the product mass remained at the end of the experiments. The mean process yield, for each experimental condition, was calculated and a statistical analysis was made by Tukey's test, at a confidence level of 90% ( $p < 0.10$ ).

$$Y = \frac{m_f}{m_i} \cdot 100 \quad (1)$$

## 2.5. In-line particle size measurement and granule growth rate

The in-line particle size was monitored by Parsum IPP70 probe (Chemnitz, Germany) that employs the SFV principle to measure the “chord” (size) of the particles. Details of the equipment, its accessories and methodology were described by Silva and Taranto.<sup>[10]</sup> For further analysis of the growth rate of the particle time dependence, an appropriate software, Inline Particle Probe 7.14, obtained the particle size data and sent it to LabVIEW<sup>TM</sup> 8.6 software via OPC server protocol, this procedure was developed by Silva and Taranto.<sup>[10]</sup> This system record the particle size and size distribution every 5.12 seconds. The ring buffer size used in the Parsum measurements, 5000 particles, was chosen according to preliminary tests performed (not shown). The median particle size in volume ( $D50v$ ) was evaluated and the last ten measurements for each run were used to calculate the mean  $D50v$  of the agglomerated. The agglomerated  $D50v$  for the three experimental condition was compared by Tukey’s test, at a confidence level of 90% ( $p < 0.10$ ).

The granule growth rate ( $R$ ) was calculated as defined by (Eq 2).<sup>[15]</sup> Its value was calculated for each period of 1.7 minutes, that means that  $d_i$  was the  $D50v$  at the initial time and  $d_f$  was the  $D50v$  reported approximately 1.7 minutes after the  $d_i$  report.

$$R(\%) = \frac{(d_f - d_i)}{d_i} \cdot 100 \quad (2)$$

## 3. Results and discussion

### 3.1. Characterization of raw and agglomerated acacia gum

The laser diffraction measurements for the raw material were  $D10$ :  $21.9 \pm 0.2 \mu\text{m}$ ,  $D50$ :  $65.2 \pm 1.0 \mu\text{m}$  and  $D90$ :  $143.6 \pm 2.0 \mu\text{m}$ . The values of  $D50v$  measured by SFV probe before the spray phase (approximately  $111.5 \mu\text{m}$ ) were higher than those obtained by laser diffraction, once the median size obtained by laser diffraction is close to the SFV probe measurement limit, i. e.,  $50 \mu\text{m}$ . However, the values of  $D90v$  measured by SFV probe (approximately  $154.0 \mu\text{m}$ ) were close to the off-line measurement, indicating that the probe measurements are reliable.

The final acacia gum powder  $D50v$  increased for all experimental conditions (Table 1). The largest increase in particle size occurred at mild drying conditions (E3). At more intense drying conditions the final particle size was smaller and the  $D50v$  was statistically equal for the conditions E1 and E2. Similar result was observed by Hirata et al.<sup>[16]</sup> for agglomeration of similar material using water as a binder. At mild drying conditions, the adhesion among particles is favored by the more wet and sticky surface. Milder conditions also favored higher process yield (Table 1). Under drier conditions (E1) the particle size was smaller and the process time is longer which resulted in larger material elutriation. This was also observed

during fluid bed agglomeration of rice protein concentrate, very fine particles, by Andreola et al.<sup>[14]</sup>

*Table 1: Experimental conditions and their results.*

Conditions	Q <sup>1</sup>	Tair <sup>2</sup>	D50v <sup>3</sup>	Y <sup>4</sup>	h <sub>out</sub> <sup>5</sup>	Flowability
Raw material	-	-	65.18±1.0			moderate
E1	1,5	85	270.7±19.6 <sup>a</sup>	50.4±6.0 <sup>a</sup>	34.9±2.7	moderate
E2	2,3	75	275.3±8.2 <sup>a</sup>	61.4±6.0 <sup>a,b</sup>	47.0±6.4	moderate
E3	3,0	65	285.7±13.7 <sup>b</sup>	64.3±6.0 <sup>b</sup>	53.4±8.2	moderate

<sup>1</sup>Binder flow rate (mL/min); <sup>2</sup>Fluidizing air temperature (°C); <sup>3</sup> Median particle size in volume (µm);

<sup>4</sup>Process yield (%) and <sup>5</sup>Mean relative humidity of the warm-moist air flowing out of the bed (%).

The agglomeration process presented different results concerning the handling properties, wetting time and flowability. All agglomeration conditions improved the acacia gum instant properties. The raw material did not get completely wetted even after 600 s, on the other hand the agglomerated were completely wetted in less than 5 s. Regarding to the flowability, agglomerated acacia gum was similar to the raw material (Table1).

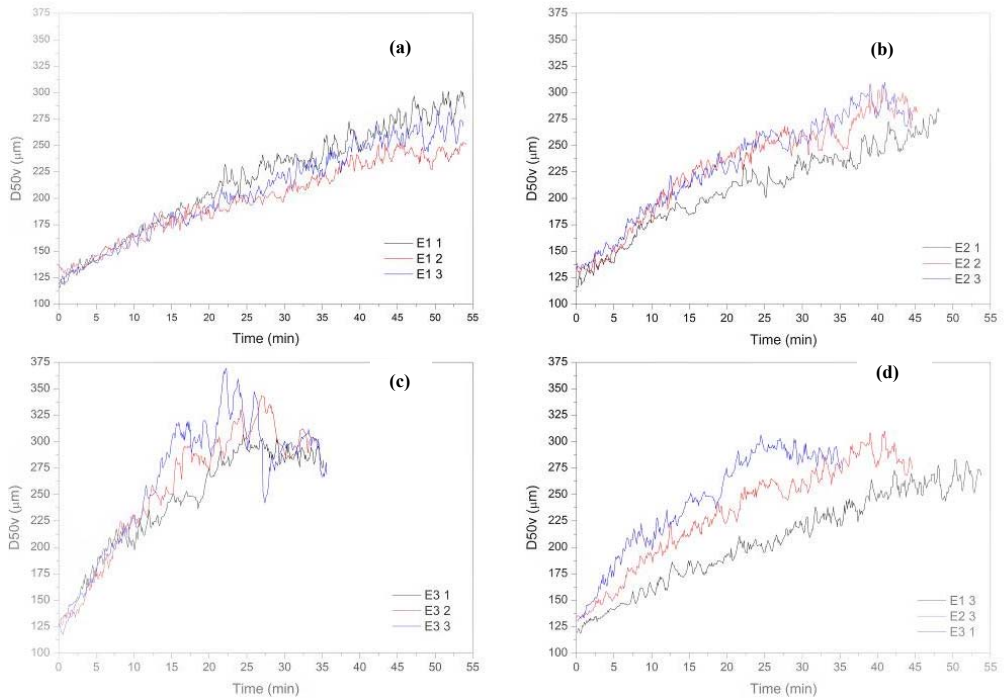

### 3.2. Particle growth rate

The triplicate of the granule growth kinetics for the different experimental conditions is presented in Fig. 1, it shows that there was reproducibility of the particle growth behavior for the process. Although the final particle size was similar for the three experimental condition, the particle growth behavior was different.

At condition E1, with more intense drying condition, the particle growth was almost continuous (Fig. 1(a)). However, the particle size enlargement was slower compared to the other two conditions (Fig. 1 (d)). At that condition, binder availability is smaller and consequently less liquid bridges were formed between the particles.

The particle growth rate (*R*) for the three experimental is presented in Fig. 2. The particle growth rate oscillated during the process showing that the particle size growth results from positive a balance from agglomeration and break.

The *R* for the E1 condition confirms a slower size enlargement presented since it presents the lowest mean value (Fig. 2). It oscillated around 2% during the process and presented few negative values that indicates an absence of particle breaking by attrition and collision. This is observed because in that condition a constant wetting occurred causing a continuous increasing of the particle size. In that condition, the fluidization was more vigorous which associated with the highest temperature and time of process could have contributed to form stronger and larger granules as observed by Andreola et al.<sup>[14]</sup>

**Figure 1: In-line D50v triplicate data for (a) E1, (b) E2, (c) E3. Comparative in-line D50v data for E1, E2 and E3 (d).**

The experimental condition E2 presented a larger particle growth at the beginning of the process that decreased with the binder spraying time (Fig. 1(b)). In that condition, the particle growth rate (Fig. 2) presented a smaller oscillation, compared to the other conditions, and a downward trajectory with the progress of the process. The particle growth rate presents some negative values, especially in the drying period, indicating that there were some breaking of particles by attrition and collision.

The milder drying condition E3 presented the higher particle growth at the beginning ( $R > 10\%$ , Fig. 2) that results in the largest particle size recorded ( $D50v > 350 \mu\text{m}$ ). However a decreasing at the D50v during the drying period was observed (Fig. 1(c)). The R for condition E3 had a higher oscillation and more expressive negative value in comparison to the condition E2. It is related to the fact that the wetter and larger granules are more susceptible to the broken down by attrition.<sup>[17]</sup> Under these conditions, the worst fluidization regime was observed due to the formation of large agglomerates, which may also have impaired the consolidation of the granules. In spite of the breaks, the final particle size was the largest of the three conditions.

Figure 2: Particle growth rate for the different experimental conditions.

#### 4. Conclusion

The fluidized bed agglomeration process improved the acacia gum powder instant properties. The in-line SFV particle size measurement made it possible to observe the growth rate of the particle. The operating conditions influenced both the particle final D50v and the behavior of the granule growth kinetics. The milder drying condition provided larger granules and higher yield in the process. However, it is interesting to analyze an intermediate condition between E2 and E3 for the production of larger and more stable granules.

### Abstract

*Hydrolyzed collagen (HC) is a fine powder applied in the pharmaceutical and food industries which has shown good results in the treatment of diseases related to bones, skin and joints. In this study, HC particles were agglomerated in order to increase particle size, optimizing its use as a food ingredient, its handling and its storage. Agglomeration is a process that not only enlarge the size of fine particles, but also improves its properties, such as instantanization time and flowability. The aim of this work was the agglomeration of HC in a fluidized bed having blackberry pulp as a liquid binder. A full factorial design 2<sup>2</sup> was used to study the effect of the temperature of the fluidizing air (60, 70, 80°C) and the flow rate of the liquid binder (0.8, 1.2, 1.6 mL/min) on the process yield, mean particle size, water activity and total anthocyanins content. It was observed that anthocyanins content from the blackberry pulp had higher values with lower temperatures. Water activity had lower values with higher temperatures, but in all conditions, it was lower than 0.6. The enlargement of the granules was observed in all conditions studied, increasing up to 275%. Process yield varied from 67,9 to 80,0%. In all conditions, the instantanization time and flowability improved compared to hydrolyzed collagen before agglomeration.*

## **1. Introduction**

Chronic non-communicable diseases (NCD) are responsible for almost 60% of the global mortality rate [1] and for 72% of the Brazilian mortality rate [2]. Chronic respiratory diseases, cardiovascular diseases and diabetes are examples of NCD, caused mainly by poor diet and physical inactivity. To change that, it is essential to increase the consumption of vegetables, fruits, cereals and replace foods rich in sodium or simple carbohydrates [2]. To contribute to the reversal of such a scenario, this work presents a feasible production method of agglomerated HC as an instant functional food and protein supplement rich in anthocyanins.

Agglomeration, also known as granulation, increases the size of particles, which then are called granules or agglomerates. This process is applied in the chemical, pharmaceutical and food industries to improve particle handling, storage and transportation, as well as particles' properties, such as flowability and instantanization time [3]. Regarding the food industry in particular, agglomeration enables the granules to achieve specific properties and size intervals [4].

The agglomeration process using a fluidized bed, although complex, shows many advantages, such as good heat and mass exchange and the performing of all steps of a given process in the same equipment [5]. The agglomeration process occurs when the particles are fluidized and dried by the heated air which is admitted through the bottom of the bed, while an atomization nozzle humidifies the particles with a binder.

This work aims to find the most suitable condition (binder flow rate and fluidizing air temperature) for the agglomeration of HC in a fluidized bed, using blackberry pulp as a binder in order to increase the particles' sizes, improve the particles' properties and add the nutritional benefits of blackberry pulp to the agglomerates. Collagen has been studied for over a century and its demand in the market only increases [6], because it is a protein product with amino acids that are essential to the human diet [7], which shows positive results in the treatment of diseases related to the bones, skin and joints [8, 9, 10]. Blackberry pulp, on the other hand, is rich in vitamins, iron and anthocyanins, which helps in the prevention of degenerative diseases such as cancer and diabetes [11].

## **2. Materials and Methods**

### **2.1 Equipment and process variables**

The lab-scale fluid bed (Fig. 1) used to perform the experiments has a cylindrical Plexiglas base and column (11). On top, there is a cyclone (13) to collect the elutriated fine particles. In the entrance of the bed, a perforated plate (10) distributes the air uniformly. The inlet air is supplied by a 7.5 HP WEG (2) air blower, delivered to the system by a 2" internal diameter galvanized steel pipe, and then passes through a bed of silica gel (5). The blower is connected

to a frequency inverter (2a) (WEG CFW 08). The air velocity was determined by a hot wire anemometer (IMPAC, Delta Ohm, HD2903TC2.2) (4).

**Fig 1. Experimental System**

The air temperature in the plenum chamber was adjusted by a set of electrical resistors (7) controlled by a PID regulator (Novus, N1100). Pt-100 Thermoresistances (Novus, Ø 3.0 mm x 100 mm) measure the temperature of the system in the plenum chamber (9a) and the other three points (9b, 9c and 9d) the column. Two sensors (6a and 6b) (RHT-XS, Novus) provide the values of relative humidity and dry bulb temperature at the input (before the resistors) and in the fluid bed output, controlled by a PID regulator (Novus, N1200). The pressure drop in the bed is provided by a differential transducer (Cole Parmer, XLDP) (8).

A peristaltic pump (15) (Cole Parmer, 7780-60, Masterflex L / S) carries blackberry pulp (14) used as a binder in the granulation process. A double fluid type spray nozzle (Spraying Systems, SU12A) produces a cone-shaped spray of droplets. The atomizing pressure for obtaining the droplets is provided by a compressor (MSV 40 Max, 10 horsepower) (1) and

regulated by a Norgren pressure regulator. This compressed air is filtered (16) (Parker, Hannifin Ltd.) before being used in the atomization.

The pressure, temperature and humidity sensors are connected to a computer, by a data acquisition system, which consists of a NI cDAQ-9172 (National Instrument) (17) board that collects the data at a defined sampling rate. LabVIEW 8.6TM (Virtual Instrument Engineering Workbench) software, by means of virtual instruments (VI), makes the interface between the process and the data acquisition board. The program was installed on an Intel® Core i5 computer with 4.0 GB of RAM (18).

## **2.2 Water Activity**

The water activity was measured by AQUALAB S3TE.

## **2.3 Particle Diameter**

The HC particles were observed using a digital microscope (Dino-Lite AM4515ZT) after being dispersed on several glass slides to obtain at least 500 particles. The images were analyzed using the software IMAGE J v1.50i (National Institutes of Health, USA), allowing the calculation of the particles mean diameters[12].

## **2.4 Anthocyanins Content**

The anthocyanins content was determined using the differential pH method [13].

## **2.5 Process Yield**

The process yield was calculated by the ratio of the mass of HC fed per the final mass in the fluid bed.

## **2.6 Instantanization time**

The instantanization time was considered the time required for 3 g of the sample to disappear from the water surface (60 mL at 27 °C), using an apparatus described by [14].

## **2.7 Flowability**

The flowability of raw and granulated HC was obtained using the Carr index (Table 1). The powder is submitted to 500, 750, or 1250 taps in the equipment Autotap Tap Density Analyzer (DAT-4, Quantachrome instruments®), following the standard 616 of the North American Pharmacopeia [15].

**Table 1. Classification of powder flowability based on the Carr index**

<b>Icarr (%)</b>	<b>Flowability</b>
< 15	Very Good
15-20	Good
20-35	Fair
35-45	Bad
> 45	Very Bad

## 2.8 Moisture Content

The humidity was determined by a Moisture Analyzer with halogen light heating (HR83, Mettler Toledo).

## 3. Results and Discussion

The yield was higher with the lowest binder flow rate and with the maximum or minimum temperature ( $T_f$ ) used, resulting in a surface plot with significant curvature (Fig 2-a). The biggest particles (275% bigger than raw HC) occurred with lower binder flow rate and temperature (Fig. 2-b), since in this condition the moisture content was lower. Partial defluidization was observed using higher values of binder flow rate, reducing the impact between particles and, therefore, their size, as also observed by [16]. As for the moisture content (Fig. 2-c), lower binder flow rate and higher temperature resulted in a minimum value of moisture content, as expected and observed by [16]. However, even at higher temperature, the binder flow rate had more impact in the moisture content, since higher values of  $Q_{lig}$  resulted in a moister agglomerated HC. The AT (dry basis) was higher when the temperature was minimum (Fig. 2-d), as the degradation of anthocyanins was minimum in this case.

Water activity was lower than raw HC and higher than Commercial HC (Table 2), and since all the values were  $aw < 0.6$ , microbial growth will not happen in the powder [17]. The instantanization time of agglomerated HC reduced considerably when compared to raw HC and Commercial HC because of the size and morphological changes in the particles, as observed by [17]. Therefore, the bigger the HC particles, the faster was the IT. Moreover, the flowability of agglomerated HC improved from Fair (raw HC) to Good or Very Good.

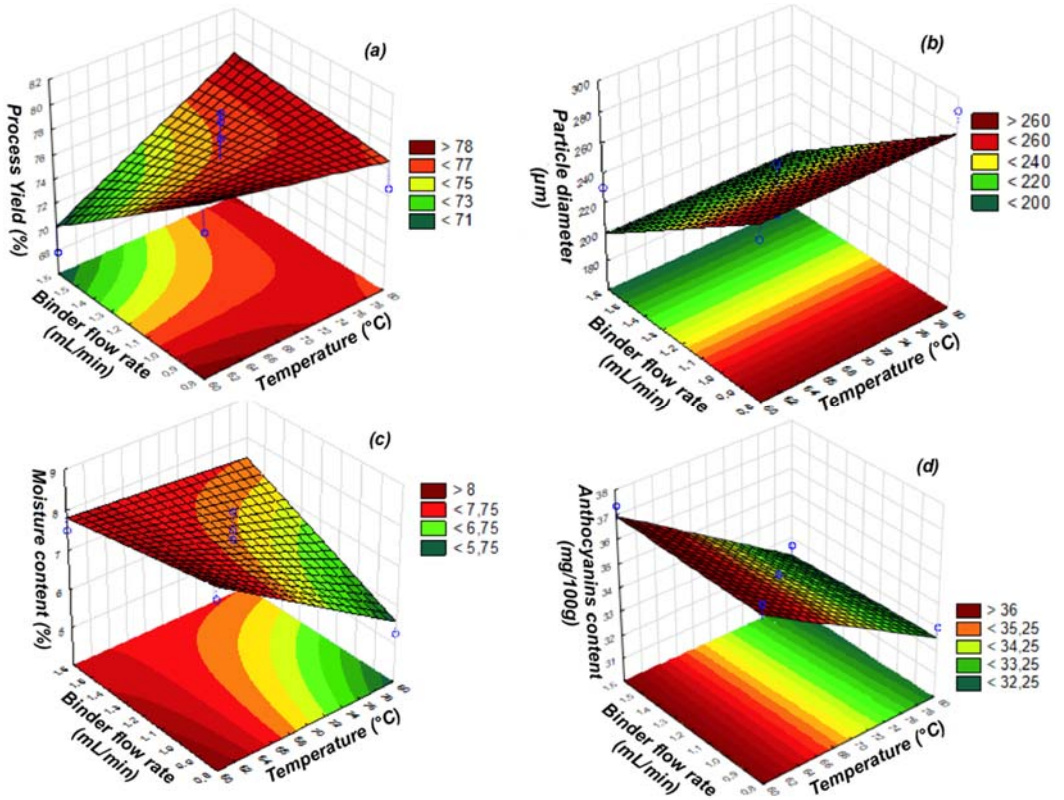

Fig 2. Surface plot of Process Yield, Particle diameter, Moisture content and Anthocyanins content versus Temperature and Binder flow rate.

Table 2. Results of the experimental design (nozzle height: 300 mm, mass of sample: 500g).

Experimental Run	$T_f$ (°C)	$Q_{lig}$ (mL/min)	Yld (%)	Mst (% d.b.)	$d_{pm}$ (µm)	AT (mg/100g)	IT (s)	$a_w$	Icarr (%)
HC	-	-	-	7.45	96.96	-	170	0.490	22.18
1	80 (1)	1.6 (1)	76.2	7.17	172.03	32.67	2.2	0.396	17.39

7	60 (-1)	0.8 (-1)	77.8	8.24	266.64	37.31	1.85	0.430	13.51
Commercial HC <sup>1</sup>	-	-	-	8.15	198.2	-	9	0.404	16.52

<sup>1</sup> Commercial Agglomerated HC already sold in market (Commercial HC - GELITA)

## 4. Conclusions

The central points (tests 4, 5 and 6) presented the best overall results: they presented bigger particles than the ones of Commercial HC, an increase of more than 200% compared to raw HC. In those tests, the process yield was, in average, 79.1%. The moisture content values had an average of 7.78%, lower than that of the Commercial HC. The AT content values were low in all the tests and further studies are needed to reduce the degradation of anthocyanins by light and high temperature. The water activity values were in a range that assures product safety for all the tests and the instantanization time decreased in relation to raw HC and Commercial HC. Thus, we produced a powder larger in size, with adequate moisture and process yield, which can be commercialized or used as an ingredient rich in anthocyanins.

### **Abstract**

*The studies present convective drying of parsley with an intermittent microwave application. Eight different drying programs including convective drying (CV) were carried out in a laboratory-scale hybrid dryer. The influence of intermittent conditions on drying time, drying rate, energy efficiency and product quality was analysed. The results demonstrated that intermittent–microwave convective drying improves the drying kinetics and reduces energy consumption. Moreover, a higher retention of vitamin C, smaller color change and a better ability to rehydration were observed for the parsley samples dried using intermittent drying than for CV.*

**Keywords:** *intermittent drying, microwaves, energy, vitamin C, rehydration.*

## 1. Introduction

Many experimental investigations have shown that combined drying methods result in higher drying effectiveness from both kinetic and quality aspect. Drying based on the combination of various techniques, i.e., hybrid drying, is still an emerging drying technology in food industry. [1,2] One of the possibilities to improve the drying kinetics and product quality can be intermittent drying. As one of the recommended methods for vegetable and fruit dehydration, consists of drying at non-stationary conditions, where the process parameters change periodically in time, e.g. varying temperature or varying mode of energy input. [3,4] The main aim of this solution is to prevent the loss of product quality and to enhance the energy efficiency. Intermittent microwave-convective drying has the opportunity to develop, as it is competitive to other more expensive alternative methods, such as, for example lyophilization. Parsley (*Petroselinum crispum*) is a popular plant of celery family (*Apiaceae*). Both its roots and leaves are used for culinary, medical and cosmetic purposes. It is a valuable spice vegetable which owes its aromatic properties to the essential oil. Ingredients found in parsley, e.g., vitamin C and E, polyphenols, carotenoids, have strong antioxidant properties, and their presence in the human diet is considered to be an important factor reducing the risk of civilization diseases. [5]

The aim of the studies was to analyze the effectiveness of hybrid drying in non-stationary conditions with respect to process kinetics, energy consumption and quality of dry parsley. The influence of intermittent microwave application in convective drying on the total drying time, drying rate, energy usage and quality characteristics such as colour change (dE), water activity (aw), retention of vitamin C, radial shrinkage (RS) and rehydration capacity (RC) were investigated in this study, and compared with processes carried out in constant conditions (convective and convective-microwave drying).

## 2. Materials and Methods

Fresh parsley roots (*Petroselinum crispum*) cultivated in Poland were used as a research material. 50g parsley samples in the form of slices (32 mm diameter, 5 mm thick) were dried in a laboratory-scale hybrid dryer equipped with an air-heating system, microwaves (2.45 GHz, max. power of 500 W) generated by a magnetron, pyrometer (infrared thermometer) and a standard electricity meter. The samples with an average initial moisture content of 0.84 kg·kg<sup>-1</sup> w.b. were dried to a final moisture content of 0.1 kg·kg<sup>-1</sup> w.b. using eight drying programs including convective drying as a reference (Table 1). The first four drying procedures were conducted using stationary conditions (i.e., convective drying (CV) and convective-microwave drying (CVMW)), whereas the next four procedures were performed using non-stationary conditions (i.e. intermittent–microwave and convective drying (IT1-4)). The basis for all IT programs was continuous CV with MW (ON/OFF)

cycles applied at the beginning of each drying test. The drying conditions were changed in terms of the air temperature, number of MW cycles or MW power to avoid overheating of the dried material. The drying processes were operated at 30°C or 50°C, or with a variable air temperature  $T_a$  (50°C/30°C). The microwave power was constant and set at 100 W, 300 W or 500 W. Irrespective of the type of drying program, the air velocity was constant throughout the entire process, i.e. 0.4 m/s.

*Table 1. Description of the drying programs.*

No.	Acronym	Description	$T_a$ [°C]	MW [W]	MW cycles duration
1	CV30	Convective drying	30	0	NA
2	CV50	Convective drying	50	0	NA
3	CVMW30	Convective-microwave drying	30	100	CONT
4	CVMW50	Convective-microwave drying	50	100	CONT
5	IT1	Intermittent drying	50/30	100	ON up to $T_m=50^\circ\text{C}/$ 15 min OFF
6	IT2	Intermittent drying	50/30	100	ON up to $T_m=50^\circ\text{C}/$ 30 min OFF
7	IT3	Intermittent drying	30	500	ON up to $T_m=50^\circ\text{C}/$ 15 min OFF
8	IT4	Intermittent drying	30	300	ON up to $T_m=50^\circ\text{C}/$ 15 min OFF

CV – convection, MW – microwaves, IT – intermittent,  $T_a$  – air temperature,  $T_m$  – material temperature, CONT – continuous, NA – not applicable

## 2.1. Process kinetics and energy consumption

The drying kinetics was assessed on the basis of the moisture ratio (MR), drying rate (DR), drying time (DT) and the energy consumption (EC). The parameters were determined as follows:

$$MR = \frac{MC_t - MC_{eq}}{MC_i - MC_{eq}}, \quad (1)$$

$$DR = \frac{dm}{DT}, \quad (2)$$

where:  $MC_i$ ,  $MC_t$  and  $MC_{eq}$  are the initial, instantaneous (for a given time of the process) and equilibrium moisture contents,  $dm$  is the total weight loss of the sample, and  $DT$  is the total drying time, i.e. until the moisture content reaches equilibrium.

The initial moisture content of the raw material was determined using a moisture analyser (XM120 Precisa, Switzerland). Each drying program was repeated in triplicate and the total drying time ( $DT$ ) was averaged for data interpretation. The energy consumed by the whole apparatus during the drying processes was measured with a standard electricity meter and recalculated to MJ per 1 gram of evaporated moisture. The average EC was determined by:

$$EC = \frac{E_p \cdot 3.6}{dm}, \quad (3)$$

where:  $E_p$  is the average energy consumption in kWh measured in drying process, and  $dm$  is the total weight loss of the sample.

## 2.2. Quality assessment

The product quality was assessed in terms of the total colour change ( $dE$ ), water activity ( $aw$ ), retention of vitamin C (AA), radial shrinkage (RS) and the rehydration capacity (RC). The total colour change was measured using a colorimeter (CR-400 Konica Minolta, Japan) and indicated using CIELab colour space:

$$dE = \left( dL^{*2} + da^{*2} + db^{*2} \right)^{0.5}, \quad (4)$$

where:  $L^*$  indicates lightness and  $a^*$ , and  $b^*$  are the chromaticity coordinates which indicate color directions from red to green ( $a^*$ ) and from yellow to blue ( $b^*$ ).

Water activity ( $aw$ ) was measured for fresh and dry product at 25°C using the LabMaster-aw Standard (Novasina AG, Switzerland). The measurement of  $aw$  for dry samples was conducted after a 24-hour incubation in a desiccator, since the moisture profile needs to be aligned after drying. Retention of vitamin C (AA) in the parsley root was determined by the spectrophotometric method. [6] The Radial shrinkage (RS) was assessed on the basis of image analysis. Photographs taken on the samples were subjected to basic treatment and used in Fiji software (v. 1.51u) for calculation of shrinkage in accordance with equation:

$$RS = \left( \frac{1 - A_d}{A_0} \right) \cdot 100\%, \quad (5)$$

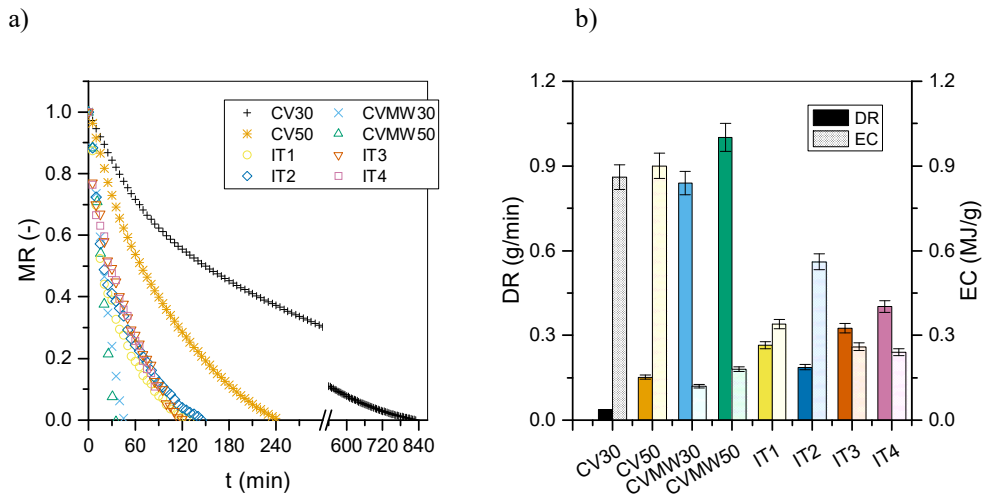

where:  $A_d$  and  $A_0$  are the surfaces of dry and raw parsley samples, respectively.

Dried samples were rehydrated in boiling distilled water at temperature of 100°C for 5 min, without stirring. The ratio of material to water was 1:50 (w/w). After rehydration the samples were blotted with a filter paper and weighed. The rehydration capacity (RC), described as percentage water gain, was calculated according to Seremet et al., 2016. [7]

### 3. Results and discussion

#### 3.1. Drying kinetics

The drying kinetics of parsley root was evaluated on the basis of drying and temperature curves. Figure 1 shows the results of moisture ratio, average drying rate and energy consumption obtained during drying in constant and intermittent conditions.

**Fig. 1. Moisture ratio MR (a) and average values of drying rate DR, and energy consumption EC (b) for different drying programs.**

The CV drying was found to be the longest process as the parsley samples achieved the final moisture content after about 14 and 4 hours for 50°C (CV50) and 30°C (CV30), respectively. As can be seen in Fig. 1b, also CV the smallest value of the drying rate was obtained. The results of hybrid drying, i.e., CVMW, showed a significant reduction in drying time, namely about 95% as compared to CV. Similarly, the average drying rate for CVMW was the highest amongst all the drying procedures. In turn, intermittent drying (IT) demonstrated shorter drying times, namely by 82-86%, in comparison to CV, but on the other hand a considerable increase in DT and lower values of DR than those of the CVMW. As follows from Fig. 1a, longer OFF cycles during IT2 increased the total drying time and thus decreased noticeably the drying rate, as compared to IT1. However, which is surprising, a lower MW power applied in IT4 increased the drying rate in comparison with IT3. In case of the energy effectiveness (Fig. 1b), the lowest energy efficiency was

observed for CV, as the highest EC was obtained. The average energy consumption was definitely lower for all the IT processes, but the highest energy efficiency was found for CVMW. It was noticed that energy usage is proportional to the total drying time.

### 3.2. Product quality

The quality of parsley samples was evaluated on the basis of several quality characteristics. Figure 2 presents the results of colour change and water activity between fresh and dry product.

Fig. 2. Total colour change dE (a) and water activity aw (b).

The highest total color change (16.79) was observed for CV30. Thus, the discoloration of parsley was due to continuous and prolonged application of hot air during drying. Astonishingly, despite continuous MW in CVMW, the colour change was visibly lower than for CV as well as for IT. As follows from Fig. 2a, dE after intermittent drying (IT1-4) was found to be similar to that of CV50, i.e. 14, on average. However, the results of colour coordinate ( $L^*$ ) proved that the overall change in colour for CV and IT samples increased due to higher value of lightness after drying. In consequence, it means a positive change in colour, i.e., “brightening” of the samples dried by CV and IT. The next quality factor was water activity aw (Fig. 2b), which allows to verify the microbiological stability of dry product, e.g., development of microflora, product durability. The fresh material was characterized by the water activity of 0.970, on average. After each drying process water activity was less than its critical value, i.e. 0.6, thus the microbial growth (bacteria, yeasts and molds) was inhibited and biologically stable products were obtained. Secondly, aw of dry parsley samples was lower than 0.4, which means that many reactions, e.g. enzymatic, non-enzymatic (Maillard) and oxidation have been blocked. [8]

Figure 3 presents the results of vitamin C retention, radial shrinkage and rehydration capacity. CVMW50 contributed to the lowest vitamin C retention amongst all the analysed drying programs (Fig. 3a). In turn, for CVMW30 the retention was 57%, and was also higher than for CV. In case of IT, the value of AA was in the range of 54-93%. The highest content of AA was obtained for IT3. In general, intermittent application of microwaves in convective drying allowed the parsley to retain more vitamin C then in case of CV or CVMW.

a)

b)

Fig. 3 Retention of ascorbic acid AA (a), radial shrinkage RS and rehydration capacity RC (b).

The results of radial shrinkage (Fig. 3b), showed that type of process may influence the appearance of samples significantly. The products dried in stationary conditions were characterized by a slightly lower RS in comparison to the non-stationary ones. The only exception is CVMW30, where the observed RS was similar as for IT. Nevertheless, the smallest shrinkage was observed for the material dried by CV, regardless of the air temperature. The last quality parameter evaluated in this work was rehydration capacity (RC), which gives information on the ability of the material to absorb water. As follows from Fig. 3b, the rehydration capacity of samples dried by CV and CVMW increased with the decrease of temperature. Therefore, due to the increase in air temperature (i.e., from 30°C to 50°C), a destruction of plant tissue structure must have occurred. In case of IT1-4, a higher RC was observed. Moreover, the value of RC increased with the OFF time and also with MW power applied during intermittent drying.

#### 4. Conclusions

The effect of different methods including non-stationary drying on kinetics and quality characteristics of parsley root was discussed. The results of the drying tests showed that intermittent drying reduces drying time by 86%, increases the drying rate and thus

improves the energy efficiency (up to 80%) as compared to convective drying. Furthermore, it was found that microwaves applied intermittently in convective drying contributes to better product quality from the colour, vitamin C retention and rehydration property point of view.

### **Abstract**

*This study aimed to evaluate the spouted bed drying of okara with inert particles of polypropylene. A central composite rotatable design was carried out to verify the effect of drying air temperature and air flow on moisture content, techno-functional properties and trypsin inhibitors activity of dried product. Higher temperatures decreased emulsifying properties and trypsin inhibitor activity, probably due to thermal protein denaturation. In order to obtain a dried okara with maximum techno-functional properties and minimum moisture content and trypsin inhibitor activity, the optimal drying conditions were suggested: air temperature of 60°C and air flow of 180 m<sup>3</sup>/h.*

**Keywords:** soy pulp; spouted bed drying; trypsin inhibitor activity; techno-functional properties; optimization

---

## **1. Introduction**

During the processing of soymilk and tofu, an insoluble residue, also known as okara or soy pulp, is generated. Since the sales volume of soymilk worldwide reached 13.5 billion liters in 2015<sup>[1]</sup>, significant quantities of okara are underutilized as animal feed or discarded, resulting in environmental problems. However, okara can be used for human consumption or as ingredient to increase the functional properties of food products due to its considerable high protein content<sup>[2]</sup>.

Soy proteins play an important role in the food industry due to their nutritive value and ability to improve the functional properties. Okara proteins, whose main fractions are the basic 7S globulin and 11S<sup>[3]</sup>, presented better emulsion stability and similar emulsion activity than soy protein<sup>[4]</sup>. Moreover, unlike other vegetable proteins, okara proteins have all of the essential amino acids necessary for good health<sup>[5]</sup>. However, okara contains trypsin inhibitor, which has been considered an antinutritional factor of soy consumption by promoting the reduction of protein digestibility<sup>[6]</sup>.

Thus, aiming the use of okara by the food industry, some preservation method must be applied to improve its shelf life, since okara contains high moisture content (75-80%) and is very perishable. Amongst the several methods employed for preservation, drying is a process in which water activity of food is reduced by removal of moisture by vaporization or sublimation. However, okara is a material difficult to dry, since its wet particles are cohesive. Moreover, the diffusion of internal moisture is slow, resulting in long drying time when it is dried in static dryers<sup>[7]</sup>. These drawbacks can be solved using dynamic dryers, such as spouted bed dryer, and by adding inert particles to the moist and cohesive material.

The objective of the current work is to evaluate the spouted bed drying of okara, analyzing the influence of process parameters on dried product quality.

## **2. Materials and Methods**

### **2.1. Material**

Soybean (*Glycine max* (L.) Merr.) cultivar BRS 257, which is lipoxygenase-free, was acquired from SL Alimentos (Mauá da Serra, Brazil). Polypropylene particles were used as inert material. Trypsin and benzoyl-DL-arginine-4-nitroanilide hydrochloride substrate (BAPNA) (Sigma-Aldrich, St. Louis, USA) were used for analysis of the trypsin inhibitors.

### **2.2. Preparation of okara**

The okara was obtained from soymilk processing according to Baú and Ida<sup>[8]</sup>. Soybeans were soaked in water at 1:3 ratio (w:w, soybean:water) for 12 h at 8°C, drained and homogenized with distilled water at 1:8 ratio (w:w, soybean:water) using an industrial blender (model LB-25, Skymesen®, Brusque, Brazil) for 5 min. The mixture was filtered, obtaining the insoluble

fraction okara. The moisture content of okara was  $75.2 \pm 0.1\%$  (wet basis). Ash, lipid and protein contents of okara, obtained by AOAC<sup>[9]</sup>, were in dry basis  $3.5 \pm 1.0\%$ ,  $13.9 \pm 0.5\%$  and  $35.1 \pm 1.0\%$ , respectively. Carbohydrate content (dry basis), calculated by difference, was  $47.4 \pm 1.5\%$ . Samples were stored at  $-18^\circ\text{C}$  and thawed according to the quantity required for spouted bed drying.

### 2.3. Spouted bed drying of okara

The drying of okara was carried out in a spouted bed dryer (model FBDG3, O'Hara Technologies, Ontario, Canada). The dryer consists of a conical base with an inferior diameter of 85 mm, superior diameter of 393 mm, height of 400 mm and inlet orifice diameter of 48 mm. The upper part of conical base consists of a cylindrical column.

Previous to drying of okara, the spouted bed dryer was put into operation with 1 kg of inert particles. Heated air was blown at the inferior part of conical base at different flow rates (Table 1). After the permanent regime was reached, 500 g of moist okara were introduced into the dryer. For all experiments, total drying time was 30 min. The load of inert particles, mass of okara:mass of particle inert ratio and drying time were determined in preliminar tests. At the end of drying, dried okara was separated from the inert particles by sieve with 2 mm opening.

A central composite rotatable design was carried out to verify the effect of drying air temperature (40 to  $80^\circ\text{C}$ ) and air flow (140 to  $180 \text{ m}^3/\text{h}$ ) on moisture content, techno-functional properties (emulsifying capacity, emulsion stability and water absorption index) and trypsin inhibitors activity of dried product. Experimental data were fitted to Equation (1)<sup>[10]</sup>.

$$y = b_0 + b_1x_1 + b_2x_2 + b_{11}x_1^2 + b_{22}x_2^2 + b_{12}x_1x_2 \quad (1)$$

Where:  $y$  is the response,  $b_0$ ,  $b_1$  and  $b_2$ ,  $b_{11}$  and  $b_{22}$ , and  $b_{12}$  are the constant, linear, quadratic and cross-product regression coefficients, respectively, and  $x_1$  and  $x_2$  represent the coded values of the  $T_{in}$  and  $W$  variables, respectively.

Regression coefficients of the predictive models were obtained by the Protimiza software (<http://experimental-design.protimiza.com.br>). Coefficients within a confidence level above 90% were considered significant ( $p < 0.1$ ). Non-significant terms were eliminated, and the model was tested for adequacy by analysis of variance (Anova), coefficient of determination ( $R^2$ ) and F-test.

## 2.4. Analytical methods

### 2.4.1. Physicochemical properties of the dried okara

Moisture content was determined gravimetrically in triplicate in an oven at 105°C for 24h<sup>[9]</sup>. The water absorption index (WAI, g absorbed water/g sample) analyses were carried out according to Seibel and Beléia <sup>[11]</sup>. The emulsifying capacity (EC, mL oil/g protein) was analyzed by continuous addition of oil to the sample until phase inversion of the emulsion, when the conductivity of the emulsion was below 10 µS<sup>[12]</sup>. For emulsion stability (ES, %), emulsion was prepared with okara and oil and placed in a 50 ml graduated cylinder and stored at room temperature. The volume of the emulsified layer was observed until no variation was observed<sup>[13]</sup>. The ES was calculated as the ratio of the emulsified layer and the total volume. The trypsin inhibitor activity (TIU/g solid) was determined according to the AOCS<sup>[14]</sup>, by

extracting of the deaged sample with water for 30 min, followed by buffer Tris (0.05 mol/L, pH 8.2, containing CaCl<sub>2</sub> 0.02 mol/L). One trypsin unit (TU) was arbitrarily defined as an increase of 0.01 absorbance units at 410 nm for 10 mL of a reactive mixture (2 mL sample aliquot, 2 mL trypsin solution, 5 mL benzoyl-DL-arginine-4-nitroanilide hydrochloride substrate solution and 1 mL acetic acid solution). The trypsin inhibitor unit (TIU) was calculated as the difference in the absorbance between a standard test and the sample test.

### 3. Results and Discussion

#### 3.1. Spouted bed drying of okara

The experimental data for moisture content (X), water absorption index (WAI), emulsifying capacity (EC), emulsion stability (ES) and trypsin inhibitor activity (TI) were fitted to Equation 1. The regression coefficients, F-values, p-values and R<sup>2</sup> are presented in Table 1. After exclusion of non-significant terms (p>0.1), the predictive models were tested for accuracy of fit by Anova. When the calculated F-value F<sub>c</sub> was greater than the tabulated F-value F<sub>t</sub>, the variation was explained by the regression and not by the residues. Thus the regression was significant, and the model could be considered predictive. However, for the WAI, the R<sup>2</sup> was low and the model was not predictive. Figure 1 shows the response surfaces generated by the proposed models.

As expected, higher temperature and air flow led to lower moisture content (Fig. 1a). Air flow played a significant role in fluid dynamic of particles. At higher air flow, there is a better contact between sample particles and air drying, improving the heat and mass transfer. Analyzing Figures 1(b) and 1(c), temperature had a significant and negative effect on emulsifying capacity and emulsion stability, in which higher temperatures led to lower response values. These results were expected, since the okara proteins are thermosensitive, probably occurring their denaturation during the drying process. Several process parameters, such as pH and ionic strength, affect the functionality of proteins, especially temperature. Heat treatment has a great impact on the structure and, as consequence, on the emulsifying functionality of proteins<sup>[15]</sup>. Similarly to the emulsion properties, lower values of trypsin inhibitor activity were obtained at higher temperature and air flow (Fig.1d). Besides trypsin inhibitor is reversibly denatured by short heating to 80°C and irreversibly denatured by heating to 90°C<sup>[16]</sup>, the highest drying temperature used in the current work (74°C) caused significant losses on its activity.

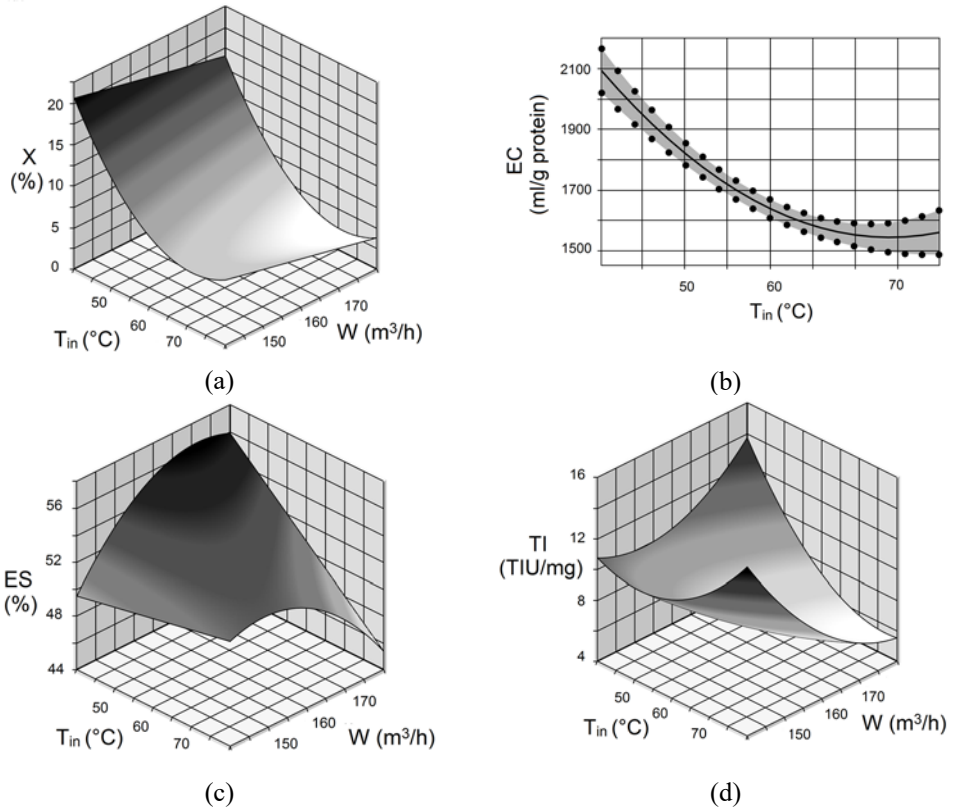

Fig. 1. Influence of independent variables on the responses: (a) moisture content; (b) emulsifying capacity; (c) emulsion stability and (d) trypsin inhibitors activity

### 3.2. Characterization of the spouted bed dried okara obtained under the optimum condition

Analyzing the responses surfaces (Fig. 1), the spouted bed drying of okara was optimized for maximum techno-functional properties and minimum moisture content and trypsin inhibitor activity. The optimal drying conditions were: 60°C and 180 m<sup>3</sup>/h. Under optimal conditions, dried okara had a moisture content of 4.8±0.1% emulsifying capacity of 1754.3±18.0 ml/g protein, emulsion stability of 48.8±0.3%, water absorption index of 4.7±0.52 g/g sample and trypsin inhibitor activity of 6.7±0.1 TUI/mg sample.

In order to verify the influence of spouted bed drying on okara, these quality properties were also determined for freeze dried okara. As results, the emulsifying capacity and emulsion stability of freeze dried okara was respectively 2182.8±30.7 ml/g protein and 51.48±0.4%. On the other words, spouted bed drying caused a reduction of 19.6% and 5.1% on emulsion properties. On the other hand, an improvement on nutritional properties was observed, in

which spouted bed drying reduced 27% of trypsin inhibitor activity of product (9.3±0.3 TUI/mg sample).

#### 4. Conclusions

The spouted bed drying showed to be suitable to obtain dried okara with good technofunctional properties, mainly emulsifying capacity. In order to obtain maximum emulsion properties and minimum trypsin inhibitor activity, the optimal condition was proposed: 60°C and 180 m<sup>3</sup>/h. There was a significant retention of emulsifying capacity and emulsion stability and reduction on trypsin inhibitor activity after spouted bed drying.

#### 5. Nomenclature

EC	emulsifying capacity	ml g <sup>-1</sup> protein

### **Abstract**

*Germinated parboiled rice (GPR) is recognized as a functional food because it is rich in bioactive compounds, especially gamma-aminobutyric acid (GABA). GPR was produced by soaking, incubating, steaming, and then drying using a high-precision hot air dryer. The results indicated that air flow mode and drying temperature had significant effects on the quality of GPR. Drying at higher temperatures and shorter times conserved GABA content. Using through-flow mode decreased drying time and prevented color change. However, a slightly lower percentage of head rice yield was observed. Moreover, using through-flow mode negatively affected the hardness loss after cooking.*

**Keywords:** *Germinated parboiled rice; Drying mode; Gamma-aminobutyric acid; Head rice yield*

---

## **1. Introduction**

Germinated parboiled rice (GPR) is a product that can be promoted as a functional food. The characteristics of GPR are shorter cooking time, softer texture and higher contents of bioactive compounds than the normal rice. Nowadays, the GPR production in Thailand is performed by soaking paddy rice in water and then incubating until the radicle grows to a length of 0.5 - 1.0 mm. After that, the germinated paddy is steamed until being cooked. Subsequently, the germinated parboiled paddy is sun dried to a final moisture content of 14%.<sup>[1]</sup> Dried germinated parboiled paddy is dehusked, then the final product is packed.

During the germination, enzymes in paddy rice are activated and bioactive substances greatly increase.<sup>[2]</sup> Gamma-aminobutyric acid (GABA) is a free amino acid, substantially increased by the germination process.<sup>[3]</sup> GABA has a beneficial effect on human health, such as decreasing stress-related nerve impulses in the brain and promoting relaxation and sleep.<sup>[4]</sup> Parboiling is a hydrothermal process, causing certain changes in paddy rice, including taste, texture, starch gelatinization, inactivation of enzymes, easier dehushing and increased head rice yield.<sup>[3]</sup> Sootjarit et al.<sup>[5]</sup> reported that germinated rice rapid drying at high temperatures (80°C - 140°C) resulted in a significant higher GABA content in comparison to drying at a lower temperature (50°C). However, high temperature can easily cause overheating and cracking of grains which leads to low milling quality.<sup>[6]</sup>

Therefore, the suitable drying temperature for GPR production to conserve overall quality considering GABA content, milling and cooking properties is essential. Besides the drying temperature, the effect of air flow mode in the drying chamber is also important for efficient the drying process of a good quality GPR.

“Hom-Nil” is a pigmented Thai rice. It is also known as purple rice, that contains varieties of bioactive compounds such as antioxidants, phenolics,  $\beta$ -carotene and anthocyanins.<sup>[7]</sup> Nowadays, it is commonly used for producing GPR in Thailand. Thus, the objective of this study was to study the effect of drying temperatures and modes of drying air on the GABA content and quality of germinated parboiled purple rice.

## **2. Materials and Methods**

Thai purple paddy rice variety ‘Hom Nil’ with a moisture content of  $11.28 \pm 0.28\%$  (w.b.) was used in this study. Paddy rice was purchased from the farmer in Nakorn Pathom, Thailand and brought to Stuttgart, Germany by airfreight. It was cleaned to separate foreign matter before conducting the experiments.

### **2.1. Preparation of germinated parboiled rice (GPR)**

Purple paddy rice ‘Hom Nil’ was soaked in water at 35°C for 24 h before draining then incubated at 35°C for 16 h. Germinated paddy rice was then parboiled by steaming for 30

min. The germinated parboiled paddy was dried under various conditions. Thin layer convective drying was conducted using a high-precision hot air laboratory dryer designed at the Institute of Agricultural Engineering, University of Hohenheim, Germany.<sup>[8]</sup> Germinated parboiled paddy samples were dried under two different air flow modes, over-flow (OF) and through-flow (TF), in a drying chamber (Fig. 1). Drying temperatures were varied at 40, 50, 60, 70 and 80°C with a constant specific humidity of 25 g/kg dry air and an air velocity of 1.0 m/s. The temperature inside the germinated parboiled paddy was monitored by thermocouples inserted into the middle of rice kernels during the drying process. Drying was carried out until the moisture content of germinated parboiled paddy rice reached 13% (w.b.). Drying experiments were performed in triplicate. Dried germinated parboiled paddy was kept in vacuum-sealed aluminium foil pouches at 23 ± 2°C and humidity of 52 ± 3% for 1 day before dehusking. The husk was removed from kernel using a laboratory de-husker (TR250, Kett, California, USA). One hundred grams of germinated parboiled rice (GPR) was then vacuum packed in aluminium foil pouches and kept at a temperature of 23 ± 2°C and humidity of 52 ± 3% before quality analyses.

**Fig. 1 Hot air direction in two air flow modes inside drying chamber of the dryer.**

## 2.2. Quality analyses

### 2.2.1. Head rice yield (HRY)

After dehusking, the head rice yield was determined using the following formula:<sup>[9]</sup>

$$\text{HRY (\%)} = (\text{mass of head rice} / \text{mass of GPR}) \times 100 \quad (1)$$

### 2.2.2. Color measurement

A colorimeter (CR-400, Minolta Co., Ltd., Tokyo, Japan) was used to measure color of a whole kernel of dried GPR. Rice samples were filled in a petri dish with diameter of 100 mm and thickness of 15 mm. Measurements were made with illumination area of 11 mm in five positions of a petri dish. The color values were reported in L\*, a\*, b\* color coordination system with a D65 illuminant and 10° observer.

### 2.2.3. Texture analysis

Hardness of cooked GPR was measured using a texture analyzer (TA-XT2i, Stable Micro systems, Surrey, UK) with slightly modified method of Srisang et al.<sup>[10]</sup> Before testing, the

samples were prepared by cooking 25 g GPR samples in a 250 mL beaker, with 75 mL distilled water about 30 min. Ten of cooked rice kernels were selected from the center of the beaker after cooled at  $23 \pm 2^\circ\text{C}$  for 30 min. The cylindrical probe with a size of 50 mm was used for testing cooking characteristics. The peak force of the first compression is represented as hardness. The texture profile analysis was repeated five times per replicate.

#### *2.2.4. Determination of gamma-aminobutyric acid (GABA) content*

Sample extraction was performed with a modified method of Hayat et al.<sup>[11]</sup> GPR samples were ground and sieved through 1 mm mesh. Five grams of ground sample were added 20 mL of 80% (v/v) methanol and then homogenized for 3 min. The suspension was centrifuged at 5000 rpm,  $4^\circ\text{C}$  for 10 min and the supernatant was collected. Extraction steps were repeated twice then the whole supernatant was filtered through a  $0.45 \mu\text{m}$  of nylon membrane filter with vacuum pump. Supernatants were evaporated under a vacuum at  $60^\circ\text{C}$  using a rotary evaporator and adjusted to 5 mL using 80% methanol. The extracted solution was kept at  $-18^\circ\text{C}$  until analysis.

The GABA contents were determined by a HPLC (model RF-20A prominence, Shimadzu, Kyoto, Japan). The extracted solution (1 mL) was mixed with 1 mL of derivatizing reagent (0.75% of 2-hydroxynaphthaldehyde) and 0.6 mL of borax buffer (pH 8.0). The reaction was performed at  $80^\circ\text{C}$  for 10 min.<sup>[12]</sup> After the derivatization, chromatographic separation was done by a  $\text{C}_{18}$  column (Phenomenex, California, USA) at  $30^\circ\text{C}$  using methanol : water (62 : 38 v/v) at a flow rate of 1 mL/min as a mobile phase and detected by a diode array UV detector at 254 nm. Results are expressed in mg GABA per 100 g (d.b.). Authentic GABA (Sigma-Aldrich, Munich, Germany) was used as a standard.

### **3. Results and Discussion**

#### **3.1. Drying time**

After germination, samples absorbed water, and therefore, the moisture content increased from  $11.28 \pm 0.28$  to  $36.32 \pm 0.19\%$  (w.b.). After steaming, the moisture content of paddy increased to  $41.51 \pm 0.71\%$  (w.b.). The drying times required for removing the water in parboiled germinated paddy to the moisture content of 13% (w.b.) at the drying temperatures of 40, 50, 60, 70 and  $80^\circ\text{C}$  in an OF mode were 390, 195, 130, 100 and 85 min, respectively, while in TF mode were 180, 110, 75, 55 and 45 min, respectively. As expected, higher drying temperature reduced the drying time in both drying air flow modes. Drying using a TF mode shortened the drying time by about half compared to an OF mode at each temperature. This result could be explained by the more uniform airflow distribution in a drying chamber when using a TF mode compared with an OF mode.<sup>[13]</sup> Uniformity of drying air velocity is known to improve the heat distribution.<sup>[14]</sup>

### 3.2. Quality of dried GPR

#### 3.2.1. Head rice yield

Fig. 2 presents the temperatures of drying air, inside temperatures of GPR kernels during drying and the percentages of HRY after dehusking. For a TF mode, a slightly lower percentage of HRY was observed, as compared with the same drying temperature in an OF mode (Fig. 2 F). This present finding is consistent with other research which found that HRY decreased when drying temperature increased.<sup>[9]</sup> This result can be explained in part by the kernel temperature of TF samples, which increased faster than those of OF samples at the same drying temperature (Fig. 2 A-E). This phenomena caused the cracking inside GPR kernels and lead to kernel breakage during dehusking. The findings are in agreement with Tirawanichakul et al.<sup>[15]</sup> where the drying air temperature affected HRY of paddy.

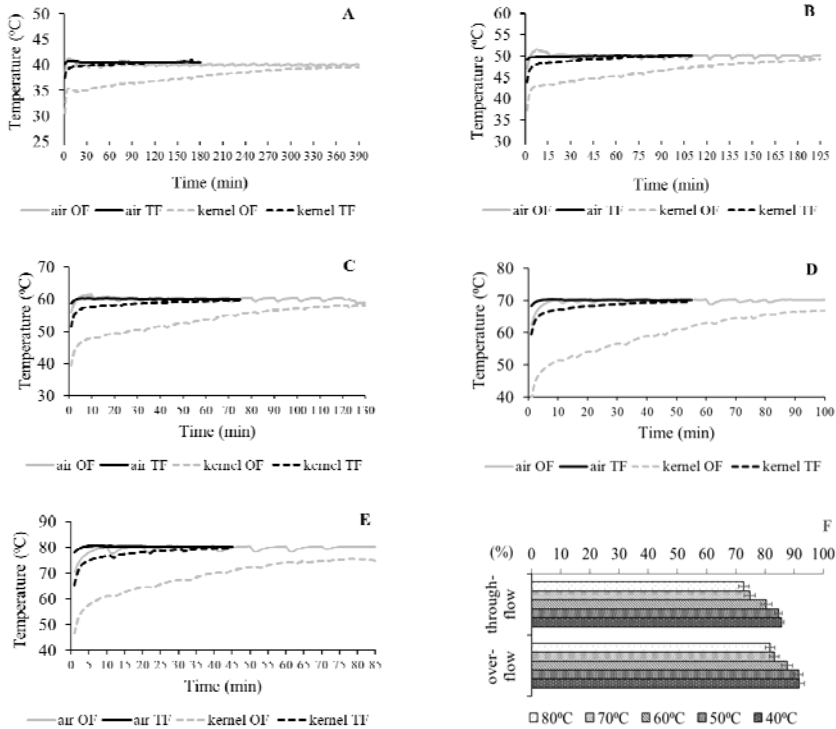

Fig. 2 Hot air and GPR kernel temperature during drying at 40°C (A), 50°C (B), 60°C (C), 70°C (D), 80°C (E) and percentage of head rice yield (F) in two airflow modes.

#### 3.2.2. Color of GPR

In this study, airflow mode had a significant effect on color of GPR (Fig. 3). GPR obtained from the drying process with a TF mode had higher lightness ( $L^*$ ) and redness ( $a^*$ ) than

using an OF mode. Comparing between two drying air flow modes, TF mode showed color values closed to the color of raw materials. The purple color of rice kernels is due to the presence of anthocyanin in the bran.<sup>[16]</sup> Difference in color changes in these two airflow modes might be caused by different contact intensity between hot air and rice bran that affected the degradation of anthocyanin contents. However, the study of an impact of airflow modes on the anthocyanin contents in GPR is currently ongoing. Chen et al.<sup>[17]</sup> reported that using different drying methods, significantly affects the rice color.

Fig. 3 Color of GPR obtained from drying at various drying temperatures in two airflow modes.

### 3.2.3. Hardness of cooked GPR

Hardness of cooked GPR was different among the difference drying conditions (Table 1). Hardness of dried GPR samples using OF mode was higher than TF mode. This study found a decreasing trend in hardness when increased drying temperature was used under both airflow modes. Drying GPR at 40 and 50°C in OF mode showed higher hardness than brown rice (123 ± 6 N). However, higher drying temperature leads to the reduction of hardness after cooking. Cracking inside grain kernels could result in an increase of water uptake and consequently cause lower hardness in rice. This was confirmed by a percentage of HRY mentioned in previous section of this study.

Table 1. Hardness of cooked dried GPR at various drying temperatures in two airflow modes.

Drying Temperature (°C)	Hardness (N) of cooked GPR	
	over-flow	through-flow
40	140 ± 6 <sup>a</sup>	111 ± 4 <sup>b</sup>
50	133 ± 4 <sup>a</sup>	109 ± 5 <sup>bc</sup>
60	99 ± 5 <sup>d</sup>	73 ± 0 <sup>e</sup>
70	101 ± 8 <sup>cd</sup>	66 ± 1 <sup>ef</sup>
80	94 ± 1 <sup>d</sup>	60 ± 1 <sup>f</sup>

Data are the mean values ± standard deviation and different letters indicate significant difference among mean values in lines and columns ( $P \leq 0.05$  according to Duncan's test).

### 3.2.4. GABA content

GABA content significantly increased after germination process and elevated again after parboiled process (Fig. 4A). After drying (Fig. 4B), GABA content decreased, especially after prolonged drying at low temperature. Drying at higher temperatures and shorter times prevented GABA degradation, especially at 80°C. This finding is in agreement with Cheevitsopon and Noomhorm<sup>[18]</sup> who showed drying temperature and time had significant effects on GABA content in rice. In addition, this study found that airflow modes did not significantly influence the levels of GABA.

**Fig. 4** GABA content of GPR dried at various temperatures in two airflow modes.

Values are the mean and bars indicate standard deviation and different letters indicate significant difference among mean values ( $P \leq 0.05$  according to Duncan's test).

## 4. Conclusions

The present study was designed to determine the effect of drying conditions on GABA content and quality of GPR. After drying, GABA content of all samples increased compared to the paddy rice due to the germination and steaming process. However, GABA content decreased after drying, especially after prolonged drying at low temperature. Overall, this study showed that GPR drying under the optimal drying conditions, namely using TF mode, significantly conserved color of GPR. However, using an TF mode at high drying temperature leads to low percentage of HRY and reduced hardness after cooking.

### **Abstract**

*Lignite, a kind of low rank coal, has the characteristics of high moisture, high volatile, high ash and low heat value. The low-temperature pyrolysis technology is potential to improve the utilization efficiency of lignite. Therefore, a lignite-based energy system integrated with pre-drying and low-temperature pyrolysis was proposed in this paper. To assess the influence of pre-drying process, theoretical models were developed based on thermodynamics, and a case analysis was then performed to get the quantitative effect of pre-drying on efficiency of energy utilization. Results show that pre-drying on PPPS theoretical model can significantly improve the utilization of lignite by 1.46%.*

**Keywords:** *Lignite; Pre-drying; Low-temperature pyrolysis; Energy efficiency; Case analysis.*

---

## 1. Introduction

Lignite is worldwide considered as inferior fuel with abundant supply.<sup>[1]</sup> It is mainly used in power plants. However, the conventional lignite-fired power system (CLPS) is costly, not efficient and with high pollutant emissions. Lignite upgrading technologies, including pre-drying and pyrolysis, are effectively to improve lignite utilization efficiency. Therefore, many researches were conducted for the lignite pre-drying<sup>[2, 3, 4]</sup> and pyrolysis<sup>[5, 6]</sup> technologies. However, these two technologies are isolatedly used. The integration of the lignite pre-drying and pyrolysis may realize the energy cascade utilization and then increase the utilization of lignite. Therefore, a pre-dried pyrolysis coupled lignite-fired power system (PPPS) was proposed in this paper.

The proposal of PPPS aims to overcome the disadvantages of the pyrolysis process by the integration of pre-drying. However, the research on influences of pre-drying process on pyrolysis system is not deepgoing and unambiguous. In this paper, theoretical models were developed based on thermodynamics, and a case analysis was then performed to get the quantitative effects of pre-drying. Moreover, the energy and exergy analysis were carried out to uncover the energy saving mechanism.

## 2. System proposal

The schematic of a PPPS is schematically presented in Fig.1 Raw lignite (point 1) is fed into the steam dryer and pre-dried primarily. The primary pre-dried lignite (point 2) is then fed into the drying unit and pre-dried ultimately. Afterwards, the ultimate pre-dried lignite (point 3) is led to the pyrolysis unit, heated by the elevated temperature flue gas, pyrolyzed and separated into char (point 4), tar (point 13), pyrolysis gas (point 21) and water (point 12) in pyrolysis furnace. The tar and pyrolysis gas are recycled as products. Nevertheless, the char is converted by a series of energy forms and transformed into electricity (point 20), eventually. Waste steams (point 5, 6, and 12) generated in the process are exhausted to environments. The heat source of pyrolysis furnace is the elevated temperature flue gas (point 11) extracted from the boiler unit and led to the inlet of the burner. The heat source of the drying unit in the pyrolysis system is the flue gas (point 10) exhausted from the pyrolysis chamber. The flue gas (point 9) is extracted to the boiler unit by the pump after releasing heat in the drying unit, the waste heat of which is recycled by the regenerative air preheaters. The heat source of the steam pre-drying unit is the 5# low-pressure extraction steam (point 7) from the turbine unit. The steam is led to the steam dryer, condensed after releasing heat, and recovered in the de-aerator. The steam dryer makes full use of the low grade energy contained by the extraction steam from regenerative system, and reduces the heat load in the pyrolysis system.

**Fig.1 The pre-dried pyrolysis coupled lignite-fired power system.** Note: APH, air preheater; HPT, high-pressure turbine; IPT, intermediate-pressure turbine; LPT, low-pressure turbine; DEA, de-aerator; RH, regenerative heater; CP, condensate pump; BP, boiler feed-water pump exchangers; DP, drain water pump; FP, flue gas backflow pump; CV1, steam pre-drying unit; CV2, drying furnace unit; CV3, pyrolysis unit; CV4, boiler unit; CV5, steam turbine unit.

### 3. Model development

In this paper, the reference pressure and the temperature are given, as follows;

$$p_0=0.1013 \text{ MPa} \tag{1}$$

$$T_0=298.15 \text{ K} \tag{2}$$

The calculations of enthalpy, higher heating value, and exergy are all based on this condition. In this part, the belt pyrolysis furnace is selected as pyrolysis model. The following pyrolysis reaction occurs when the temperature and pressure of the pyrolysis furnace remains constant.

The parameters in pyrolysis process are shown in Table 1, where HHV\* is higher heating value;  $h^*$  is the specific enthalpy at  $\text{kJ}\cdot\text{kg}^{-1}$ ;  $t^*$  is the temperature at  $^{\circ}\text{C}$ ;  $\lambda^*$  is pyrolysis production rate defined as the (\*) mass rate produced from unit mass of feed for pyrolysis furnace,  $\text{kg}\cdot\text{kg}^{-1}$ .  $\mu(\gamma)$  is the degree of pre-drying defined as the moisture mass released from unit mass of raw lignite (primary predried lignite),  $\text{kg}\cdot\text{kg}^{-1}$ .

Table 1. The parameters of pyrolysis process.

Predried lignite	Char	Tar	Gas	Water
$P_0$	$P_0$	$P_0$	$P_0$	$P_0$
$h_{ul}$	$h_c$	$h_t$	$h_g$	$h_{wa}$
HHV <sub>ul</sub>	HHV <sub>c</sub>	HHV <sub>t</sub>	HHV <sub>g</sub>	–
$t_{ul}$	$t_p$	$t_p$	$t_p$	$t_p$
□–	$\lambda_c$	$\lambda_t$	$\lambda_g$	$\lambda_{wa}$
$B(1-\mu)(1-\gamma)$	$\lambda_c \cdot B(1-\mu)(1-\gamma)$	$\lambda_t \cdot B(1-\mu)(1-\gamma)$	$\lambda_g \cdot B(1-\mu)(1-\gamma)$	$\lambda_{wa} \cdot B(1-\mu)(1-\gamma)$

By applying an enthalpy balance for the overall pyrolysis, the flue gas mass flow ( $D'_f$ ) needed in the pyrolysis can be obtained:

$$D'_f = \frac{\lambda_c (\text{HHV}_c + h_c) + \lambda_t (\text{HHV}_t + h_t) + \lambda_g (\text{HHV}_g + h_g) + \lambda_{wa} h_{wa} - (\text{HHV}_{ul} + h_{ul})}{(h_{pin} - h_{fin}) \cdot \eta_p} \cdot B(1 - \mu)(1 - \gamma) \quad (4)$$

where  $\eta_p$  is the thermal utilization efficiency of the pyrolysis furnace; and  $h_{pin}$  is the specific enthalpy of flue gas in pyrolysis furnace inlet. Pyrolysis gases products are obtained as mixture, containing CO, H<sub>2</sub>, CO<sub>2</sub> and hydrocarbons (CH<sub>4</sub>, C<sub>2</sub>H<sub>4</sub>, C<sub>2</sub>H<sub>6</sub>, C<sub>3</sub>H<sub>6</sub> and C<sub>3</sub>H<sub>8</sub>). The HHV<sub>g</sub> is calculated as follow;

$$\text{HHV}_g = \sum w_i \cdot \text{HHV}_i \quad (5)$$

where HHV<sub>i</sub> is the higher heating value of constituent (i) in pyrolysis gas calculated by CoolProp and  $w_i$  is the mass fraction of constituent (i).  $D_f$  and  $D'_f$  are equal by adjusting  $t_{fin}$  in MATLAB.  $D_f$  is the flue gas mass flow needed in the drying furnace unit. The energy and exergy flow ratios of each control volume and the power system to the input energy or exergy are defined as follows;

$$\varepsilon_L^{en} = \frac{Q}{B \cdot \text{LHV}_{raw}} \times 100\% \quad (6)$$

$$\varepsilon_H^{en} = \frac{Q}{B \cdot \text{HHV}_{raw}} \times 100\% \quad (7)$$

$$\varepsilon^{ex} = \frac{E}{B \cdot \text{HHV}_{raw}} \times 100\% \quad (8)$$

where LHV is the lower heating value at kJ·kg<sup>-1</sup>;  $Q$  is the energy flow based on LHV in equation (6) and based on HHV in equation (7) at kW;  $E$  is the exergy flow at kW; and  $\varepsilon$  is the efficiency.

## 4. Results and discussion

### 4.1. Results of calculation

#### 4.1.1 Reference case

The lignite pyrolysis power system (LPPS, only involving CV2, CV3, CV4 and CV5 in Fig.1) is derived from a conventional lignite-fired power system (CLPS)<sup>[7]</sup> with the pyrolysis system integrated, the parameters of which are set with reference to the CLPS. The parameters of live steam and reheat steam, including temperature, pressure and mass flow rate of LPPS are assumed similar to those of the CLPS. The temperature of boiler flue gas before the air preheater is assumed to be the same as the CLPS. The boiler exhaust temperature decreases to 126°C in the LPPS. The performances of the LPPS are calculated, and the thermodynamic properties of the state points of the LPPS are shown in Table 2.

*Table 2. Thermodynamic properties of the state points of LPPS.*

Point	Substance	Temperature °C	Pressure MPa	Mass flow rate, kg·s <sup>-1</sup>	Exergy kJ·kg <sup>-1</sup>	Exergy flow, kW
2	Raw lignite	25	0.1013	187.9878	13080	2458900
3	Predried lignite	300	0.1013	122.9542	20111	2472700
4	Char	550	0.1013	84.7154	23913	2025800

9	Flue gas	350	0.1013	526.1187	119.11	62665
10	Flue gas	752.2	0.1013	526.1187	409.53	215460
11	Flue gas	1200	0.1013	526.1187	823.43	433220
12	Steam	550	0.1013	8.6068	927.96	7986.8
13	Tar	550	0.1013	6.4797	34652	224530
14	Air	25	0.1013	799.1080	0	0
15	Flue gas	126	0.1013	863.3152	18.178	15693
16	Water	284	30.400	527.7806	348.08	183710
17	Steam	323.3	4.8310	448.2778	810.70	363420
18	Steam	566	24.200	527.7806	1533.3	809260
19	Steam	566	4.3480	448.2778	1125.3	504460
20	Electricity	-	-	-	-	600000
21	Pyrolysis gas	550	0.1013	19.8079	17956	355670

By calculation, the thermal efficiency of the LPPS is 52.886% based on LHV, and 47.997% based on HHV. The exergy efficiency of the LPPS is approximately 48.00%.

4.1.2 Pre-dried pyrolysis coupled lignite-fired power system

The PPPS is put forward in previous part as shown in Fig.1. The parameters are assumed similar to those of the LPPS. The performances of the PPPS are calculated, and the thermodynamic properties of the state points are shown in Table 3.

Table 3. Thermodynamic properties of the state points of PPPS.

Point	Substance	Temperature °C	Pressure MPa	Mass flow rate, kg·s <sup>-1</sup>	Exergy kJ·kg <sup>-1</sup>	Exergy flow, kW
1	Raw lignite	25	0.1013	168.4627	13080	2203492
2	Predried lignite	99.6	0.1013	126.6086	17417	2205200

4	Char	550	0.1013	75.9166	23913	1815400
5	Steam	99.6	0.1013	41.8541	485.45	20318
6	Steam	200	0.1013	16.4249	545.46	8959.2
7	Steam	258.1	0.4232	53.4036	783.17	41824
8	Water	145.7	0.4232	53.4036	82.178	4388.6
9	Flue gas	420.96	0.1013	356.1046	162.25	57778
10	Flue gas	600	0.1013	356.1046	287.78	102480
11	Flue gas	1200	0.1013	356.1046	823.44	293230
12	Steam	550	0.1013	7.7129	927.96	7157.3
13	Tar	550	0.1013	5.8067	34652	201210
14	Air	25	0.1013	716.1097	0	0
15	Flue gas	126	0.1013	773.6530	18.177	14063
16	Water	284	30.400	527.7806	348.08	183710
17	Steam	323.3	4.8310	448.2778	810.70	363420
18	Steam	566	24.200	527.7806	1533.3	809260
19	Steam	566	4.3480	448.2778	1125.3	504460
20	Electricity	–	–	–	–	569870
21	Pyrolysis gas	550	0.1013	17.7506	17956	318730

By calculation, the thermal efficiency of the PPPS is 54.507% based on LHV, and 49.458% based on HHV. The exergy efficiency of the PPPS is approximately 49.46%. Obviously, due to the steam pre-drying process, the PPPS theoretical model can evidently increase the efficiency of the LPPS by approximately 1.46% based on the HHV, and by 1.62% based on the LHV at the calculation condition.

## 4.2. Energy and exergy analysis

### 4.2.1 Energy analysis

The energy flows and losses of the LPPS and PPPS are illustrated in Fig.2a and Fig.2b respectively. The energy input to the system is expressed by the HHV of raw lignite in order to avoid the phenomenon of “Non-conservation of energy”<sup>[8]</sup>. The energy outputs involve 14.46% in the pyrolysis gas, 9.13% in the tar and 24.40% in electricity. The highest amount of energy loss is from the turbine unit, followed by the drying furnace in the LPPS. 29.63% energy is extracted from the boiler unit and only 56.83% energy is transferred to the steam. Comparatively, the electricity output in the PPPS is improved by 1.46%. However, the pyrolysis gas and tar outputs are invariable because of the constant yield for the pyrolysis unit. Only 22.38% energy is extracted from the boiler unit and 63.42% energy is transferred to the steam. Using the energy analysis, the reason for the improved efficiency of the PPPS can be explained. The energy mostly discharged from the turbine is recycled by pre-drying lignite, and this energy is mainly transferred to the available energy in lignite.

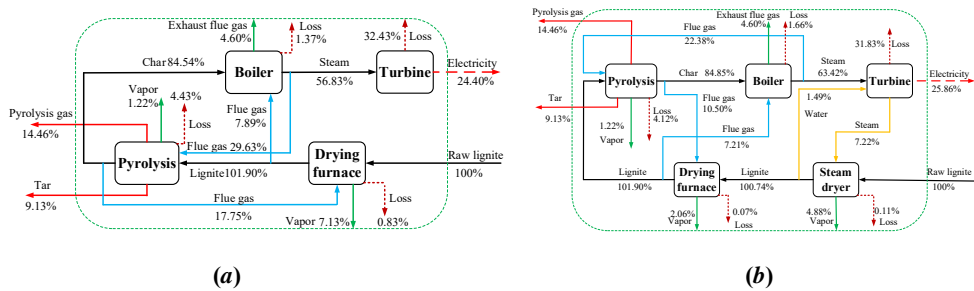

Fig.2 Energy flow and loss charts:(a)LPPS and (b) PPPS.

### 4.2.2 Exergy analysis

On the basis of the Table 2 and Table 3, the exergy flow, loss and destruction charts between the units of the LPPS and PPPS are illustrated in Fig. 3a and Fig. 3b, the data of which represent the exergy ratio to the input exergy of the system. The maximal loss and destruction in LPPS are the combustion process in the boiler unit, followed by the drying furnace unit. The low grade steam is firstly used to pre-dry the lignite, and then, the flue gas at the low temperature is used as the pre-drying heat source. In the whole drying process, the heat transfer temperature difference of PPPS is much lower than that of LPPS. Therefore, the exergy lost during the pre-drying is decreased significantly. Meanwhile, the lesser exergy extracting from the boiler also decreases the exergy lost in the boiler unit. Because of the exergy extracting, the lost in turbine is increased slightly. The exergy analysis suggests that the low heat transfer temperature difference and low grade energy recycling make the exergy efficiency increased.

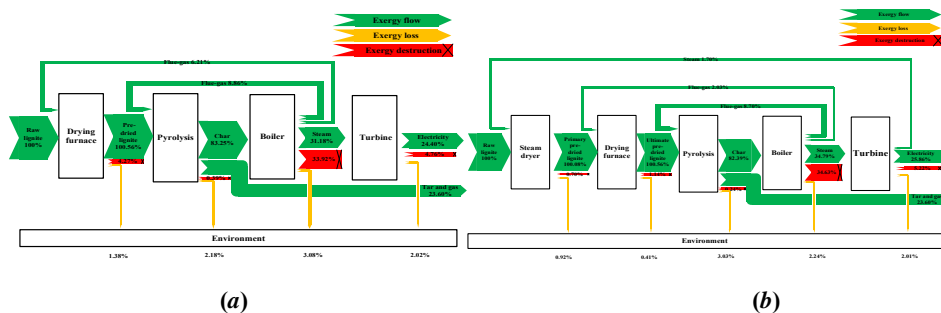

Fig.3 Exergy flow, loss and destruction charts:(a)LPPS and (b) PPPS.

## 5. Conclusions

A novel lignite-based energy system integrated with PPPS was proposed and thermodynamically analyzed in this paper. The thermal efficiency of the power system could be significantly increased by 1.62% (1.46%) based on the LHV (HHV). The energy mostly discharged from the turbine is recycled by pre-drying lignite, and this energy is mainly transferred to the available energy in lignite. The exergy analysis suggests that the low heat transfer temperature difference and low grade energy recycling make the exergy efficiency increased.

### **Abstract**

*In this study, effects of ohmic pretreatment on the drying rates and color kinetics of apple were investigated. Apple slices were treated at different electric field strengths (20-30 and 40 V/cm) at 60°C for 1 min. Drying process was applied at 60°C-2 m/s by using a tray-dryer.  $\Delta E$  and moisture content were calculated. These values were fitted to the semi-theoretical thin-layer drying and the zero and first-order kinetic model. The shortest drying time was found samples treated with 30 V/cm. Wang&Singh model gave the superior fit to the experimental data.  $\Delta E$  fitted well to the zero-order kinetic model.*

**Keywords:** : Ohmic heating, drying, kinetic models, thin-layer models, apple.

## **1. Introduction**

The main purpose of drying is to reduce the water activity in order to extend the shelf life. The dried product has the lowest microbiologic deterioration and enzyme activity.[1] Besides, quality attributes like aroma and the nutritional value are protected by reducing the moisture. The other purpose of the drying process is to provide convenience for transportation and storage via reducing the volume of product.[2] The drying process is generally applied to fruits and vegetables.

The apple which belongs to Rosaceae, the rose family, is a mild season fruit. Apple which has rich antioxidant components, carbohydrates, essential minerals and dietary fiber has a great importance in terms of taste and nutritional value [3]. North Anatolia, Black Sea shore region, Central Anatolia, and East Anatolia plateau are the fields in Turkey which are suitable for apple cultivation. In our country, mainly Starking, Golden Delicious, Star Crimson and Granny Smith are cultivated among 30 strains of apples from all over the world.[4]

Pretreatment of foods before drying takes place to reduce the drying time and also increase the quality of the product. There are different types of pretreatment such as hot-water blanching, osmotic dehydration, ultrasonication. Ohmic heating is one of the newest alternative pretreatment methods.[5-7] With ohmic process, the alternative electric current is passed through the food. The process is also called thermal processing method.[8]

Thin layer drying is the drying of food samples by layer. Thin layer drying has been taken part in several studies in recent years. The reason is the convenience of application and less data requirement.[9]

The main purpose of this study is to pretreat the apple samples (Golden Delicious variety) with ohmic heating and to dry using tray dryer. The samples were pretreated at different electric field strengths (20, 30, 40 V/cm) at 60°C for 1 minute. After the pretreatment process, the samples were dried by a tray dryer at 2 m/s air velocity at 60°C. Moisture ratio and changes in color were recorded. These values were fitted to the semi-theoretical thin-layer drying and the zero and first-order kinetic models.

## **2. Material and Methods**

### **2.1. Material**

Apples used in this study were bought from local market in Ankara, Turkey. They were peeled and cut into slices with dimensions of 15×15×5 mm. The initial moisture content of the fresh apple samples was 85±1% (wb) and it was measured by infrared moisture analyzer (MA150, Sartorius, Germany) at 105°C.

## 2.2. Methods

### 2.2.1. Ohmic Heating Pre-Treatment

Ohmic heating pretreatment was performed using (CLOH-1000, CLS, Turkey), specially designed and manufactured by Caliskan company. 90 mL of water was added to the 20 g of apple sample. Afterwards, apple slices were exposed to different electric field strengths (20, 30 and 40 V/cm) at 60°C for 1 min. Samples were filtered and weighed at the end of the process. All experiments were done in duplicates.

### 2.2.2. Hot-air Drying

Hot-air drying was performed in a tray dryer (Eksis, TK-LAB, Turkey). Samples dried without pretreatment was used as a control. The control samples were treated with air at 60°C and velocity of 2 m/s. For the main drying process, the ohmic pretreated samples were dried at 60°C and with an air velocity of 2 m/s. The weight of samples was recorded at 5 min intervals and drying was continued until no further variation in their weight were observed. The dried samples were cooled in desiccators and vacuum packed in heat-sealed low-density polyethylene bags.

### 2.2.3. Thin Layer Modelling

To define drying kinetics of apple samples, dimensionless moisture ratio (MR) values were calculated. MR were determined from moisture content data (kg water/kg db) obtained during drying by using equation 1:

$$MR = \frac{M_t - M_e}{M_0 - M_e} \quad (1)$$

where,  $M_t$ ,  $M_0$  and  $M_e$  are the moisture content at time  $t$ , the initial moisture content and the equilibrium moisture content of the sample (kg water/kg db), respectively.

Four different thin layer drying models (Table 1) were applied to drying curves. Sigma plot was used to predict model parameters. The model with the lowest Root Mean Square Error (RMSE) and the chi-square ( $\chi^2$ ) was defined as the best model describing the thin layer drying behavior of apple.[10] The parameters were calculated using equation 2 and 3.

$$RMSE = \left[ \frac{1}{N} \sum_{t=1}^N (MR_{exp,t} - MR_{pre,t})^2 \right]^{1/2} \quad (2)$$

$$\chi^2 = \frac{\sum_{t=1}^N (MR_{exp,t} - MR_{pre,t})^2}{N - n} \quad (3)$$

where  $MR_{exp;i}$  and  $MR_{pre;i}$  are the experimental and predicted moisture ratios of data  $i$ , respectively.  $N$  is the number of experimental data points and  $n$  is the number of constants in the model.

Table 1. Thin layer models equations

Model	Model Name	References
$MR=exp(-kt^n)$	Page	[11]
$MR=aexp(-kt)$	Henderson and Pabis	[12]
$MR=aexp(-kt)+c$	Logarithmic	[13]
$MR=l+at+bt^2$	Wang & Singh	[14]

#### 2.2.4. Color Values and Color Kinetics

The color values of dried and fresh apple samples were measured by using Minolta Color Reader (CR-400, Japan) and expressed as the CIE  $L^*$ ,  $a^*$ , and  $b^*$  color scale. The average of ten different readings from the same region was reported.

Total color differences were calculated using equation 4:

$$\Delta E = \sqrt{(L^*_0 - L^*_t)^2 + (a^*_0 - a^*_t)^2 + (b^*_0 - b^*_t)^2} \quad (4)$$

where  $L^*_0$ ,  $a^*_0$ ,  $b^*_0$  are the initial color measurements of raw apple samples and  $L^*_t$ ,  $a^*_t$ ,  $b^*_t$  are the color measurements at specified time.  $\Delta E$  values are applied to zero (equation 5) and first order (equation 6) kinetic models:[15]

$$C = C_0 \pm kt \quad (5)$$

$$C = C_0 exp(\pm kt) \quad (6)$$

where  $C_0$  is the initial value of color,  $C$  is the color value at a specified time,  $k$  is the kinetic rate constant and  $t$  is time.

### 3. Results and Discussions

The effect of electric field strengths on drying time was depicted in Fig. 1. The results showed that the samples treated with 30 V/cm electric field strength was found to have the shortest drying time. Compared to control group, ohmic heating pretreatment have decreased the drying time by 24, 35 and 29% for the samples treated with 20, 30 and 40 V/cm electrical field strengths, respectively. It was also observed that moisture ratio decreased continuously with drying time.

Fig. 1. Effect of electric field strenghts on drying time

The moisture ratio data were fitted to four different thin layer drying models (Table 1). RMSE (Root Mean Square Error),  $\chi^2$  (chi-square) and  $R^2$  (coefficient of determination) values were used to compare the relative goodness of fit of experimental data. The results showed that Wang & Singh model gave the superior fit to the experimental data compared to other models (Table 2). Similar model results were found in the other papers with different drying methods.[16-20]

Table 2. Statistical parameters and coefficients of models at different electrical field strengths for Wang & Singh model

Process Conditions	RMSE	$\chi^2$	$R^2$	a	b
Control	0.010166735	0.000116283	0.9978	-0.005576	-0.0000773
20 V/cm	0.010646449	0.000132238	0.9983	-0.001900	-0.0002048
30 V/cm	0.001837387	0.000004051	0.9987	-0.006242	-0.0002164
40 V/cm	0.002985566	0.000010534	0.9998	-0.006250	-0.0001698

Final color values and color kinetics of ohmic pretreated dried apples were determined in the study. The color differences ( $\Delta E$ ) were calculated by using the measurable color values ( $L^*$ ,  $a^*$  and  $b^*$ ) at different electrical field strengths. The  $\Delta E$  values were fitted to zero and first order kinetic models (Fig. 2 and 3). The results showed that the  $\Delta E$  values were fitted well to the zero-order kinetic model. Similar results can also be found in the literature.[21-25]

	C=C <sub>0</sub> exp(-kt)	0.785924	0.0263	0.9209

#### 4. Conclusions

Ohmic heating is an emerging thermal process technology. Ohmic heating can be used successfully as a pretreatment method in the drying process of food materials. As a conclusion in this study, the samples treated with 30 V/cm electric field strength was found to have the shortest drying time. Compared to control group, ohmic heating treatments have decreased the drying time by 24, 35 and 29% for the samples treated with 20, 30 and 40 V/cm electrical field strengths, respectively. Wang & Singh models gave the superior fit to the experimental data compared to other models. In addition, the color values fitted well to the zero-order kinetic model.

### **Abstract**

*Drying is an energy demanding industrial process and methods for reducing the energy consumption of drying is of interest to industry as well as society. This article presents the drying system of a biofuel factory. Steam is used as the refrigerant. Superheated steam is used as drying gas in a flash dryer with 28.8 tons/h dewatering capacity. The system includes an energy recovering water heat pump that receives its heat from the excess drying steam and heats the dryer. The SMER of the drying process ranges between 3 and 4 and the COP of the heat pump process ranges between 4 and 5.5 during one production season of peat drying. Variations in performance can be explained by variations in inlet moisture content and production rate. The example of this drying system shows the feasibility of drying in superheated steam, heat pump drying and water as refrigerant in high-temperature heat pumps.*

**Keywords:** *steam drying; heat pump process; peat; sawdust; industrial operation*

---

## **1. Introduction**

Methods for reducing the energy consumption of drying processes are of interest to industry as well as society. There is also a desire to replace fossil fuels with renewable fuels, such as fuel pellets or briquettes made from biomass. Compact biomass in the form of fuel pellets or briquettes has a higher heating value, lower moisture content and higher density than unprocessed biofuel; their properties are also more uniform. Pelletizing or briquetting thus improves transport properties as well as storage and combustion properties [1].

Wet biomass must be dried before briquetting and pelletizing. Various dryer designs can be chosen, depending on the properties of the material being dried and on available sources of energy [2]. Packed moving bed dryers can achieve the desired moisture content of 5-25 % at drying temperatures of 80-150 °C. They are relatively cheap, but require a larger installation area than other dryers. Rotary dryers are common for drying woodchips and sawdust. They operate reliably and enable heat recovery from the exhaust drying medium, which increases the energy efficiency of the system. Pneumatic dryers, also known as flash dryers, are compact and suitable for drying particles or granules [3]. In a flash dryer the particles are mixed with a high temperature drying gas, often air or flue gas, and transported by the drying gas at a high velocity. High flow velocity mixes well and gives high heat and mass transfer rates. The technology is, however, associated with high energy consumption. Typical energy consumption for a flash dryer is 4500-9000 kJ/kg of water [2], but energy efficiency can be improved by heat recovery of the exhaust drying medium [3]. In a flash dryer, steam can be used as drying gas. Steam has many advantages over air and flue gas. The energy advantage of steam as drying gas is that it simplifies heat recovery by enabling dryer integration, which is the factor that determines the energy efficiency of a steam dryer [4]. By recovering energy in a superheated steam drying process, more than 90 % of energy needs can be reduced [5]. As an example, a superheated steam flash dryer at Rockhammar mill, Sweden, uses 0.4-0.7 GJ per ton pulp whereas the same flash dryer with air as drying gas requires 3.0-3.5 GJ per ton pulp, a reduction by 75-90 % [6]. The environmental advantage of steam drying is that the dryer does not result in air pollution, since drying gas is not released into the atmosphere. The excess steam condensate will, on the other hand, need wastewater treatment as it can contain terpenes, fatty acids, formaldehyde and other types of contamination, depending on type of biomass and drying conditions. These organic compounds are released from the biomass as it is heated [7] [8] [9] [10] [4]. A further benefit of steam drying is that since there is no oxygen present in the dryer no oxidation can occur, this in turn leads to a minimal risk of ignition during operation [6].

Heat pump drying is a way of reducing energy consumption even further. It also brings additional benefits such as improved process control, which in its turn is beneficial for the quality of many dried products, such as foodstuffs. Drying of foodstuffs and timber are the two fields in which heat pump drying has so far reached the market [11]. The technology of

heat pump drying has been known for decades, but it is still under-exploited. Heat pump dryers are claimed to be complex systems: a change in one component brings changes to other components as well [11] [12].

This article describes an example of large-scale industrial heat pump drying of biofuel. In the heat pump drying system, steam is used both as drying gas in a flash dryer, and as refrigerant in a vapor compression heat pump cycle. It was designed by GEA Exergy and built by MoDo Chemetics in 1989 for peat drying, but is today also used for sawdust drying. Production data differs between sawdust and peat drying. To enable comparison with dimensioning data this article focuses on peat drying. The system layout is presented, along with its energy performance for one production season of peat drying. Variations in energy performance, deviation from dimensioning data, and experiences from operation are considered. Implications of this drying system for the design of future biomass dryers are finally discussed.

## **2. Materials and Methods**

The dryer is part of a stand-alone biofuel factory with two identical lines for drying, each one with a design capacity of dewatering 28 tons/h. The plan for 2016-2017 is to produce 83,000 tons of wood fuel pellets and 25,000 tons of peat fuel briquettes. This drying system uses steam both as drying gas in a flash dryer, and as refrigerant in a vapor compression heat pump cycle. These two steam cycles are never mixed. In this article, drying steam denotes steam in the drying cycle and refrigerant denotes the water vapor in the vapor compression cycle.

### **2.1. Dryer**

A flash dryer is used in which small particles of peat or sawdust are mixed with drying steam and transported through the dryer. Two fans in series circulate the drying steam. The dryer consists of five vertical shell-and-tube heat exchangers, each 20 meter high, as can be seen in Figure 1.

Refrigerant condenses on the shell side of the heat exchangers, transferring its latent heat to the drying steam. Drying steam and wet biomass flow inside the tubes. Each shell holds 73 or 97 tubes. The number of tubes increases with the direction of the drying process. Wear has caused some tubes to break, and to prevent leakage from the shell side to the tube side, these tubes have been welded shut, which reduces the heat transfer area of the dryer by 12 % in Line 1 and 8 % in Line 2 compared with design. The residence time of the biomass in the flash dryer is approximately 20 seconds.

*Fig. 1 The five 20m high heat tube shells.*

## **2.2. Biomass**

Inlet moisture content of the grinded peat varies between 55 % and 65 % during a season. Short-term variations in moisture content of incoming raw material can cause fluctuations in the system and need to be avoided, whereas the long-term variations are well known. Lower moisture content is found at the end of the summer and the moisture content then increases during winter due to outdoor storage.

The first step before drying is preheating. Preheating is done at atmospheric pressure with an excess flow of flash steam and venting steam that is in contact with the biomass. Since steam condenses on the biomass in the preheater, it is impossible to determine the temperature and moisture content of the biomass accurately as it enters the flash dryer. The biomass enters the dryer through a mixing chamber where it is mixed with the drying steam; it is then transported through the five heat exchangers of the flash dryer by the flow of drying steam. Dry biomass is separated from the drying steam in a cyclone. Before leaving the system, the material goes into the flash tank where the pressure is reduced to atmospheric pressure. The moisture content at the outlet is 8-10 %.

## **2.3. Refrigerant**

The refrigerant is water and works in a vapor compression heat pump process. After the compressor, the refrigerant pressure is 1.0-1.4 MPa and the temperature is 220-240 °C. At this state the refrigerant enters the flash dryer, where it is cooled down to its saturation temperature, condensates and leaves the dryer as saturated liquid. Its heat is transferred to the

drying steam and enables the water in the biomass to evaporate. In the superheater/subcooler, the liquid refrigerant is subcooled, thereby superheating the drying steam. The expansion valve is included in the steam converter, where the refrigerant pressure is dropped to 0.32 MPa. Liquid refrigerant receives heat from the excess drying steam and vaporizes. It then enters the four-stage turbo compressor as saturated steam at 0.32 MPa. The refrigerant mass flow rate is approximately 8 kg/s and the compressor has a maximum power consumption of 4.0 MW. If required, more refrigerant can be added to the system from a supply water tank included in the steam converter.

#### 2.4. Performance parameters

The Specific Moisture Evaporation Rate (SMER) is defined as

$$SMER = \frac{\text{amount of water evaporated}}{\text{energy input to dryer}} = \frac{m_{\text{excess steam}}}{w_{\text{compressor}} + w_{\text{fan}}}, \text{ kg/kWh} \quad (1)$$

The reciprocal of SMER is the Specific Energy Consumption (SEC);

$$SEC = \frac{\text{energy input to the dryer}}{\text{amount of water evaporated}} \quad (2)$$

In Equations 1 and 2, the amount of water evaporated is the same as the amount of excess steam condensate. The total energy supplied to the dryer is the electrical energy supplied to the compressor and the fans.

The COP, the coefficient of performance, determines the effectiveness of a heat pump process:

$$COP = \frac{\text{Desired output (heat)}}{\text{Required input (work)}} = \frac{Q_{\text{dryer}}}{w_{\text{compressor}}} \quad (3)$$

In Equation 3 the desired output is the heat released from the refrigerant as it condenses in the dryer and the required input is the electrical power to the compressor. The desired output ( $Q_{\text{dryer}}$ ), is calculated using Equation 4.

$$Q_{\text{dryer}} = (h_{\text{in}} - h_{\text{sat}} + h_{\text{fg}}) \cdot m_{\text{refrigerant}}, \text{ kW} \quad (4)$$

### 3. Results

Results are presented for the averages of the selected performance indicators and their variations during the production season. Dimensioning data of the factory are included for comparison. The average values of the performance parameters are reported in Table 1, in which the dimensioning data and operational data during 2014-2015 are compared. The dimensioning data represent the maximum capacity of the drying system under ideal conditions. As can be seen in Table 1, it was not operated at maximum capacity during the

production season of 2014-2015. The dewatering rate was approximately 76 % of the dimensioning value. It should be noted that the total power consumption was larger in the operational data, despite a lower production rate. Contrary to what could be expected based on production rate and power consumption, the value of COP is higher in operational data than in dimensioning data.

*Table 1. Average values of performance parameters along with dimensioning data.*

	Dimensioning data	Operational data	
		Line 1	Line 2
Production rate {tons/h}	22.2	13.8	15.6
Moisture evaporation rate (MER) {tons/h}	27.8	20.6	21.5
Inlet moisture content (MC) {%}	60.0	63.6	61.9
Total power consumption {kW}	5390	5680	5550
Coefficient of performance (COP)	4	4.32	4.64
Specific energy consumption (SEC) {kWh/ton}	210	276	260
Specific moisture evaporation rate (SMER) {kg/kWh}	5.16	3.63	3.87

#### 4. Discussion

As reported in Table 2, the operational data shows lower values of production rate and moisture evaporation rate than does the dimensioning data. This result is expected; the factory is not operated at its full production capacity. More interesting results from Table 2 is that both the total power consumption and the value of COP is higher during operation than in the dimensioning data. The lower refrigerant condensation temperature that is required to achieve the desired drying rate can explain the higher value of COP. As the temperature difference between condenser and evaporator of the heat pump cycle decreases, COP increases. This also explains the variations in COP that are seen during the season. In order to achieve a higher production rate, the discharge pressure of the compressor is raised, thereby raising the condensing temperature and decreasing COP. The larger value of total power consumption can perhaps be due to deterioration of the components after many years of use, and the decrease in heat transfer are that is seen due to wear. SMER ranges between 3 and 4 with averages of 3.63 and 3.87. As can be seen in Figure 8 and Figure 10, the maximum values of SMER and COP are not coinciding. This shows the importance of specifying both dryer performance, such as SMER or SEC, and heat pump performance,

COP, when reporting the performance of a heat pump dryer. The differences in performance between Line 1 and Line 2 are likely to be due to larger heat transfer area in Line 2.

The factory has supplied all data that are used in calculations of performance parameters. Data on power consumption and production rate are very important for their economic monitoring and should be considered as highly reliable. The only measurement that can be doubted on its quality is the refrigerant flow rate, which is used in the calculation of COP. Its average value is however correct and the average values of COP presented in this article can thereby be considered as reliable.

Heat pump performance and temperature range largely depends on the refrigerant used. Refrigerants today often have negative side effects on environment and human health and represent a fire hazard. Water has none of the negative side effects that are seen in other refrigerants. Using water as refrigerant enables heat pumps to reach higher temperatures; the temperatures needed for many industrial purposes. Water refrigerant heat pumps can thus find application both in upgrading waste heat into useful heat or steam, and in drying systems requiring a higher drying temperature than what can be reached with traditional refrigerants. The compressor is reported by scientific literature to be a challenging component in the water refrigerant heat pump, but in this drying system there have been no compressor problems. In high-temperature heat pump systems, water is the ideal refrigerant.

This heat pump dryer is a complex drying system. The drying cycle and the heat pump cycle are linked together both in the flash dryer and in the steam converter. Fluctuations in inlet moisture content of raw material will cause fluctuations in the amount of excess steam available for vaporizing the refrigerant. Finding and maintaining the energy balances at the right pressures represents a difficulty when operating the system as fluctuations causes variations in outlet moisture content and product quality. But this unique system has proven successful by running continuously with only small modifications from 1989 until today (2017).

## **5. Conclusion**

Knowledge from operation of this dryer is valuable for designing efficient new drying systems. It proves both that complexity does not have to be a problem for heat pump dryers and that water is an excellent refrigerant in high temperature heat pumps.

### **Abstract**

*The aim of this work was to evaluate the effect of inlet air temperature and gum Arabic concentration on yield of spray drying of soymilk and powder quality (moisture content, water activity and antioxidant capacity). Since soymilk had a significant lipid content, gum Arabic played a significant role as an emulsion stabilizer, improving process yield and preserving antioxidant capacity. However, temperature did not affect antioxidant capacity. The optimal condition to obtain higher antioxidant capacity was: 30% of gum Arabic and 160°C. The powder obtained under optimized condition was characterized regarding to bulk density, particle size distribution and morphology.*

**Keywords:** *soymilk; spray drying; ferric reduction power FRAP; DPPH scavenging ability; scanning electron microscopy.*

---

## 1. Introduction

Recently, the ready-to-drink soymilk has become popular, in which sales volume of worldwide in 2015 reached 13.5 billion liters<sup>[1]</sup>. Vegan and healthy diet followers are one of the major consumers because it is lactose- and gluten-free beverage and contains high-quality proteins, dietary fiber and antioxidant compounds, such as phenolic compounds<sup>[2,3]</sup>. However, some conservation method is necessary in order to increase its shelf life. Of the several drying methods, spray drying is suitable for heat-sensitive products, such as soymilk, promoting higher retention of nutrients due to the short residence time<sup>[4]</sup>.

When exposed at higher temperature during spray drying, fat present in soymilk (18 g/100 g solids)<sup>[5]</sup> becomes molten, resulting in particle adhesion on the dryer chamber and low product recovery<sup>[6]</sup>. Part of this problem can be solved by adding a carrier agent to the feed solution before drying, in order to decrease the fat content<sup>[7]</sup>. Moreover, since soymilk is an oil-in-water emulsion, the thermodynamic instability of this system can result in larger oil droplets due to coalescence of droplets dispersed in soymilk. The larger the oil droplets are, the higher the breakup during atomization of the emulsion in the spray dryer chamber<sup>[8]</sup>. This breakup of the emulsion favors the increase in of the surface oil, decreasing the product recovery<sup>[9]</sup>. Thus, the addition of carrier agent with good emulsifying properties, such as gum Arabic, enhances emulsion stability and, as consequence, product recovery.

The objective of this work was to evaluate the effect of inlet air temperature and gum Arabic concentration on the process yield and powder quality (moisture content, water activity and antioxidant capacity).

## 2. Materials and Methods

### 2.1. Material

Soybean (*Glycine max* (L.) Merr.) cultivar BRS 257, which is lipoxygenase-free, was acquired from SL Alimentos (Mauá da Serra, Brazil). Gum Arabic (GA) Instantgum BB (Nexira, São Paulo, Brazil) was used as the wall material. DPPH 2,2-diphenyl-1-picrylhydrazyl and TPTZ 2,4,6-tris(2-pyridyl)-S-triazine were used as reagent for the analysis of antioxidant capacity, and Trolox 6-hydroxy-2,5,7,8-tetramethylchroman-2-carboxylic acid as standard (Sigma-Aldrich, Saint Louis, USA).

### 2.2. Preparation of soymilk

Soymilk was obtained according to Baú and Ida<sup>[2]</sup>. About 3 kg of soybeans were soaked in water at 1:3 ratio (w:w, soybean:water) for 12 h at 8°C. The grains were drained and homogenized with distilled water at 1:8 ratio (w:w, soybean:water) using an industrial blender. The slurry was filtered and pasteurized at 90°C for 3 min, obtaining the soymilk. The chemical composition of soymilk, obtained by AOAC<sup>[10]</sup>, was (wet basis): moisture

content of  $94.8 \pm 0.1\%$ , ash content of  $0.2 \pm 0.0\%$ , lipid content of  $1.3 \pm 0.1\%$ , protein content of  $2.4 \pm 0.0\%$  and carbohydrate content, calculated by difference, of  $1.4\%$ . Samples were stored at  $-18^\circ\text{C}$  and thawed according to the quantity required for spray drying.

### 2.3. Spray drying of soymilk

Before spray drying, gum Arabic was dissolved in soymilk at different concentrations (Table 1) using a magnetic stirrer. After, the mixture were homogenized at 20,000 rpm for 5 min in order to emulsify the fat soymilk and break up the clots, returning to a fluid consistency. About 400 g of feed solution were fed into the laboratory scale spray dryer (MSD 1.0, Labmaq, Ribeirão Preto, Brazil) by a peristaltic bomb at flow rate of 0.4 L/h. The feed solution was atomized into spray dryer chamber by a two-fluid atomizer spray nozzle with an orifice of 0.7 mm in diameter, using compressed air at flow rate of 40 L/h. Inlet air temperature was used according to Table 1. For each assay, the collected powder was weighed for subsequent calculation of process yield, which was the ratio of total solids mass in the powder to total solids mass in the feed solution.

Spray drying experiments were carried out according to a central composite rotatable design (Table 1) in order to evaluate the effect of inlet air temperature and gum Arabic concentration on the responses process yield, moisture content, water activity and antioxidant capacity. Experimental data were fitted to Equation (1) [11].

$$y = b_0 + b_1x_1 + b_2x_2 + b_{11}x_1^2 + b_{22}x_2^2 + b_{12}x_1x_2 \quad (1)$$

Where:  $y$  is the response,  $b_0$ ,  $b_1$  and  $b_2$ ,  $b_{11}$  and  $b_{22}$ , and  $b_{12}$  are the constant, linear, quadratic and cross-product regression coefficients, respectively, and  $x_1$  and  $x_2$  represent the coded values of the  $T_{in}$  and GA variables, respectively.

Regression coefficients of the predictive models were obtained by the Protimiza software (<http://experimental-design.protimiza.com.br>). Coefficients within a confidence level above 90% were considered significant ( $p < 0.1$ ). Non-significant terms were eliminated, and the model was tested for adequacy by analysis of variance (Anova), coefficient of determination ( $R^2$ ) and F-test. For powder moisture content, the analysis of results indicated the model was linear, and the expansion of the screening design to a central composite rotatable design, with the addition of axial points (tests 5 to 8), was not necessary.

## 2.4. Analytical methods

### 2.4.1. Physicochemical properties of the powders

Moisture content was determined gravimetrically in triplicate in an oven at 105°C for 24h<sup>[10]</sup>. A thermohygrometer Aqualab (4 TEV, Decagon, Pullman, USA) was used to measure water activity at 25°C. Bulk density was calculated by dividing the mass of powder by the volume occupied in the cylinder after tapped by hand. Particle size distribution and mean diameter particle D<sub>43</sub> were obtained, in triplicate, using a laser light scattering analyzer (Mastersizer, model 2000, Malvern, UK). Particle microstructures were evaluated by a scanning electron microscope (Leo 440i, LEO Electron Microscopy/Oxford, Cambridge, England).

#### 2.4.2. Antioxidant capacity of the powders

Prior to the analysis, 0.5 g of powder were dissolved in 8 mL of distilled water. Antioxidant capacity by donating hydrogen atoms to the DPPH radical and by ferric reduction power FRAP were determined according to Brand-Williams et al.<sup>[12]</sup> and Benzie and Strain<sup>[13]</sup>, respectively. For DPPH and FRAP method, after reaction, the sample absorbance was measured at 517 and 595 nm, respectively, using an UV-visible spectrophotometer. Analytical curves with different concentrations of Trolox, ranging from 1,000 to 5,000  $\mu\text{M}$  for DPPH and 50 to 600  $\mu\text{M}$  for FRAP method, were used for the subsequent calculation of the results in  $\mu\text{mol}$  Trolox equivalent (TE)/g of soymilk solids. All assays were performed in triplicate.

### 3. Results and discussion

#### 3.1. Spray drying of soymilk

The regression coefficients for the responses, F-values, p-values and  $R^2$  are presented in Table 1. After exclusion of non-significant terms ( $p > 0.1$ ), the predictive models were tested for accuracy of fit by Anova. When the calculated F-value  $F_c$  was greater than the tabulated F-value  $F_t$ , the variation was explained by the regression and not by the residues. Thus the regression was significant, and the model could be considered predictive. Figure 1 shows the response surfaces generated by the proposed models.

Analyzing Figure 1(a), GA had greater influence on process yield than  $T_{in}$ . As expected, the increase of GA up to 22.5% enhanced powder recovery, since the addition of carrier agent decreased the fat content in the feed solution. This fact reduces the particle adhesion on the dryer chamber, which could occur due to the fat melting during spray drying<sup>[7]</sup>. However, an opposite behavior could be seen at GA above 22.5%. This result can be related to the high powder moisture content (Fig. 1(b)). Higher carrier agent concentration increases the feed viscosity, resulting in greater droplets atomized during spray drying. Thus, there is a poor heat and mass transfer between the droplets and drying air, resulting in the formation of wetter and sticker particles.

The antioxidant capacity of spray-dried soymilk ranged from 168.3 to 543.3  $\mu\text{mol}$  TE/g for DPPH and 25.1 to 46.6  $\mu\text{mol}$  TE/g solids of soymilk for FRAP method. Since soymilk solution presented  $742.6 \pm 36.2$  and  $200.2 \pm 6.2$   $\mu\text{mol}$  TE/g solids, there was a retention of antioxidant capacity varying from 22.7 to 73.2% and 12.5 to 23.3%, for DPPH and FRAP methods, respectively. Figures 1(c) and 1(d) show the positive effect of gum Arabic concentration on antioxidant capacity for both methods. Since soymilk had a significant lipid content, gum Arabic played a significant role in spray drying as an emulsion stabilizer, encapsulating and preserving the antioxidant substances present in soymilk.

**Fig. 1.** Influence of independent variables on the responses: (a) process yield, (b) moisture content and (c) antioxidant capacity by DPPH and (d) FRAP methods

### 3.2. Characterization of the powder obtained under the optimum condition

Higher process yield and antioxidant capacity were obtained at 160°C and 30% of GA. Under this optimum condition, process yield was 58.7%. The powder presented moisture content of  $1.5 \pm 0.2\%$ , antioxidant capacities by FRAP and DPPH methods of  $38.9 \pm 1.6 \mu\text{mol TE/g}$  and  $586.0 \pm 0.1 \mu\text{mol TE/g}$ , respectively; bulk density of  $0.40 \pm 0.01 \text{ mg/ml}$  and mean diameter size of  $9.18 \pm 0.33 \mu\text{m}$ . Particle size distribution and the morphology evaluated by scanning electron microscopy were shown in Figure 2. Particles presented a continuous wall without fissures or cracks. Such characteristics is desirable to effectively protect the antioxidant compounds. However, particles had an irregular structure, which adversely affect the flow properties of the powders. This morphology can be result from slow film formation during drying of the atomized droplets, causing their shrinkage during the final stages of drying and cooling<sup>[14]</sup>.

Fig. 2. Particle size distribution (a) and micrograph of the spray-dried soymilk with magnification of  $\times 2000$  (b)

#### 4. Conclusions

This work demonstrated the significant role of gum Arabic in spray drying of soymilk as an emulsion stabilizer, since there was an improvement on product recovery and retention of antioxidant capacity. In order to obtain maximum process yield and antioxidant capacity, the optimal condition was proposed: 30% of GA and 160°C, in which process yield was 58.7%. There was a significant retention of antioxidant capacity by donating hydrogen atoms to the DPPH radical (78.9%) after spray drying; however only 19.4% of ferric reduction power of soymilk solution was preserved.

#### 5. Nomenclature

Aw	water activity	
DPPH	DPPH scavenging ability	$\mu\text{mol TE/g soymilk solids}$
FRAP	ferric reduction power	$\mu\text{mol TE/g soymilk solids}$
GA	gum Arabic concentration	%
T <sub>in</sub>	Inlet air temperature	°C
X	moisture content	% (wet basis)
Y	process yield	%

### **Abstract**

*A mathematical model was established to predict the mean value and variance of tobacco strip during drying processing, based that the physical and chemical properties of tobacco strip as agriculture products show probability distributions. The results show that the model can predict the mean value of moisture content at different times, and there is a certain deviation in predicting the variance of moisture content at initial stage of drying process. However, the prediction value of the variance of tobacco strip is much more accurate while the moisture content is between 8% and 10%, which is the interval of quality requirements.*

**Keywords:** tobacco strip; drying; mean value; variance model.

---

## **1. Introduction**

The studies on the drying process of tobacco raw materials[1] focused on the dynamic characteristics of water migration, due to its important effect on the physical and sensory quality of tobacco products[2-3]. Moreover, the water stability was an important product quality control target in the drying process. The current researches on the dynamic drying process of tobacco materials mainly involved the prediction of the water migration law under different drying methods, temperatures, humidities and pressures through thin layer models, semi experiences and empirical models[4-6]. However, as a agricultural product, tobacco raw materials did not have the uniform physical and chemical properties, always showing widespread characteristics. Tobacco strip was constantly switched between the humidifying section and the drying section, leading to a non-equilibrium state during the dynamic processing of tobacco strip. Therefore, It is difficult to describe the production stability by the mean moisture content of tobacco strip. In this study, the Newton model was selected as the basic model for describing the drying processing of tobacco strip. Combining the approximate calculation method of the mean value and variance of multidimensional continuous random variable nonlinear function, a prediction model of water stability was finally established to describe the mean value and variance of tobacco strip's moisture content during the drying processing of tobacco strip. Moreover, the model validation was carried out by comparing with the measured experimental data.

## **2. Materials and Methods**

### **2.1. Materials**

The experimental tobacco samples included tobacco strips(C<sub>2</sub>F and C<sub>2</sub>L, 2015) from Fujian, Jiangxi, Hunan, Sichuan, Anhui, Henan, Jilin, Liaoning and other provinces.

The length and width of tobacco strip samples were about 2cm×2cm, and the tobacco strips were put into a constant temperature and humidity box with 40°C and 80% relative humidity(RH), equilibrated 24 hours, then were sealed in self-sealing bag.

### **2.2. Measurement of tobacco strip's equilibrium moisture content**

The equilibrium moisture contents of tobacco strip samples were measured by an test device for tobacco isothermal adsorption/desorption property. The mass of samples were 1.0g, The gas flow rate was 4800ml/min, the drying temperature was set at 70°C, the relative humidity was set to 30%, and the drying time was 2h. The equilibrium moisture contents were calculated by the final mass and the initial mass of tobacco strip samples.

### 3. Prediction model of moisture content stability during tobacco strip drying process

Although tobacco strip drying process were carried out under the same temperature and humidity treatment conditions, the initial moisture content, the balance moisture and the drying rate of the tobacco strip samples showed random distribution. Therefore, the drying model should be further established base on its probability distribution characteristics.

#### 3.1. The mathematical expectation and approximate variance

When each factor is a continuous random variable, and the influence to the result is a nonlinear function, the expectation and variance of the random variable function can be calculated by an approximate method. The calculation method is to expand the nonlinear function of the random variable at its expected value Taylor series, abandon the high order term and calculate the expectation and variance of the random variable function. For multivariate random variables, the expression of mathematical expectation and variance is as follows:

If  $x_i$  ( $i=1, 2, \dots, n$ ) were the independent random variables, the mathematical expectation  $E(x_i) = \mu_i$ , the variance  $D(x_i) = \sigma_i^2$ , and the random variable function  $Z(x_i) = g(x_1, x_2, \dots, x_n)$  has two order continuous partial derivative at point  $(\mu_1, \mu_2, \dots, \mu_n)$ , then the mathematical expectation

$$E(Z) \approx g(\mu_1, \mu_2, \dots, \mu_n) + \frac{1}{2} \sum_{i=1}^n \frac{\partial^2 g}{\partial x_i^2} \sigma_i^2 \quad (1)$$

And the approximate variance

$$D(Z) \approx \frac{1}{2} \sum_{i=1}^n \left( \frac{\partial g}{\partial x_i} \right)^2 \sigma_i^2 \quad (2)$$

#### 3.2. Newton drying model based on multidimensional continuous random variables

The Newton model was used as the basic drying model, and the decision coefficient( $R^2$ ) and the chi square( $\chi^2$ ) were used for the evaluation of the model. For Newton model, the drying rate is proportional to the moisture content.

$$\begin{aligned} \frac{dx}{dt} &= -k(x - x_e) \\ x(0) &= x_0 \end{aligned} \quad (3)$$

In the upper formula,  $x$ ,  $k$ ,  $x_e$  and  $x_0$  respectively indicate the mean value of the moisture content(db.), drying rate constant, equilibrium moisture content(db.) and initial moisture content(db.) of tobacco strips. The relationship between water and time is obtained as follows by solving the above equations.

$$x(t) = (x_0 - x_e) \exp(-kt) + x_e \quad (4)$$

During the actual drying process of tobacco strips,  $\sigma_k^2$ ,  $\sigma_e^2$  and  $\sigma_x^2$  respectively indicate the variance value of drying rate constant, equilibrium moisture content(db.) and initial moisture content(db.) of tobacco strips. As the drying rate constant, equilibrium moisture content(db.) and initial moisture content(db.) of tobacco strips were independent, The moisture content's mean and variance value of tobacco strips at  $t$  time could be calculated as follows as a mean and variance of a random variable function.

$$E[x(t)] \approx [(x_0 - x_e) \exp(-kt) + x_e] + \frac{1}{2}(x_0 - x_e) \exp(-kt) t^2 \sigma_k^2 \quad (5)$$

$$D[x(t)] \approx \exp(-2kt) [\sigma_x^2 + (x_0 - x_e)^2 t^2 \sigma_k^2 + \sigma_e^2] - 2 \exp(-kt) \sigma_e^2 + \sigma_e^2 \quad (6)$$

From the formula (5) and (6), the mean and variance values of moisture content during the actual drying process could be calculated by mean values of Newton model parameters, and the error decreased with exponential function. Moreover, the variance of moisture content decreased exponentially with the increasing drying time, and finally decreased to the variance of equilibrium moisture content ( $\sigma_e^2$ ).

## 4. Results and discussion

### 4.1. The drying kinetic curves of tobacco strips

The drying kinetic curves of 83 types of tobacco strips samples from different localities were obtained under the drying temperature of 70°C and 30% RH(Fig. 1). The above results showed that, the initial moisture contents of the sample were distributed in an interval after the same pretreatment, and the moisture contents changed at different drying rates. Moreover, the moisture of the tobacco strips rapidly decreased at the initial stage during a fast drying stage. Then the drying rates reduced gradually leading to a slow drying process, and finally reached the equilibrium moisture contents under the drying condition. The distribution of the equilibrium moisture contents was more concentrated. The moisture content decreased with exponential trend during the whole drying process.

Fig. 1 The drying kinetic curves of tobacco strips.

#### 4.2 Probability statistics

The frequency (H) distribution of the initial moisture content, equilibrium moisture content and drying rate constant (k) of Newton model under the same drying conditions were shown in Fig. 3. The results indicated that the initial moisture content, equilibrium moisture content and drying rate constant had the same normal distribution form and all the decision coefficients ( $R^2$ ) of Newton model were higher than 0.985, showing that the Newton model was suitable for calculating these drying process. The correlation analysis of the initial moisture content, equilibrium moisture content and drying rate constant (k) of Newton model was shown in Table 1. The results showed that these above factors had weak positive correlation and negative correlation, according with the model requirements for independent variables.

Fig. 2 The frequency (H) distribution of the initial moisture content, equilibrium moisture content and drying rate constant (k) of Newton model under the same drying conditions

Table 1. The correlation analysis

Factor	k	The initial moisture content	The equilibrium moisture content
k	1		
The initial moisture content	-0.296	1	
The equilibrium moisture content	-0.457	0.545	1

### 4.3 Model validation

The predicted moisture content's mean and variance values during the drying processing of tobacco strips were compared with the measured values in Fig. 3. The results showed that the difference between the predicted and measured mean values of tobacco strips moisture content (db.) was relatively small, which indicated that this model could predict the mean value of the whole drying process. Moreover, the difference between the predicted and measured variance values of tobacco strips moisture content (db.) increased first and then decreased, while the predicted variances obtained by approximate method were a little smaller than the actual statistical value, due to the nonlinearity of Newton model and a certain correlation of these model parameters. It was worth noting that the target moisture (db.) in the typical tobacco strips drying processing were between 8.7% and 11.1%, which was included in the critical area of free water and combined water. In this moisture content interval, the difference between predicted values and measured values became rather small, which indicated that the predicted model was reliable between the moisture content interval of the drying process quality requirement.

Fig. 3 The measured and predicted moisture content's mean and variance values during the drying processing of tobacco strips.

## 5. Conclusion

Combining the approximate calculation method of the mean value and variance of multidimensional continuous random variable nonlinear function, a mean and variance prediction model of the tobacco strips' moisture contents during the drying process was established base on Newton model. Moreover, the distribution and linear correlation between the initial moisture content, equilibrium moisture content and drying rate constant were discussed, which was consistent with the application requirements of the model. The predicted model showed good performance on the prediction of mean moisture contents during the whole drying process. The prediction of moisture contents' variance had a certain deviation in the initial drying stage, while the predicted variances were more accurate between the moisture content (db.) interval (8.7%~11.1%) of the drying process quality requirement, which was included in the critical area of free water and combined water.

### **Abstract**

*The aim of this work was to determine the microwave drying kinetics of *Eucalyptus Gomphocephala* wood and to investigate the influence of intermittent and continuous heating processes on the end quality of dried samples. The average moisture content evolution and temperature of wood samples under different microwave powers were analyzed in terms of drying time and internal temperature level. Results show that the increase of microwave power level decreases the drying time and increases the internal wood temperature. Based on qualitative observations on the state of dried samples, the intermittent microwave powers intensity process present the optimal processing parameter in microwave drying of *Eucalyptus* wood species.*

**Keywords:** *microwave drying; power; intermittent; continuous; *Eucalyptus* wood.*

---

## 1. Introduction

Drying is an operation process consisting of the removal or reduction of water from a product. This process is often used as a final production step before selling or packaging products, especially wood, to ensure its structural stability, to remove fungal attacks and to improve its mechanical performance... There are different methods of drying wood, and the majority of industrial dried timber is processed with convective drying. This conventional drying of wood is slow and costly process [1]. For that reason, interest is oriented to study the electro heating technology of wood, in particular, microwave energy for specific applications in the wood industry to achieve specific objectives, such as reducing the drying time and energy consumption, accelerate internal transfers of mass and heat and providing good mechanical properties with high strength [2,3].

The principle of microwave heating is based on the concept of internal generation of heat. If wood is exposed to an electromagnetic field with such high frequency as is characteristic for microwave, the water molecules, which are dipoles, begin to rotate at the same frequency as the electromagnetic field. At a frequency of 2.4 GHz the alternating electric field component oscillates very quickly and the strong agitation, provided by cyclic reorientation of molecules, produce friction of water molecules can result in an intense internal heating of wood [3,4]. The interaction between microwave and wood material depends on power and frequency of microwave oven, on geometric and dimensions of the wood sample, on water content and the dielectric properties [4]. During drying, moisture, temperature, and gas pressure gradients involve product shrinkage and then development of strain and stress fields inside the Eucalyptus wood samples. So, the quality of drying of eucalyptus wood vary according to the type of microwave drying. According to our bibliographic research, few published works concerning the impact of microwave heating on qualitative behavior of dried Eucalyptus wood and no information about Gomphocephala wood has been published, and there is a lack of information on the continuous and intermittent microwave heat treatment of Eucalyptus wood. Intermittent drying is based on oscillating of operation conditions such as the temperature, relative humidity, speed of the air flow... This technique should make it possible to relax some of the mechanical stress induced by drying inside the material [5]. Microwave drying under controlling conditions has been the subject of some research works. Lars H. [6] has shown that microwave drying under controlled temperature conditions reduces internal stress and prevents checks of samples. L. Hansson, A.L. Antti (a) [7] showed that controlled microwave drying can improve a better wood resistance in a shorter drying time and the results are comparable to those obtained by conventional drying. In addition, Bruno Monteiro Balboni et al [8] have shown that drying at high microwave power produces reductions of wood strength and more drying defects than low microwave power. The

present work is particularly interested in the microwave drying of Eucalyptus wood (Gomphocephala) from the northeastern region of Tunisia. Kinetics of intermittent and continuous microwave drying of wood sample under different microwave power were analyzed in order to determine the drying temperatures levels and to evaluate the potential of microwave irradiation on the final behavior of dried wood.

## 2. Materials and Methods

### 2.1. Eucalyptus wood (Gomphocephala)

Eucalyptus trees are characterized by their ecological plasticity and their rapid growth. It covers 18 million ha in 90 countries in the world. Eucalyptus is mainly used in the wood industry and it is also used as an energy source or in building. Previous studies have shown that Eucalyptus wood has a specific sensitivity during final drying as collapse, cracks and warps [9]. The samples of green Eucalyptus wood used in this work were recommended by the INRGREF. The samples are rectangular (30\* 5 \* 2 cm<sup>3</sup>) size boards, sawn in the fibers direction (longitudinal direction) and have an initial average moisture content of 52%, (Fig.1). The mass of dry wood was obtained after keeping the samples in a controlled temperature oven at 103°C until a constant mass was reached. These samples are wrapped with cellophane paper and stored in a refrigerator until the date of the experiments to retain their green state properties. The drying conditions achieved are presented in (Table 1).

Fig.1 Eucalyptus tree (Gomphocephala): region of Oued Ksab, Tunis, Tunisia.

Table 1: Parameters of continuous and intermittent microwave heat treatment for different microwave power.

Drying conditions	Microwave power (Watt)	Continuous drying (min)	Intermittent drying (min)		
			Total drying	Microwave drying	One complete "on -off" cycle
P <sub>1max</sub>	300	95	1020	780	7
P <sub>2max</sub>	500	40	736	363	15
P <sub>3max</sub>	1000	12	445	180	25

## 2.2. Drying unit: Laboratory Microwave oven

The experimental setup used in this work is a laboratory microwave oven (Fig.2) with a working cavity of 34 x 33 x 20 cm<sup>3</sup>, a relative humidity ranging from 10 to 90% and a vapor extracting system. This microwave oven operating at 2.45 GHz frequency is able to provide a maximum power of 1000 W. During the drying process, the lumbers were placed at the center of the drying chamber and removed periodically to measure their mass. The wood temperature is also measured during the experiment. The product moisture content in the dry basis (kg of water/ kg of dry matter) is calculated according to the following relationship:

$$M(\%) = \frac{W - W_d}{W_d} \times 100 = \frac{W_{\text{water}}}{W_d} \times 100 \quad (1)$$

The moisture content ratio was given by the following equation:

$$MR = \frac{M}{M_{\text{ini}}} \quad (2)$$

*Fig.2: Laboratory microwave oven BP-301.*

## 3. Results and discussion

### 3.1. Kinetics of continuous and intermittent microwave drying

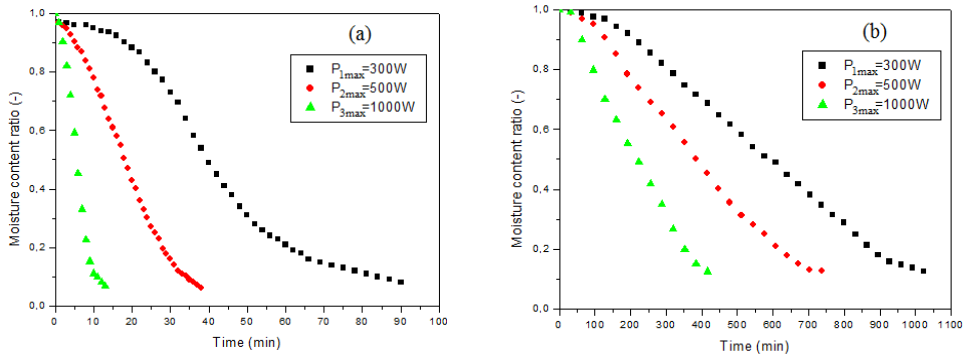

The effect of microwave power on the evolution of the average moisture content of Eucalyptus wood (Gomphocephala) is shown in (Fig.3). For both kinds of drying an increase of microwave power decreases the drying time and increases both the core temperature and therefore the internal gas pressure of wood sample.

Figure4 shows the simultaneous evolution of the average moisture content and the temperatures of the top surface, the bottom surface and the center of the wood during for a continuous microwave drying at a high level of microwave power. The beginning corresponds to a warming phase where temperature evolves quickly and water content drops slightly. The second phase corresponds to a vaporization phase where temperature is mostly constant near 100°C and water content decreases rapidly. The third phase is the

heating one, where the loss of water slows down and the temperature of the wood increases. This behavior is similar to those observed by other researchers [10].

### 3.2. Influence of continuous and intermittent process on final quality of dried wood

At this section we will focus on qualitative evaluation of the impact of continuous and intermittent heat treatment on the final quality of dried Eucalyptus wood. The adopted approach is based on qualitative observations on the final state of the dried wood in terms of deformations, warping, slits, checks, splits and colorations.

**Fig.3: Moisture content versus time for different drying conditions.(a) continuous drying; (b) intermittent drying.**

**Fig.4: Core and surfaces temperature and moisture content versus time at high microwave power.**

These observations are illustrated by photos of the wood samples relating to each type of drying achieved. Figure5 shows the wood sample dried continuously under high microwave power (1000W). After 12 min of drying, the black color appears indicating a carbonization of the ligneous material of the wood.

**Fig.5: Effect of continuous microwave drying of wood at a maximum power (1000 W).**

In addition, the darkening is located in the center of the plate illustrating the intense internal volumetric heating in the case of microwave heat treatment [11]. In the case of of continuous drying process under 500 Watts of microwave power, these defects are observed at the end of drying (Fig.6).

**Fig.6: Effect of continuous microwave drying of wood at 500 W; Before and after drying.**

During a rapid drying at high microwave power, an over gas pressure is generated under the increasing of internal temperature of wood. The temperature increases continuously (up to 120°C) and passes through the boiling point of water and the resultant intense internal gas pressure pushes the water, so the mixture of water and gas will be forced out from the wood. Indeed, the high microwave power generate the over gas pressure inside the wood, which can break some intercellular bonds and causes internal checks, cracks and fissures in the wood structure. In order to avoid the problems related to the overpressure of the internal gas and the carbonization of wood material due to high temperatures, it is necessary to apply relatively low microwave power. Also, under the low microwave power 300 Watts we observed the warping of the wood samples at the end of the continuous drying process (Fig.7). Indeed, temperature increases on the board surface. The degradation occurs in wood heated above 100°C, and can affect the chemical constituents of the cell wall or cause major structural damage. This effect was already observed by Eva Hermoso et al.[12].

**Fig.7: Effect of continuous microwave drying of wood at 300 W of power; Before and after drying.**

The second solution proposed in this study is to apply an intermittent drying process. This process is only considered at the microwave power level, and the conditions of drying are shown in (Table 1). The qualitative observations are illustrated by the photos of dried wood samples, (Fig.8). It is observed that drying defects related to the level of microwave power in the continuous drying are absent in the intermittent drying. The absence of the various defects can be explained by the cooling of wood sample and mechanical stress relaxation during the intermittency phase.

*Fig.8: Effect of intermittent microwave drying of wood at 500 W; Before and after drying.*

One can notice that oscillation of the microwave power between 0 and  $P_{max}$  increases drying time compared to continuous drying (See Figure 3) but allows to reduce average temperature and internal gas phase. The optimization of the intermittency phases make it possible to optimize drying in terms of drying time and wood quality.

#### 4. Conclusions

The experimental results indicated that increasing the microwave power decreases the drying time and increases both the core temperature and the internal gas pressure of wood samples. The phenomenon of internal heat generation during microwave drying wood was verified by the temporal evolution of temperature curves. A qualitative analysis of dried wood samples proves that the intermittent microwave drying reduces the defects related of drying and improved product quality compared with continuous microwave drying. As an extension of this work, mechanical tests of axial compression and static bending strength will be held. Optimization of intermittency phases will be also carried by the help of modelling heat, mass and mechanical behavior of wood sample on intermittent microwave drying.

#### 5. Nomenclature

P	Microwave power	Watt
T	Temperature	°C
W	Wood sample mass	kg
$W_{water}$	Water mass	kg
$W_d$	Wood sample dry mass	kg
$M_{ini}$	Initial moisture content	kg water/kg DM

### **Abstract**

*Acerola (Malpighia emarginata D.C.) is a tropical fruit which has attracted recent industrial interest, due to its high levels of bioactive compounds and vitamin C. However, acerola processing generates a substantial amount of wastes, which can represent up to 40% of total processed volume. The drying of acerola residues in a new dryer, developed by our research group, named as roto-aerated dryer, has been investigated. This dryer provides a better fluid-particle contact than the conventional rotatory dryer. A pre-drying system with infrared lamps has been installed in the feed of this new dryer. The effect of the pre-treatment of this fruit residues with ethanol was also investigated. The results shown that the roto-aerated dryer assisted by infrared radiation hybrid combined with a pre-treatment with ethanol is a good alternative for processing fruit residues, aiming their reuse. It was possible to identify conditions under which the phenolic, flavonoid, and antioxidant capacity presented high levels after drying. The main phenolic compounds were identified by HPLC.*

**Keywords:** Drying; roto-aerated dryer; infrared; acerola

---

## **1. Introduction**

Byproducts of fruit processing industries, such as seeds, kernels and bagasse, which were previously considered wastes, have high potential to be used as food supplement. This aspect, along with the increasing global interest in environmental friendly technologies, explains the interest in a better utilization of fruit processing industries residues [1].

Acerola (*Malpighia emarginata* D.C.) is a tropical fruit originates from tropical America. Its pleasant flavor and the high levels of vitamin C have led to its increasing use in the form of juice, jelly and compote. The residues of acerola processing can contain higher amounts of phenolic and other bioactive compounds than the edible fleshy parts. [1]

A challenge faced by drying of this fruit residues is to reduce the exposure time at elevated temperatures, which may cause deterioration of the bioactive compounds present in the material [2]. Rotary dryers are interesting alternatives for drying of fruit residues, because of their flexibility in handling a wider range of materials than other types of dryers. Several studies in the literature [3] have focused on developing modifications on rotary dryers to improve their performance. Thus, another version of the rotary dryer, named as roto-aerated dryer, was designed by our research group. The main characteristic of this non-conventional rotary dryer is the effective contact time between hot air and wet solids and consequently the drying efficacy [3].

In this work, a pre-drying system with infrared lamps has been installed in the infeed conveyor of this new dryer. The effect of a pre-treatment of the acerola residues with ethanol was also analyzed. The drying performance of this novel system was investigated. The quality parameters, such as phenolics and flavonoids contents were also studied.

## **2. Materials and Methods**

### **2.1. Material**

The acerola wastes used in this work came from industrial juice processing (Fruteza Company, from Sao Paulo-Brazil). The material was stored in frozen at approximately -18°C. The Samples were removed from the freezer 12 hours prior to the drying and then placed in the refrigerator at 5°C to thaw.

### **2.2. Experimental apparatus and conditions**

Figure 1 shows a schematic diagram of the experimental apparatus which consist of a 7.5-HP blower coupled to a duct; an air heating system comprised of electric resistances controlled by a variac and the roto-aerated dryer. The solids feed was performed through a conveyor belt (3) mounted below a reservoir (4), where the wet particulate material was stored. The material was conveyed to another conveyor (5) in order to more effectively adjust the feed rate. On the second conveyor belt was mounted a pre-drying system with

four infrared lamps (6). The power of the lamps was adjusted by a Variac transformer (0 to 1200 W). The drum (7) inclination angle was 3°, and the rotation speed was 2.7 rpm. The drum used in this study was 1.5 m long and 0.29 m wide. The configuration of the roto-aerated dryer had 56 mini-pipes (8): 10 mini-pipes near the solids feed, with 0.004 m diameter; 12 mini-pipes in the middle with 0.006 m diameter, and 34 mini-pipes near the solids discharge with 0.009 m diameter. The mini-pipes had a length of 0.095 m and they were placed at 0.02 m from the particle bed. The solids flow rate was of 0.045 kg min<sup>-1</sup>. The temperatures of the air and solids were measured using copper–constantan thermocouples calibrated by means of a thermostatic bath and a mercury thermometer with a precision of 0.05 °C. The relative humidity ranged between 30 and 40%. For the conditions used in the present work, the holdup ranged from 65.6 g to 194.2 g. The residence time ( $\tau$ ) was determined by the ratio between hold up and the solids flow rate. The pre-treatment with ethanol have been performed spraying 93.2°GL ethanol onto the residues, in the proportion of 2 L of alcohol to 3 kg of solids [4].

**Fig. 1 Experimental apparatus.**

The experimental conditions were chosen considering a central composed design [3] with 3 replicates at the center levels (Table 1). The independent variables analyzed were the air velocity ( $v$ ), air temperature ( $T$ ) and infrared lamp power ( $P$ ).

### 2.3. Quality parameters

The moisture content was determined by the oven method at  $105 \pm 3$  °C for 24 h. The Kjeldahl method was used to determine the protein content, while the crude lipid and total dietary fibers (TDF) were determined using the Soxhelt method and neutral detergent 20% method, respectively, according to AOAC methods [5]. The carbohydrate content was determined by the difference. Minerals were quantified by X-ray fluorescence (FRX) using a Shimadzu device (EDX-720). Total phenolics content (TPC) were determined by the Folin Ciocalteu method [6], using gallic acid monohydrate (99%). Total flavonoids content (TFC) were determined using the colorimetric method described by Zhishen et al. [7]. DPPH analyzes were performed according to Brand-Williams et al. [8] to obtain the amount of antioxidant necessary to decrease the initial DPPH• concentration by 50% (IC<sub>50</sub>). The phenolic acids was identified through HPLC according to Ribeiro et al. [9]. All analyses of antioxidant compounds were performed in triplicate and the results expressed in mean value  $\pm$  SD. The differences between means were analyzed by analysis of variances (ANOVA with  $p < 0.05$ ).

### 3. Results and Discussion

The characterization of acerola residue showed that this material had a high concentration of total fibers ( $51.12 \pm 0.52$  g/100 g d.w.). The Food Nutrition Board (FNB), through the Indicated Daily References (DRI), set the appropriate recommendation for 38 g fibers for men and 25 g for women, both adults. The amount of protein ( $10.13 \pm 0.15$  g/100 g d.w.), lipids ( $5.43 \pm 0.37$  g /100 g d.w.) and carbohydrates ( $30.86 \pm 0.12$  g/100 g d.w.) demonstrate the potential of this material to be used as a food supplement, aiming to add protein and energy values. The results of the X-ray fluorescence spectrometry (FRX) analysis showed the predominance of potassium (3650 mg/100g d.w.), calcium (805 mg/100g d.w.) and phosphorus (420 mg/100g d.w.) in the acerola residue. Magnesium (130 mg/100g d.w.) and molybdenum (30 mg/100g d.w.) were also detected. These compounds participating in metabolic reactions and are also associated with prevention of cardiovascular disease, decreased osteoporosis, diabetes and Alzheimer's [1].

Figure 2 show the results of drying of acerola residues in the roto-aerated dryer assisted by infrared radiation. The initial moisture content of the material was  $78.7 \pm 0.8$  g/100 g w.b., and after the infrared radiation ( $M_{\text{infrared}}$ ) reached until 59.1 g/100 g w.b. (Experiment 14 (E14) - 1188 W), a 24.3% of moisture reduction. The exposure time of the material to the infrared lamps was 9 min. For the powers of 600, 850 and 1100 W the average moisture reduction was  $1.9 \pm 0.1\%$ ,  $11.4 \pm 1.0\%$  and  $18.3 \pm 1.6\%$ , respectively.

**Fig. 2 Results of drying of the acerola residue after infrared and roto-aerated.**

The moisture of the material fed to the roto-aerated dryer varied according to the power of the infrared pre-drying, which was  $77.3 \pm 0.5$  (600 W),  $69.7 \pm 0.9$  (850 W) and  $64.7 \pm 1.0$  (1100 W) g/100 g w.b. The average residence time of the material in the dryer ranged from 3.0 min (E17) to 6.8 min (E3). The final moisture of the material after the roto-aerated dryer ( $M_{\text{roto}}$ ) ranged from 65.8 to 36.6 g/100 g w.b. for conditions E1 and E14, respectively. Therefore, it was possible to reduce the initial moisture content of the material by up to 53.5 % in a period of 13.5 min. This is a short time when compared to other drying techniques already used for dehydration of the acerola residue. The tray dryer requires 120 to 220 min<sup>[10]</sup> and the fixed bed of 25 cm of thickness requires 159.3 to 300.7 min<sup>[11]</sup>. The reduced time required for drying in a roto-aerated dryer is due to its excellent fluid-particle contact<sup>[3]</sup>. It is also worth mentioning that prolonged drying times can result in the degradation of bioactive compounds<sup>[2]</sup>.

The last two experiments (E18 and E19) were performed at the same operating conditions (180.0 °C, 2.3 m/s and 1188.3 W). However, the experiment E19 was performed with pre-treatment with ethanol. The moisture reduction after the infrared was 22.9% and 34.0% and after the roto-aerated was of 59.1% and 91.1%, for the acerola residue with (E19) and without ethanol pre-treatment (E18), respectively.

Considering that a drying process can affect the final quality of the product, it is also important to evaluate the quality indices. The quality of acerola residues has been evaluated by the quantification of total phenolic compounds (TPC), total flavonoids (TFC) and antioxidant activity ( $IC_{50}$ ).

Figure 2-b shows that TPC was lower in the conditions with higher power of the infrared lamps and/or higher drying air temperature. Phenolic losses may occur due to enzymatic and non-enzymatic oxidative reactions. Similar results were found by Nunes et al. [12] in guava drying. According to Maillard and Berset [13], thermal degradation also may contribute to phenolic losses. The highest reductions were 21.0 % ( $522.0 \pm 20.0$  mg/100g d.w.) and 23.6% ( $504.7 \pm 21.0$  mg/100g d.w.) for conditions E14 (moisture 36.6 g/100 g w.b.) and E18 (24.9 g/100 g d.w.), respectively. Despite the reductions in TPC, the dried material presents good potential and can be considered as with intermediate concentrations according to Vasco's classification [14].

Fig. 2-c shows that the TFC of the acerola residues after drying, in all operating conditions, have been in higher levels. The highest levels of TFC were obtained in intermediate levels of infrared power and drying air velocity (E9 and E10). This behavior might be explained by the liberation of phenolic compounds due to the breaking of the cellular constituents during the drying process and due to presence of melanoidins and from the Maillard reaction, thereby interfering with the antioxidant properties [12].

The antioxidant activity was evaluated using the DPPH\* radical capture method, the results were expressed as  $IC_{50}$  ( $\mu$ g sample / mL capable of reacting with 50% of the radical present in the DPPH \* solution). Thus, the lower the  $IC_{50}$  value, the higher the antioxidant activity of the analyzed material. The lowest  $IC_{50}$  values were found in conditions E6, E7, E8, E10, E14 and E18, which had high drying air temperature and/or high infrared power, as can be seen in Figure 2-d. These were experimental conditions with greater moisture removal. However, even under these conditions the antioxidant activity was high. The heating of the material may increase the free flavonoid content and consequently the antioxidant capacity, which may change due to several factors such as the increase of the antioxidant power of the polyphenols in an intermediate state of oxidation, the increase of the reduction of sugars and the formation of products from Mailard reaction [1].

Phenolic acids were determined in HPLC by comparison with the retention time of standards. Four phenolic acids were detected in the HPLC analyzes: gallic (165.3-280.1 mg/100 g d.w.), caffeic (4.12-18.3 mg/100 g d.w.), chlorogenic (0.6-3.5 mg/100 g d.w.) and p-coumaric (2.6-13.2 mg/100 g d.w.) acids. The gallic acid content presented a reduction in relation to the fresh residue ( $261.0 \pm 13.6$  mg / 100 g d.w.), this reduction was greater for the conditions with higher drying air temperature and infrared power. Similar behaviors were found for caffeic ( $16.9 \pm 1.2$  mg/100 g d.w.) and chlorogenic ( $7.2 \pm 0.5$  mg/100 g

d.w.) acids. During drying processes, the activation of oxidative enzymes, such as polyphenoloxidase and peroxidase, in addition to the thermal degradation can lead to the loss of phenolic compounds [15]. Drying also dissociates some phenolic compounds, thereby altering chemical structures, transforming insoluble phenolic compounds into more soluble forms and making phenolic compounds more available for quantification, besides the formation of new compounds with antioxidant properties [15].

#### 4. Conclusions

The results showed that the new dryer system developed by our research group is a good alternative for drying of acerola wastes. It was possible to identify conditions with high moisture removal and short residence times that are suitable conditions to perform an efficient drying process with a preservation of product quality. It was possible to identify conditions under which the phenolic, flavonoid, and antioxidant capacity presented high levels after drying. The main phenolic compounds were identified by HPLC.

### **Abstract**

*The aim of this work is investigate the use of a rotary dryer with inert bed for drying of microalga *Spirulina platensis*. The influence of air temperature, feed rate, rotation speed and inerts filling degree was quantified. The contents of main bioactive compounds were also analyzed. The results shown that the used drying system proved to be an interesting alternative for a possible use of this microalga, if performed under adequate conditions. It was identified conditions with high drying performance and with the preservation of product quality.*

**Keywords:** *Spirulina platensis; rotary dryer; inert bed; bioactive compounds.*

---

## 1. Introduction

*Spirulina platensis* is one of the species of cyanobacterium microalgae that has gaining recent attention because of its nutritional and medicinal properties. Several studies reported the potential use of *Spirulina* biomass due the high presence of proteins, vitamins, minerals, antioxidant and anti-inflammatory compounds as the phycocyanin<sup>[1, 2, 3]</sup>. Despite this, the *Spirulina* is very perishable due its high moisture content that contributes to degradation, hamper transport and storage, and reduce the shelf life. Thus, it is necessary apply a drying technique that allows use properly this material in food or pharmaceutical industries.

The most traditional methods used to drying microalgae are spray drying, freeze-drying, solar drying and convective hot air drying<sup>[4, 5]</sup>. However, the rotary dryers appears as an interesting alternative because their flexibility and high processing capacity. Conventional rotary dryers have flights, which lift solids and make them cascade across the dryer section. Most of the drying occurs during the free fall of solids from the flights, because of the large gas-solids surface contact area<sup>[6]</sup>. However, conventional rotary dryers are typically used for granular materials and are not suitable for pastes. Thus, the use of an inert bed (as metal or ceramic spheres, for example) is an interesting alternative for paste drying in rotary drums, since the inert increase the contact surface between hot air and material, and prevents the loss of material on the walls and dryer structures<sup>[7, 8]</sup>.

In the present work, the drying of *Spirulina platensis* in a rotary dryer with inert bed was investigated. The effects of process variables on the drying yield was quantified and the impacts of these variables on the main bioactive compounds contents (total phenolics, total flavonoids, citric acid and phycocyanin) were also analyzed.

## 2. Materials and Methods

### 2.1. Raw material

The microalga *Spirulina platensis* used in this study was provided by the company Brasil Vital, located in the state of Goias, midwest Brazil. The material was previously filtered in vacuum, stored in small portions and frozen in a freezer.

### 2.2. Experimental apparatus

The experimental apparatus, shown in Fig. 1, consists of: a radial blower (Kepler-Weber, 112M), an electric heater connected to a voltage variator to adjust the air temperature, the rotary drum coupled a rotation system composed by a motor and frequency inverter (WEG, CF08) to control the rotation speed, and a Stairmand cyclone separator (diameter 10 cm) with a flask in its underflow to collect the dried material. The *Spirulina in natura* were fed in the system with a peristaltic pump (Masterflex, 7553-70) connected to a velocity variator.

The rotary drum used in this study was a stainless steel cylinder with 12 cm of inner diameter and 36 cm of length. Three stainless flights with 2.5 cm are also placed into the drum for uniform axial distribution of inerts during the drying. The inerts particles used were porcelain spheres with diameter of 1.9 cm and density of 2.32 g/cm<sup>3</sup>.

Fig. 1 Experimental apparatus.

### 2.3. Experimental design

The experiments were conducted following a orthogonal central composed design with four independent variables and two replicates at the center level, totaling 26 experiments. The independent variables analyzed were: the air temperature (T), feed intermittence (FI), inert filling degree (FD) and rotation speed (RS). In each experiment were used about 100g of Spirulina microalga. The coded and real variable values are shown in Table 1.

Table 1. Coded and real variable values

Design Factors	-1.483	-1	0	+1	+1.483
Air temperature (°C)	40.3	50.0	70.0	90.0	99.7

Rotation Speed (RPM)	35.2	40.0	50.0	60.0	64.8

The Air Temperature (T) was measured at the inlet of the drum. The wet Spirulina was fed in cycles, in an intermittent system of feed of 10 g of material and a rest for a determined

time (defined as the variable *Feed Intermittence*). The *Filling Degree (FD)* was calculated based in the cylinder geometry and the properties of inert bed, as density and porosity, and the rotation speed (RS) were measured using a digital tachometer. The response studied was the *Drying Yield (DY)*, that is the percentage ratio of the quantity of material (dry base) collected in the cyclone underflow to the quantity of microalga fed into the dryer (in dry base).

#### 2.4. Analysis of bioactive compounds

The experiments with the highest values of *Drying Yield (DY)* had their bioactive compounds analyzed to evaluate the impact of the operational conditions on the quality of the final product. The total phenolics content (TPC) was determined by the *Folin-Ciocalteu* method<sup>[9]</sup>. The total flavonoids content (TFC) was determined using the method described by Zhishen *et al.*<sup>[10]</sup>. The acidity (CA), expressed in the presence of citric acid in the samples, was determined by AOAC<sup>[11]</sup> method. The phycocyanin content (PC) was performed based on the methodology of Costa *et al.*<sup>[2]</sup>.

### 3. Results and Discussion

#### 3.1. Analysis of dehydration yield (DY)

The most significant operating variables can be observed in Equation 1, through the parameters obtained by the multifactor ANOVA ( $R^2= 0.9048$  and  $\alpha = 0.10$ ). The effect of the studied variables on the drying yield can be visualized in Figure 2.

$$DY = 60.46 + 3.14.FD - 2.05.FD^2 + 1.51.RS - 1.99.RS^2 - 2.04.FI^2 - 0.83.T.FI - 2.08.T.RS - 1.51.FI.FD - 1.49.FI.RS \quad (1)$$

**Fig. 2 Drying Yield (DY) response surfaces.**

The variables: filling degree (FD) and rotation speed (RS) presented non linear effects on the DY (Equation 1 and Figure 2a). In general, the experiments performed at higher values of these variables produced a great quantity of dried material, hence the best results of DY. The effect of the temperature on DY was present by means of the interaction with intermittence (FI) and rotation speed (RS). The best results were obtained with the association of low temperatures and high levels of RS or with intermediate levels of RI, as can be seen in Figure 2b and Figure 2c.

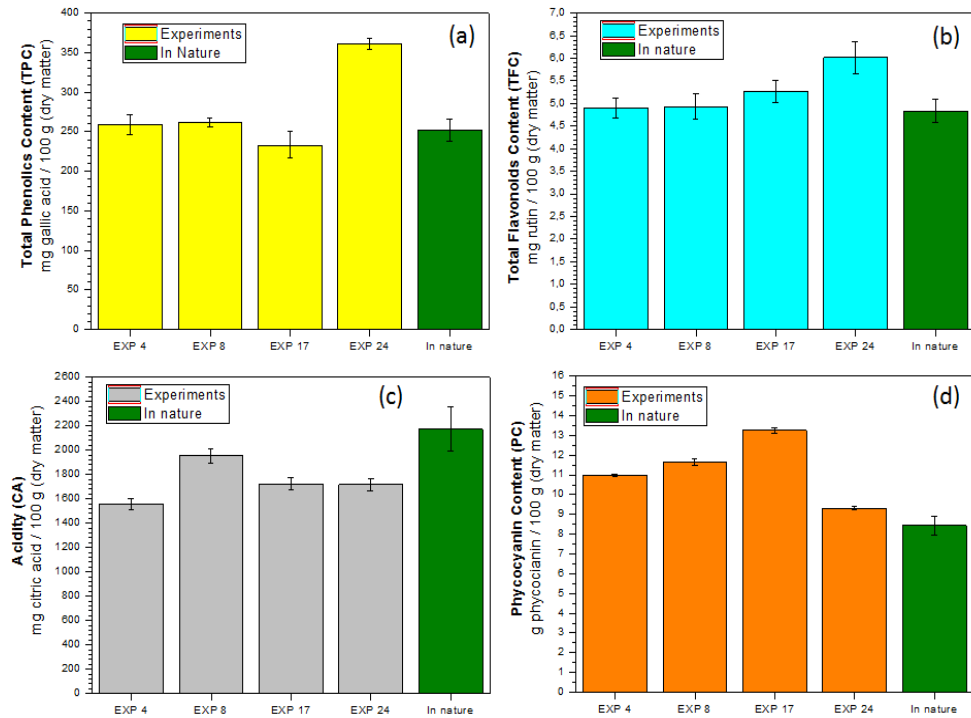

The analysis of the results showed that the higher drying yields can be obtained in experimental conditions of high Filling Degree (FD) and Rotation Speed (RS), combined with Intermediate Feed Intermittences (FI) and low process Temperatures (T). For the

conditions of the experimental design, the highest values of DY were obtained in the Experiments expressed in the Table 2.

**Table 2. Experiments with the highest Drying Yields (DY)**

Experiments	T (°C)	FR (min)	FD (%)	RS (RPM)	DY (%)
4	50.0	5.0	27.0	60.0	63.28%
8	50.0	15.0	27.0	60.0	60.12%
17	40.3	10.0	21.0	50.0	61.88%
24	70.0	10.0	21.0	64.8	60.42%

### 3.2. Analysis of Bioactive Compounds

**Fig. 3 Bioactive compounds content in the experiments with the highest Drying Yield (DY).**

The bioactive compounds content obtained in the four experiments showed in Table 2 are presented in Figure 3. It can be observed that for the experiments performed in the

conditions that led the greatest yields, the main bioactive compounds were preserved, indicating that this drying methodology has good effect on the quality of final dried *Spirulina*. This bioactive content behavior was also related by Chism & Haard<sup>[12]</sup> that observed the liberation of these compounds accumulated in vegetal cell organelles as vacuoles, due to rupture in the internal structure of the material during the moisture removal. Dorta *et al.*<sup>[13]</sup> also claimed that inactivation of certain enzymes responsible for the degradation of bioactive compounds can occur during the drying process, resulting in their preservation.

#### 4. Conclusions

The drying of microalga *Spirulina platensis* using a rotary dryer proved to be an interesting alternative for use of this material. All the variables analysed showed statistical significance in the results of yield. The combination of low temperatures, high filling degree, high rotation speed and intermediate feed intermittence allowed obtain the highest drying yields. It was also possible obtain bioactive compounds content near than present in fresh biomass in the experiments analyzed, indicating a positive effect of this process of moisture removal on the final quality of dried product.

### **Abstract**

*The objective of the study is to investigate the effects of different drying processes (convective hot air, microwave, and fluidized bed drying) and combined drying methods on the drying characteristics and physical properties of the dried wheat and the power consumption of the dryers. The lowest moisture content and water activity values were observed for the 25min of drying in fluidized bed dryer (60°C) and following 16min in microwave dryer (540W). The lowest power consumption was observed in the 60°C-180W fluidized bed-microwave combination (0.77kWh) compared to the other combined trials.*

**Keywords:** wheat; convective drying; microwave drying; fluidized bed drying intermittent drying.

---

## **1. Introduction**

The ready to us products that are precooked and dried are called as “parboiled”[1]. The main objective of parboiling on wheat is a versatile that can be used in bread, salads, casseroles, stew, desserts, and served as side dish.

Drying is applied to decrease the moisture content and water activity in the product, to inhibit the growth of the microorganisms and prolonging the shelf life of the final product. One of most common drying methods is convective hot air drying. However, this method has many disadvantages such as lengthy drying time, darkening in color [2], the high temperature damaging the product quality and high power consumption [3]. The microwave drying provided an alternative way since it is an advantageous method due to its short drying time, ease of process control, power saving and drying homogenization. In fluidized bed dryer, the products in the granular structure are fluidized and excess moisture in the product structure is removed by a drying air. In addition, fluid bed drying process provides such as a good solids mix, high-speed heat-mass transfer and easy transport of substances advantages [4]. Therefore, fluid bed dryers are preferred due to their high heat transfer rates [5]. The drying industry utilizes large quantities of energy and for this reason one of the most important challenges of the drying industry is to reduce the power cost of obtaining good quality dried products. For this reason, drying operations can be applied intermittently in order not to damage the structure of the food, to adversely affect the quality and to save power [5].

The objective of this work is to investigate the effects of different drying processes (convective hot air, microwave, and fluidized bed drying) and combined drying methods on the drying characteristics and physical properties of parboiled wheat. In addition, the power consumption of the dryers was measured to use in the comparison.

## **2. Materials and Methods**

### **2.1. Material**

Wheat (*Triticum aestivum*) was supplied from a local market in İzmir/TURKEY. Wheat samples were soaked in the water (1:10 wheat:water ratio (weight:weight), (w:w)) at the room temperature (25°C) overnight and was parboiled at 100°C for half an hour in the water (1:2 wheat:water ratio, (w:w)) and drained. The initial moisture content of the samples was 60.48±0.63 %.

### **2.2. Methods**

#### *2.2.1 Drying Processes*

Pre-processed wheat samples were dried by using different drying methods and their combinations. The weight loss of the samples was measured by using an electronic balance

(Ohaus AR2140, USA) until constant weight was reached. The drying conditions are given in the following Table 1.

**Table 1. Drying methods and conditions**

<i>Convective hot air drying</i>	<i>Fluidized bed drying</i>	<i>Microwave drying</i>
Armfield Lim., Ringwood, Hampshire, UK  70°C and 1.6 m/s air velocity  every 5 min. of weight measurement	Sherwood Scientific, UK  60, 70, 80°C and 1.6 m/s air velocity  every 5 min. of weight measurement	Arçelik MD595, Turkey  180W, 360W, 540W, 720W, and 900W  every 1 min. of weight measurement
<i>Intermittent fluidized bed-microwave drying</i>		<i>Intermittent microwave- fluidized bed drying</i>
60-70-80°C temperatures, 1.6m/s air flow for 25 min + microwave dryer (180-360-540W)		180-360-540W for 14 min + 60-70-80°C, 1.6m/s air flow

### 2.2.2 Analysis

The power consumptions of the dryers were measured by power measurement device (Makel M310.2218, Turkey). The moisture content of the dried wheat samples were determined according to AOAC (2000). The water activity and color ( $L^*$ ,  $a^*$ , and  $b^*$ ) values of the samples were measured by using a water activity measurement device (Testo-AG 400, Germany) and a colorimeter (Minolta CR-400, Japan), respectively. The results were expressed in accordance with the CIE Lab. System and the Chroma and Hue Angle ( $^\circ$ ) values were calculated according to Maskan et al. (2000) [6].

### 2.2.3 Determination of the drying behavior of the parboiled wheat samples

The moisture content versus time and drying rate versus moisture content plots were prepared according to Maskan et al. (2000) [6].

### 2.2.4 Statistical Analysis

Data were analyzed using statistical software SPSS 16.0 (SPSS Inc., Chicago, IL, USA). The data were also subjected to analysis of variance (ANOVA) and Duncan's multiple range test ( $\alpha=0.05$ ) to determine the difference between means. The drying experiments were replicated twice and all analyses were triplicated.

## 3. Results and Discussions

The power consumption of the dryers, and the moisture content and water activity values of the dried wheat samples are given in Table 2. The highest power consumption value

(18.63kWh) was observed for convective dryer because of long drying time (145min, data was not given). Considering the power consumption in the fluidized bed dryer (heating and blowing the air), the higher drying air temperatures caused a shorter drying time, and a shorter drying time caused significantly less power consumption ( $P<0.05$ ). Toğrul (2006) and Chen et al., (2001) [7,8] reported that the convective and fluidized drying methods have some disadvantages such as high power consumption due to long drying time. The lowest power consumption values were observed for microwave drying because of the low drying time (Figure 1). In addition, Alibas (2006) [9] reported that the microwave drying is a widely used method due to low drying time and power consumption. The power consumption significantly increased from 0.07 to 0.39kWh as microwave power increased from 180 to 900W ( $P<0.05$ ) and the power values 720 and 900W were eliminated from intermittent drying trials because of the higher power consumption and lower quality properties than other microwave drying powers. According to Table 1, it can be said that the power consumption of fluidized bed dryer can be decreased by combining it with microwave dryer and even the lower power consumption values were observed for fluidized bed-microwave combination compared to the microwave-fluidized bed-combination. Demiray et al. (2017) [10] reported that under convective drying conditions at the beginning of the drying the moisture removal rate is high, however, at the low moisture content values convective drying was not advantageous due to slow diffusion rate. For this reason, it can be stated that the fluidized bed-microwave combination is more advantageous with the higher evaporation rate, and lower power consumption compared to the microwave-fluidized bed-combination.

As can be seen from Table 1, the moisture content and water activity values of samples are generally lower than the limits (10% and in the range of 0.1 to 0.4, respectively (Quek et al., (2007), [11], (except convective dried samples) indicating their microbial safety for long terms of storage. The moisture content and water activity values significantly affected by the drying techniques ( $P<0.05$ ). Significantly higher moisture content values were observed for the samples which were dried at the convective dryer and fluidized bed dryer ( $P<0.05$ ). The moisture content values of samples increased depending on the increase of the drying air temperature in the fluidized bed dryer might be due to the crust formation which prevents the removal of moisture. Microwave dried samples have the significantly lower moisture content values compared to convectively dried samples ( $P<0.05$ ). The lowest water activity values were observed for the fluidized bed-microwave dried samples and the water activity values significantly decreased depending on the increasing drying air temperatures ( $P<0.05$ ). The moisture content and water activity values for the fluidized bed-microwave dried samples were found to be significantly lower compared to the convectively and microwave-fluidized bed dried samples ( $P<0.05$ ).

a– I show the significant difference between the same column in the samples according to the moisture content, water activity, and power consumption (P<0.05).

The total color change, Hue angle, and chroma values of the samples are given in Table 3. The L\*, a\* and b\* values of the parboiled wheat are measured 63.43±0.63, -0.57±0.38 and 15.13±0.12 respectively. The total color change ( $\Delta E$ ) of dried samples with respect to parboiled wheat was calculated and the significantly higher total color change values were observed for microwave dried samples (P<0.05). It was clearly seen that the total color change was dramatically decreased in the intermittent drying methods especially in the fluidized bed- microwave drying method. The color change may be due to the degradation of the pigments, browning reactions or burning. The higher hue angle values were measured for microwave dried samples indicating higher redness values in this drying method. The chroma value indicates the degree of saturation of color and is proportional to the strength of the color [6]. The lowest chroma values were observed for fluidized bed-microwave dried wheat samples.

The drying rates were calculated and plotted against the moisture content as shown in Fig. 1. The drying generally occurred in falling rate period in the all drying methods due to the high evaporation rate of moisture.

**Table 3. The total color change, hue angle and chroma values of the dried wheat**

Drying method and the condition		Colour		
		$\Delta E$	Hue Angle	Chroma
<b>Convective Hot Air</b>	70°C, 1.6m/s	7.58±0.51 <sup>a</sup>	1.51±0.00 <sup>d</sup>	21.67±0.57 <sup>ab</sup>

a-d shows the significant difference between the same column in the samples according to the total color change, hue angle and chroma (P<0.05).

Since almost all of the drying of biological products take place in the falling rate period [6] the drying rate of samples increased depending on increasing in drying air temperature and/or microwave power and the required drying time and the power consumption generally significantly decreased (P<0.05). In the all drying techniques, initially higher drying rates were observed and the samples tended to dry slowly at the last stages of drying.

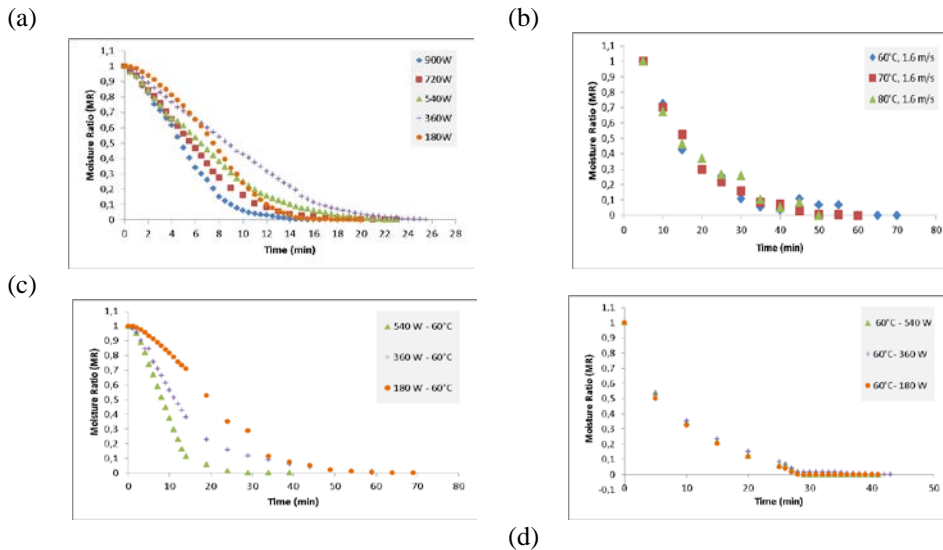

It may be due to shrinkage or crust formation resulting in low transport rate of water and prolonged drying time. The highest drying rate values were observed for the microwave dried wheat grains where the lowest values were observed for the fluidized bed-microwave dried samples. The microwave drying supplies a higher drying rate compared to convective drying methods because of the heat generation inside food material which causes a rapid moisture evaporation in microwave drying [12].

The drying characteristics of wheat samples during drying were determined from the mass loss in the samples of the known initial moisture content (66.48±0.63%, wb) and are given in Figure 2. as expected, high amounts of moisture were removed at the early stages of drying due to the higher moisture diffusion and at the later stages, the removal of moisture decreased gradually.

**Fig. 1** The drying rate versus moisture content for (a) Microwave drying, (b) Fluidized bed drying (c) Microwave-fluidized bed combination, (d) Fluidized bed-microwave drying combination.

As expected, drying time of samples decreased with increasing microwave power and/or drying air temperature. Drying behavior of the wheat samples showed similar trend for the all the drying methods.

**Fig. 2** The drying Characteristics for (a) Microwave drying, (b) Fluidized bed drying (c) Microwave-fluidized bed combination, (d) Fluidized bed-microwave drying combination.

## 4. Conclusions

In this study, the drying characteristics (moisture ratio vs. time graphs) and the physical analysis (moisture content, water activity, and color determination) of the single dried and combined dried wheat samples were determined. The power consumption for each drying method was also evaluated. Although, the lowest power consumption (0.07kWh) was observed for 180W microwave drying condition, considering the quality of the dried wheat especially the highest total color change was determined by this drying condition. The lowest moisture content (1.09%) and the water activity (0.06) values were observed at 60°C-540W fluidized bed-microwave dried and 60°C-360W fluidized bed- microwave dried wheat. The lowest total color change values were observed in fluidized bed-microwave dried wheat samples in the range between 6.28-8.98. The results showed that the fluidized bed-microwave drying methods were better for the physical properties and the low power consumption when they are compared to the microwave-fluidized bed combinations.

### **Abstract**

*Spray drying can be used to extend the shelf life of biologics stored at ambient temperature. Empirical and statistical design of experiments approaches typically require a relatively large number of experiments to determine suitable formulation and spray drying process parameters. An alternative approach, which may require fewer experiments, is to use mechanistic models to select these parameters. In this paper, mechanistic models are applied to develop a bacteriophage powder expected to have long-term physical stability at ambient temperature. The developed powder may be useful for decreasing incidences of foodborne illness in Kenya.*

**Keywords:** *bacteriophage powder; glass transition temperature; supplemented phase diagram; spray drying; stability.*

---

## 1. Introduction

Empirical and statistical design of experiments approaches are commonly used for selecting formulation and process parameters during the development of spray dried biologic products. An alternative approach is to use mechanistic models developed based on an understanding of fundamental underlying principles. That is the approach undertaken in this work wherein a dry powder bacteriophage (phage) dosage form is designed to have target characteristics without requiring a substantial number of spray drying experiments. The powder is intended for use in broiler chicken feed to decrease *Campylobacter jejuni* in the chicken gut, with the end goal of decreasing the prevalence of foodborne illness in Kenya, which is abnormally high.<sup>[1,2]</sup> The development process can be divided into the following steps, discussed individually in this paper: 1) formulation; 2) atomization; 3) solvent evaporation and particle formation; 4) particle collection and analysis; 5) storage and transport.

## 2. Materials and Methods

A modified Büchi B-191 laboratory-scale spray dryer (Büchi Labortechnik AG; Flawil, Switzerland), schematically shown in Figure 1, was used to spray dry different *myoviridae* phages that can infect *Campylobacter jejuni*: CP30A, CP20, and CP8. These phages were isolated from chicken excreta and are present in chicken gut.<sup>[3]</sup> A transmission electron micrograph (TEM) of phage CP20 is given in Figure 2.

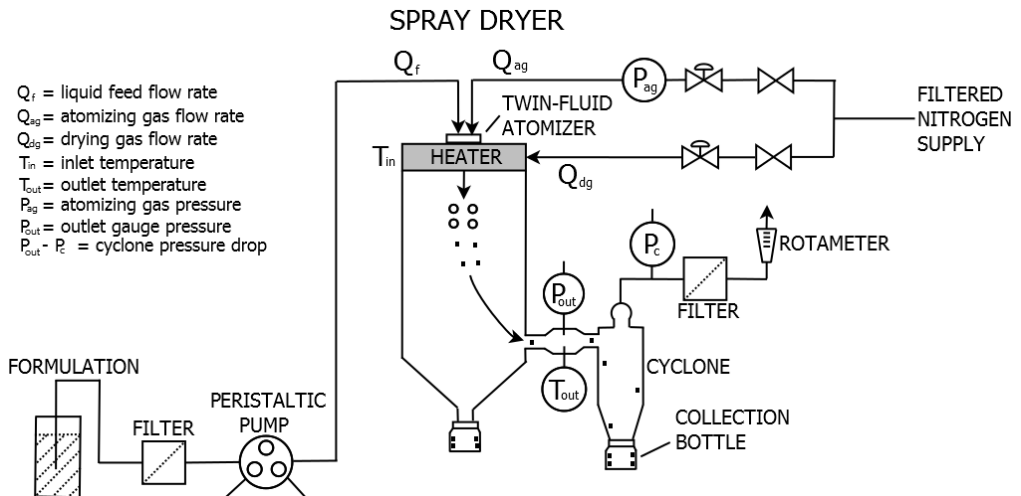

Fig. 1 Schematic of the modified laboratory-scale Büchi B-191 spray dryer.

Fig. 2 TEM of phage CP20.

## 2.1 Formulation

The formulations were chosen to consist of L-leucine (Fisher Scientific, Cat. No. AC125121000; NH, USA) and D-(+)-trehalose dihydrate (Fisher BioReagents, Cat. No. BP2687; NH, USA) as dissolved solids in aqueous solution with phage (pH ~6.5). Trehalose is thought to stabilize biologics on drying by forming an amorphous glass that allows hydrogen bonds lost on desiccation of the biologic to be replaced.<sup>[4]</sup> Leucine forms a shell that decreases particle cohesiveness.<sup>[5]</sup>

For spray drying experiments, stock phage lysates were filtered and centrifuged to reduce the impurity content to  $< 0.5 \text{ mg mL}^{-1}$ , and then diluted 1:100 into two aqueous formulations: (F1)  $7.5 \text{ mg mL}^{-1}$  leucine,  $22.5 \text{ mg mL}^{-1}$  trehalose; (F2)  $12 \text{ mg mL}^{-1}$  leucine,  $18 \text{ mg mL}^{-1}$  trehalose. In the literature similar formulations have been successfully used to stabilize spray dried phage.<sup>[6-9]</sup> Further details regarding the choice of these formulations are given in the following sections. Plaque assay was used to measure the presence and extent of titer reduction due to dilution of phage into the above formulations. The results are presented in Section 3.1.

## 2.2 Atomization

The spray dryer uses a twin-fluid atomizer to generate droplets. An atomizing gas flow rate of  $1.5 \times 10^{-4} \text{ kg s}^{-1}$  and a spray rate of  $1.7 \times 10^{-5} \text{ kg s}^{-1}$  were used. A characteristic shear rate on the order of  $1 \times 10^5 \text{ s}^{-1}$  was expected according to a model presented by Ghandi *et al.*<sup>[10]</sup> In the literature,<sup>[7]</sup> phage have remained active after atomization at similar shear rates. To verify minimal titer reduction, filtered phage CP30A lysate in formulation F1 was atomized onto a filter, from which liquid was drawn for assay. The results are presented in Section 3.2.

The air-to-liquid ratio (ALR), defined as the ratio of the mass flow rates of atomizing gas and liquid feed, was 8.8. From the ALR and data for the present atomizer given by Hoe *et al.*,<sup>[11]</sup> an initial droplet diameter of  $\sim 9 \text{ }\mu\text{m}$  was predicted. Using a model presented by

Boraey *et al.*,<sup>[12]</sup> and the formulation compositions given in Section 2.1, the aerodynamic diameter at the time of shell formation was predicted to be  $\sim 2 \mu\text{m}$ , which can be collected with the cyclone.

### 2.3 Solvent Evaporation and Particle Formation

Solvent from the liquid droplets generated by atomization quickly evaporates into the drying chamber of the spray dryer. The surface temperature of the droplets is typically assumed to remain near the wet bulb temperature for most of the evaporation process due to evaporative cooling;<sup>[13]</sup> therefore, thermal deactivation of the phage is not expected during initial stages of solvent evaporation. The dissolved solid that reaches critical supersaturation at the surface first may nucleate and form a crystalline shell. This is the particle formation stage, which has been described by Vehring *et al.*<sup>[14]</sup> The formulation compositions in Section 2.1 were designed using mechanistic models such that leucine would reach supersaturation much earlier than trehalose, allowing for enough time to nucleate and crystallize leucine at the surface (11.5 milliseconds for F1 and 15.8 milliseconds for F2). Since previous work has demonstrated that conditions similar to F1 may not be sufficient for obtaining a fully crystalline leucine structure when phage lysate is present in the formulation, F2 was also tested with the expectation that it would form a fully crystalline leucine structure.<sup>[9]</sup>

A spray dryer process model, developed based on similar models in the literature,<sup>[15,16]</sup> was used to predict the outlet temperature and the outlet relative humidity. The outlet temperature was predicted to be  $\sim 50^\circ\text{C}$  and the outlet relative humidity  $\sim 3\%$  for an inlet temperature of  $70^\circ\text{C}$ , a spray rate of  $1.7 \times 10^{-5} \text{ kg s}^{-1}$ , and a drying gas flow rate of  $8.5 \times 10^{-3} \text{ kg s}^{-1}$ .

### 2.4 Particle Collection and Analysis

A cyclone was used to collect the powder in a glass collection bottle. The collection efficiency is defined as the percent of the mass of dissolved solids in the feed solution recovered in the collection bottle. The collected powder containing phage was analyzed for solid state using Raman spectroscopy (using a custom device developed by Wang *et al.*<sup>[17]</sup>) and for particle morphology using scanning electron microscopy (SEM) (Zeiss Sigma FESEM, Oberkochen, Germany). Results are presented in Section 3.4.

### 2.5 Storage and Transport

Moisture uptake during storage and transport can result in crystallization of trehalose, which is known to deactivate phage.<sup>[18]</sup> Therefore, it is crucial that the packaging material is moisture-equilibrated. In this study, a Steady State / Stability Test Chamber (910W-4, Linaire Environmental, Williamsport, PA, USA) was used to equilibrate the powder and packaging to 4% relative humidity, with subsequent packaging occurring in the chamber.

The relative humidity was chosen according to moisture uptake data and the information contained in Figure 3, described below. The packaging consisted of the powder in a vial, which was packaged in a double heat-sealed aluminum foil bag along with a satchel of silica gel desiccant (McMaster Carr, 2189K16; Elmhurst, USA), all of which were further packaged in another double heat-sealed aluminum foil bag along with another satchel of silica gel desiccant. The packaged spray dried powder, along with liquid controls, were shipped from Edmonton, Canada, to Nottingham, UK, in a Styrofoam box to minimize temperature variations. The titer after the complete development and shipping process will be determined by resuspension of the powder and plaque assay.

Throughout long-term stability studies, the powder should remain at a near-constant moisture content as, over time, moisture can lead to glass transition and crystallization. This tendency is demonstrated in a supplemented phase diagram that was developed for a trehalose-water system and is shown in Figure 3. With this diagram, the physical stability of the amorphous solid phase can be predicted *a priori* for a designed storage temperature, moisture content, and hence relative humidity. Use of this diagram is crucial for achieving long-term physical stability. The curve of the well-mixed glass transition temperature was developed using the Gordon-Taylor equation with a k-value of 5.9 and respective glass transition temperatures of 387 K for dry trehalose and 138 K for water.<sup>[19]</sup> As a rule of thumb, long-term storage should be performed for conditions at least 50°C below the glass transition temperature.<sup>[20]</sup>

Fig. 3 Supplemented phase diagram developed for a trehalose-water system. Modified from Hoe et al.<sup>[21]</sup> with the present process parameters and material properties.

### 3. Results and Discussion

#### 3.1 Formulation

Filtered phage CP30A lysate had no titer reduction over a period of 20 days when stored at 30°C in water, buffer, or formulation F1. A storage temperature of 40°C led to no titer reduction in buffer after 1 day but to > 1 log(pfu/mL) titer reduction after 10 days. A storage temperature of 50°C led to no titer reduction in buffer for at least 6 hours. No titer reduction was observed shipping CP30A in F1 within a vial in a Styrofoam box without temperature control from Nottingham, UK, to Edmonton, Canada, and back. This stability indicated that it is feasible to perform liquid control measurements with each experiment.

#### 3.2 Atomization

The atomization titer reduction of phage CP30A in F1 was ~0.25 log(pfu/mL), which is less than the value of ~0.75 log(pfu/mL) reported in the literature for phages PEV2 and PEV40,<sup>[7]</sup> where similar predicted shear rates were used.

#### 3.3 Solvent Evaporation and Particle Formation

The outlet temperature matched predictions from the process model within 2°C.

#### 3.4 Particle Collection and Analysis

The collection efficiency was 54% for both formulations, which is typical for nominal batch sizes of ~1.5 grams. Raman spectroscopy confirmed trehalose was amorphous while leucine was mostly crystalline for both formulations. SEM (Figure 4) indicated that the phage lysate affected the particle morphology. It is possible that residual components in the phage lysate concentrated on the surface and interfered with the sensitive shell deformation and crystallization processes. This morphology was also present for other phage spray dried with leucine and trehalose in the literature, for which good powder flowability and long-term biological stability at 20°C were still achieved.<sup>[9]</sup>

*Fig. 4 SEM of spray dried F1 without (left) and with (right) phage CP20. The same scale bar applies to both images.*

### 3.5 Storage and Transport

The supplemented phase diagram in Figure 3 suggests that the developed powder will have long-term physical stability without the need for refrigeration when a low relative humidity is maintained in the packaging. The biological stability of the phage in the powder during storage and transport will be determined.

## 4. Conclusions

Mechanistic models were used to select formulation and spray drying process parameters for stabilizing phage. Further results will be presented at the conference.

### **Abstract**

*Drying of moist porous media such as paper, pulp and food products is one of the most energy intensive processes in industry. Impinging jet nozzles are commonly used in various drying processes. There have been many efforts to improve the transport characteristics of impinging jet nozzles. Utilizing innovative Slot Jet Reattachment (SJR) nozzle is an approach to make the drying process more efficient. This is mainly because these nozzles overcome the high flow rate constraint associated with the traditional Slot Jet (SJ) nozzle.*

*In this paper, the drying characteristics of the SJR nozzle with exit angles of +20° and +45° are experimentally investigated. The samples used are snack cookies. The results are compared with those of SJ nozzle under the same mass flowrate. The results indicate that significant enhancements in drying rates are achievable with both SJR nozzles compared to SJ nozzle.*

**Keywords:** Drying; Porous Food Snack; Slot Jet Reattachment Nozzle; Slot Jet Nozzle

## **1. Introduction**

Energy is one of the grand challenges for manufacturers in the 21<sup>st</sup> century. In traditional industrial processes, the energy required for drying can take up to 25% of the corresponding total energy use [1]. Energy efficient and uniform drying of food products such as fruits, chips, and cookies is of critical importance to the product quality. Slot Impinging Jet (SJ) nozzles are widely used to dry food in traditional food industry, providing the principal heat and mass transfer mechanism in the drying process. To design a proper impinging jet nozzle with sufficient efficiency, many factors need to be considered: nozzle geometry and size, nozzle configuration, nozzle-to-surface separation, jet-to-jet separation, cross flow, jet exit velocity and surface motion [2].

Among such various factors, an innovative Slot Jet Reattachment (SJR) nozzle, has been developed by Page and Seyed-Yagoobi [3] and Seyed-Yagoobi et al. [4]. Compared to the conventional SJ nozzle, the innovative SJR nozzle can alter the direction of impinging air flow to an outward radial direction, with a flow reattaching on a ring away from the centerline, where the stagnation point occurs (see Fig. 1). Heat and mass transfer is maximized along the reattachment ring. Due to the nature of turbulent viscous mixing along the boundary layers of the impinging air, a secondary flow is introduced through mass entrainment, which means part of the air steam directs inward radially to form a circulation region underneath the bottom plate of the nozzle. A relatively low-pressure distribution is maintained. The intense turbulent flow is the principal reason for the high mass and heat transfer rate. These flow characteristics of the SJR nozzles provides significant advantages over the conventional SJ nozzles. By using SJR nozzles, the average heat transfer over the surface as well as local heat transfer rate can be greatly enhanced, and a controllable exerted force minimizes the mechanical impact to fragile food products.

## **2. SJR Nozzle**

SJR nozzle is a modified version of SJ nozzle. The schematic of SJR nozzle with exit angle of 45° is shown in Fig. 1 [5]. This innovative nozzle can be fabricated in different exit angles. Based on the application, exit angle can be toward the surface (positive angle) and outward the surface (negative angle). Explicitly, net force exerted on the impingement surface can be controlled by the exit angle of the nozzle. The flow exits the nozzle in two directions, First is in direction of minor axis which is in oval shape and second is in direction of major axis which is radial [4] [5] (Fig. 2).

In SJ nozzle, stagnation point is right under the center line and maximum heat transfer happens at the center of impingement surface but in SJR nozzle reattachment point is observed in an oval shape away from the center line of the nozzle. Therefore, reattachment area in SJR nozzle covers a larger space than that of SJ nozzle and moves outward and inward direction which leads to a higher average heat and mass transfer coefficient.

Fig. 2 Schematic of SJR nozzle

Fig. 1 Flow direction on impingement surface under SJR nozzle

In this study, all the tests were conducted with two SJR nozzles with exit angles of  $+20^\circ$  and  $+45^\circ$ . The geometrical parameters of these nozzles and SJ nozzle are listed in Table 1.

Table 1. Geometrical parameters of SJ and SJR nozzles

Parameters (mm)	SJ Nozzle	SJR $20^\circ$	SJR $45^\circ$
L	73	73	73
b	-	4	4
$X_p$	80	14	16
$Z_w$	-	18	14
$Z_{ws}$	9.25	10	9.25

### 3. Experimental Set Up and Procedure

The experiments were conducted at the optimum distance between the exit opening of nozzle and the impingement surface. Drying test with SJ nozzle was run based on optimal height of nozzle to surface spacing of 80 mm [4].  $X_p$  for SJR $+20^\circ$  and SJR $+45^\circ$  was fixed at 14 mm and 16 mm, respectively, to accommodate for swelling of the samples during the early stage of drying [5]. In this paper, the samples used are raw cookie doughs. Each experiment consisted of two cookies. The drying characteristics with SJR and SJ nozzles are experimentally obtained and compared to illustrate the resultant enhancements in drying rates with the use of SJR nozzle. The comparisons are made under identical air mass flowrates.

The schematic of the apparatus used for this study is shown in Fig. 3. Air was conducted to the apparatus through 0.5 in diameter plastic hose from an upstream air supply. A threaded on/off valve was used to control the air mass flowrate. A rotameter was utilized to measure the air mass flow rate. For heating the air, an 8.5 kW torch electrical heater was utilized which

was connected to a PID unit controller to regulate the power required to reach the desired temperature. Following the electrical heater, a solenoid valve activated with a timer was used to redirect the incoming air away from the sample during the sample weight recording. Threaded nozzle was connected interchangeably to the solenoid valve. A scale with an accuracy of 0.001 g was used to capture the sample weight during the drying process. Adjustable stand was used to hold the digital scale and adjust the distance between the nozzle and impingement surface. J-type thermocouples were used to measure the temperatures in different locations such as at the exit of electrical heater, nozzles exit, and impingement surface. Surface pressure was measured by a pressure transducer. The apparatus was well insulated to minimize the heat loss to ambient.

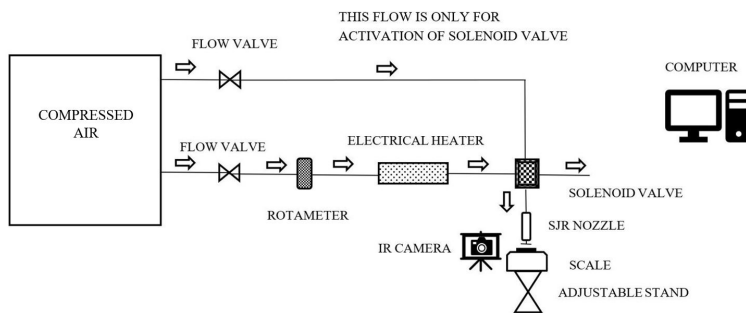

Fig. 3 Simplified schematic of apparatus used for this study

#### 4. Experimental Results

All the tests were conducted under the same air exit temperature of 260 °C and two different mass flow rates. Operating conditions for mass flowrates of 0.005 kg/s (i.e. case 1) and 0.01 kg/s (i.e. case 2) are listed in Table 2 and Table 3.

Table 2. Operating conditions for case 1

	SJ Nozzle	SJR 20°	SJR 45°
$b/Z_w$	-	0.22	0.22
<b>Re</b>	6134	3875	4613
$\dot{m}$ (kg/s)	0.005	0.005	0.005
<b>V</b> (m/s)	6.19	7.34	8.74
$V_{s/c}$ (m/s)	6.19	6.19	6.19
<b>T</b> (°C)	260	260	260

Table 3. Operating conditions for case 2

	SJ Nozzle	SJR 20°	SJR 45°
$b/Z_w$	-	0.22	0.22
<b>Re</b>	12269	7750	9226
$\dot{m}$ (kg/s)	0.01	0.01	0.01
<b>V</b> (m/s)	12.38	14.69	17.48
$V_{c/s}$ (m/s)	12.38	12.38	12.38
<b>T</b> (°C)	260	260	260

Figure 4 shows the percent dry basis moisture content (DBMC) as a function of drying time. The corresponding operating conditions are shown in Table 2. The results indicate that the drying times to reach a specific DBMC with SJR nozzles are much shorter than those of SJ

nozzle. For example, it took 31 minutes with SJ nozzle to reach a 10 percent DBMC level while with SJR+20° and SJR+45° the DBMC of 10 percent was reached in 18 and 15 minutes, respectively, corresponding to 42 and 52 percent decrease in drying time. To reach a lower DBMC of 4.5 percent, the SJ, SJR+20°, and SJR45° required 76, 40, and 38 minutes, respectively, corresponding to 47 and 50 percent reduction in drying times. Figure 4 also shows that the performance of the two SJR nozzles are almost similar with air flowrate of 0.005 kg/s.

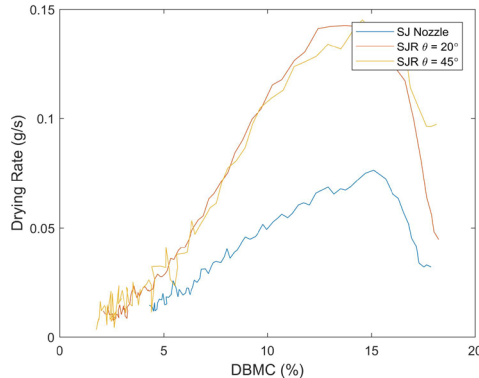

**Fig. 4** Dry basis moisture content with air flowrate of 0.005 kg/s

Figure 5 shows similar results to those of Fig. 4 but under a higher air mass flowrate of 0.01 kg/s. The corresponding operating conditions for Fig. 5 are listed in Table 3. According to Fig. 5, the drying rates are higher with SJR nozzles compared to SJ nozzle at this higher air flowrate as well. However, the percent enhancements are lower than those of lower air flowrate of 0.005 kg/s. This is expected because as the air flowrate increases the drying rate increases as well regardless of the type of nozzle used making it more difficult to enhance the drying rate with SJR nozzles. However, the main reason for the SJR nozzles superior performance compared to SJ nozzle performance under the same exit air flowrate is mainly due to the differences in their flow fields. Specifically, the reattachment zone associated with an SJR nozzle is by far larger than the stagnation zone of the SJ nozzle resulting in a higher averaged heat transfer coefficient with SJR nozzles.

**Fig. 5** Dry basis moisture content with air flowrate of 0.01 kg/s

Another appropriate way of evaluating the performance of three nozzles is to compare their drying rates as a function of percent DBMC as illustrated in Fig. 6. According to this figure, the drying rates of innovative nozzles are substantially higher than those of conventional nozzle over the whole range of sample moisture content. For instance, at DBMC of 15%, the drying rates for SJ, SJR+20°, and SJR+45° nozzles are 0.07, 0.141, and 0.146 g/s, respectively.

**Fig. 6** Comparison of drying rate between SJ and SJR nozzles

To confirm repeatability of the data, drying experiments with SJR+20° under the mass flowrate of 0.01 kg/s and temperature of 260°C were carried out three times. The minimum and maximum percent standard deviations of dry basis moisture content were 0.04 and 1.52. Additionally, the same repeatability tests were performed for SJ nozzle under the same operating conditions. The minimum and maximum percent standard deviations of dry basis moisture content were 0.05 and 0.92.

## 5. Conclusions

The convective air drying characteristics of two SJR nozzles with exit angles of +20° and +45° were compared to a conventional impinging SJ nozzle drying characteristics. The results confirmed that both SJR nozzles provide superior drying performance compared to that of SJ nozzle under the equivalent air mass flowrate. SJR nozzles are especially suitable for drying applications where it is crucial to protect fragile samples from being damaged by direct airflow impingement.

### **Abstract**

*Spray drying has become not merely a drying process, but also an important tool for engineering solid structures, specially for multi-component feeds. In that way, it is important to know how the drying conditions and liquid formulations affect the particle final solid structure. In the present study, we investigated the changes on the solid structure of a spray-dried binary mixture of lactose and whey protein isolate under different process and formulation conditions. Particle morphology, diameter, porosity and occluded air were analyzed. Total solid content in the feed was the parameter of highest impact on the spray-dried particle's occluded air volume.*

**Keywords:** *spray drying; solid structure; porosity; hollow particles.*

---

## **1. Introduction**

The first significant industrial use of spray drying concerned the dairy industry in the 1920s. This operation first attracted attention for its capacity of quickly producing particulate material with controllable size distribution, bulk density, moisture content and the possibility of drying heat-sensitive substances [1]. For many years, spray drying had been mainly seen as solely a drying operation to produce large amounts of powder, remove most of the feed's solvent and enhance product storage and stability.

However, this perception changed over the years driven by the increasing demand for particles with engineered end-use properties, that is to say particles with improved properties like dissolution rate, controlled release, flowability, wettability, compactibility and coating [2, 3]. Therefore, spray drying has become nowadays a tool for designing solid structures, specially from multi-component feeds.

The aforementioned particle properties are affected by the drying parameters, such as air temperature, air humidity and initial droplet size, as well as the feed liquid state (solution, emulsion, suspension), nature of the substances to be dried and their concentration [4]. To accurately design solid particles, it is important to understand how the particle solid structure is influenced by the drying conditions and feed composition.

The aim of the present work was to investigate the effect of some drying and formulation parameters on the solid structure of particles produced by spray drying. An aqueous solution of lactose and whey protein isolate (model solution in the food industry) was dried under different air inlet temperatures, nozzle diameters and initial solid loads. The variation of particle morphology, diameter, porosity and occluded air were analyzed.

## **2. Materials and Methods**

### **2.1. Materials**

$\alpha$ -lactose monohydrate and whey protein isolate (WPI) were kindly provided by Pierre-Fabre Laboratory (France) and Lactalis (France), respectively, and used as received.

### **2.2. Methods**

#### *2.2.1. Solution preparation*

The sample solutions were prepared by mixing lactose and WPI powders in distilled water at a constant protein-to-sugar mass ratio of 50:50. The total dissolved solid content in the liquid feed varied from 10, 20 to 26 % w/w. In order to completely dissolve the solutes and to avoid protein denaturation, the samples were heated at 30 °C and gently agitated with a magnetic stirrer for 8 hours.

### 2.2.2. Spray drying

A laboratory-scale spray dryer (B-290 Advanced, Büchi, Switzerland) was used to spray dry the sample solutions. The air inlet temperature was fixed at 103 °C or 120 °C. Two different nozzle diameters were used, 0.5 mm and 2.0 mm. The experiments were carried out with an aspiration rate of 95 % with a corresponding air flow rate of 33.25 m<sup>3</sup>/h and a feed rate of 4.27 mL/min. The powder collected after drying was stored at room temperature in a flask. Table 1 represents the experimental conditions employed in the present work.

*Table 1. Sample solutions parameters and drying conditions*

Sample	Lactose percentage (% w/w)	WPI percentage (% w/w)	Total solid content (% w/w)	Nozzle diameter (mm)	Air inlet temperature (°C)
S1	5.0	5.0	10.0	2.0	103.0
S2	9.9	9.9	19.8	2.0	103.0
S3	13.0	13.0	26.0	2.0	103.0
S4	10.0	10.0	20.0	0.5	120.0

### 2.2.3. Spray-dried particles characterization

The particle diameter was evaluated by laser diffraction (Malvern Mastersize 3000, Malvern Instruments) after dispersing the powder in 2-propanol. The particle size distribution was calculated with the Mie theory using the refractive index values of  $n = 1.378$  for 2-propanol and  $n = 1.57$  for the spray-dried particles.

To assess the particle morphology, the spray-dried samples were examined with scanning electron microscopy (SEM) (ESEM FEG Philips). The acceleration voltage was 8 kV. The particles were placed on an adhesive carbon tape and sputter-coated with platinum.

Liquid pycnometry was employed in order to evaluate the apparent density of the spray-dried powder. The apparent density was calculated by knowing exactly the mass of powder and 2-isopropanol inserted into the pycnometer. The measurements were done in triplicate.

Helium pycnometry (Accupyc 1340, Micromeritics) was used to determine the particle true density. Two grams of powder were dried under vacuum in an oven at 70 °C, to evaporate any remaining moisture, and added to the pycnometer's measuring cell. The true density was obtained after 25 cycles of filling-draining helium in the measurement cell.

### 3. Results and discussion

Lactose is a compound frequently present in spray drying of dairy products, since it is the main carbohydrate in bovine milk. This sugar is also employed as protective agent when stress-sensitive substances are spray dried, like whey protein [5].

The different drying conditions presented in Table 1 did not cause any change in the particle morphology. The spray dried powders presented a hollow core with a wrinkled surface, as can be seen from the SEM micrographs in Figure 1. A wrinkled morphology was also observed in previous studies with protein-to-sugar mass ratios of 70:30 [6] and 80:20 [5]. Spray-dried skim milk [7] also presented the same surface roughness.

The laser diffraction results in Table 2 are given in volume fractions. The particle size distribution is represented by three percentages of particles having at most the indicated diameters. The Span number displays the distribution width. From these measurements, it is possible to observe as expected an increase in the mean spray-dried particle size with more concentrated feed formulations.. The solid crust appears sooner on more concentrated liquid droplets in comparison to more diluted ones, due to the proximity to saturation. Therefore, the resulting external diameter remains bigger.

*Table 2. Laser diffraction measurements for the mixture 50 % lactose – 50 % whey protein isolate (w/w, on dry basis) on the different samples*

Sample	Total solid	Volume mean				Span
	content (% w/w)	diameter d-4,3 (µm)	d-10 (µm)	d-50 (µm)	d-90 (µm)	
S1	10.0	9.1 ± 0.0	2.6 ± 0.0	8.9 ± 0.0	15.4 ± 0.1	1.4 ± 0.0
S2	19.8	10.5 ± 0.1	2.8 ± 0.0	10.3 ± 0.0	17.9 ± 0.1	1.5 ± 0.0
S3	26.0	12.3 ± 0.1	2.6 ± 0.0	12.1 ± 0.1	21.8 ± 0.1	1.6 ± 0.0
S4	20.0	5.4 ± 0.0	1.6 ± 0.0	5.2 ± 0.0	9.5 ± 0.0	1.5 ± 0.1

The measure of apparent density from the liquid pycnometry includes open and closed pores in the particles. The helium pycnometry gives the particle true density from the adsorption of helium to the solid's surface through the open pores. Due to the low-porous nature of the present spray-dried samples, the presence of closed pores can be neglected for the sake of density and porosity calculations. These density values are presented in Table 3. It is important to note that the particles (micrographs in Figure 1) show a densely packed crust region, so one can suggest that the porosity estimations take into account mainly the air fraction presented in the particle hollow core.

**Figure 1.** SEM micrographs of spray-dried lactose-whey protein isolate particles illustrating the same trend of wrinkled surface produced from droplets of different total solid content. 10 % w/w (a – b), 20 % w/w (c – d), 30 % w/w (e – f)

For the purpose of visualization, the density results were written in terms of particle porosity, and thus occluded air, so that a modification of the particle crust can be examined. To calculate the porosity, the mass of air contained in the particle's pores was neglected. In that way, the apparent and true densities were used to evaluate the porosity, as indicated in Equation 1.

**Table 3. Evolution of occluded air measured from the spray-dried particle's porosity and apparent density**

Sample	Total solid content (% w/w)	Apparent density (g/cm <sup>3</sup> )	True density (g/cm <sup>3</sup> )	Porosity	Occluded air (cm <sup>3</sup> /g)
S1	10.0	0.81 ± 0.0	1.37 ± 0.0	0.41	0.50
S2	19.8	0.88 ± 0.0	1.30 ± 0.0	0.32	0.36
S3	26.0	0.92 ± 0.0	1.25 ± 0.0	0.26	0.28
S4	20.0	0.86 ± 0.0	1.37 ± 0.0	0.37	0.43

$$\varphi = \frac{\rho_{true} - \rho_{apparent}}{\rho_{true}} \quad (1)$$

Where  $\varphi$  is the particle porosity. The volume of occluded air in the particle per gram of powder can be calculated from the porosity as follows,

$$V_{occluded\ air / g\ powder} = \varphi \frac{1}{\rho_{apparent}} \quad (2)$$

It is interesting to note from Table 3 that an increase of approximately 40 % on the particle occluded air was accomplished by reducing the total solid content from 26 % w/w to 10 % w/w, for the same air inlet temperature and nozzle diameter. However, an increase of only 10 % on the particle occluded air was obtained by modifying the air inlet temperature and the nozzle size from [103 °C, 2 mm] to [120 °C, 0.5 mm], for the same total solid fraction.

The displayed occluded air results along with the mean particle diameters (d-4.3) from Table 2 give an indirect qualitative information about the particle crust width. When comparing the samples S1 and S3, the mean particle diameter is relatively close, but the particle occluded air difference is more important, as mentioned in the previous paragraph. Consequently, one can suggest that the lower solid content on the particles from sample S1 generated a thinner crust compared to that of the particles from S3.

The amount of occluded air in the particle is an important issue in cases when there are oxidation-sensitive compounds present in the particle solid structure. In that way, to avoid a particle inner oxidation, a reduction of the occluded air should be considered [8].

## 4. Conclusions

In the present study, particles containing an equal mixture of lactose and whey protein isolate were obtained through spray drying. In order to observe changes in the particle solid structures, the sample solutions were spray dried under different total solid contents, air inlet temperatures and nozzle diameters. The resulting particles were analyzed through scanning electron microscopy, laser diffraction, liquid pycnometry and helium pycnometry. In that way, the particle morphology, diameter, porosity and occluded air could be assessed.

It was observed that a hollow and wrinkled particle morphology was obtained from all the spray dried samples. A slight increase in the mean particle diameter was observed with higher solid contents. A change in the total solid content had a higher impact on the particle's occluded air than the coupled air inlet temperature and nozzle diameter. It is important to note that the porosity and occluded air estimations were related to the quantity of air present in the particle hollow core, due to the low-porous nature of the particle's crust obtained. A higher occluded air amount can lead to oxidation issues if there are sensitive substances in the particle solid structure. A possible solution would then be the use of higher solid contents in the liquid feed, to generate particles with a lower occluded air volume.

### Abstract

*The influence of pulsed electric fields (PEF) treatment on freeze-drying for potato and strawberry tissues was investigated. Samples were pre-treated by PEF ( $E = 400 \text{ V cm}^{-1}$ ) for different treatment times. Freeze-drying was carried out at  $-17^\circ\text{C}$  and 18.4 Pa or 30 Pa for potato and strawberry tissues, respectively. The effects of PEF pre-treatment was compared with intact samples. The drying time was reduced by 35% for potato and 30% for strawberry. The sample rehydration capacity and the electrolytes released during the rehydration were higher for pre-treated samples. Strawberries texture was characterized by the hardness, the cohesiveness and the springiness.*

**Keywords:** Pulsed Electric fields; Freeze-drying; Potato; Strawberry; Textural Properties.

## 1 Introduction

Freeze-drying process is well-known to produce high quality products. However, the use of this process is limited because of the long drying time and the high energy consumption. For this reason, scientists keep searching for new pre-treatments to improve heat and mass transfers during the freeze-drying process without affecting the quality of the final products.

The relevance of using the pulsed electric fields (PEF) to enhance the performances for various modes of drying was pointed out.<sup>[1]</sup> It was reported that, exposing a biological tissue to an external electric field for few microseconds cause a transient increase in the transmembrane potential. This alters the organization of the cytoplasmic membrane by forming pores which increases the cell membrane permeabilization.<sup>[2]</sup>

A few studies have shown the ability of the PEF treatment on fruits and vegetables to accelerate the freeze-drying process by increasing the drying rate and/or reducing the drying time.<sup>[3-6]</sup>

While these results are promising, researches are still needed to confirm these findings for different plant tissues and to examine the efficiency of the PEF assisted freeze-drying process on the quality of the final products. The objective of this work was to investigate the influence of coupling PEF treatment and freeze-drying on the dehydration kinetics of potato and strawberry tissues, and to investigate the effect of using this innovative process on the rehydration and textural properties of freeze-dried products.

## 2 Materials and Methods

### 2.1 Sample preparation

Potatoes (Agata) and strawberries (Charlotte and unknown variety from Spain) were bought from a local market (Pontivy, France) and stored in a refrigerator (4°C). Initial moisture contents were  $(85.2 \pm 1.0)$  % and  $(91.7 \pm 0.4)$  % in wet basis (w/w), respectively. Cylindrical potato (18 mm diameter and 25 mm height) and strawberry samples (20 mm diameter and 27 mm height) were prepared.

### 2.2 Pulsed Electric Field (PEF) pre-treatment

The electric field treatment was carried out using a PEF generator (2.5 kV/24 mA, Effitech, Pau, France). The generator supplies near-rectangular monopolar pulses.  $N$  series of pulses (-) were imposed during the treatment. Each series was composed of  $n$  pulses (-) with pulse duration  $t_i$  ( $\mu$ s) and pulse repetition time  $\Delta t$  (s). Two consecutive series were separated by an intertrain time  $\Delta t_r$  (min). This time between series was fixed at 5 min in

order to control the increase in the product temperature (10°C in our case). The total PEF treatment time (s) was defined as  $t_t = n \cdot N \cdot t_i$ .

For potato samples, the PEF treatment was realized according to the following protocol:  $E = 400 \text{ V cm}^{-1}$ ,  $N = 12.5$ ,  $n = 240$ ,  $t_i = 100 \text{ } \mu\text{s}$ ,  $t_t = 0.3 \text{ s}$ .

For strawberry samples, the same electric field strength, pulse duration and pulse number in each series were applied ( $E = 400 \text{ V cm}^{-1}$ ,  $n = 240$ ,  $t_i = 100 \text{ } \mu\text{s}$ ). For the study of the disintegration kinetics during the PEF treatment,  $N = 16$  series were required to reach the totally disintegrated tissue which corresponds to a PEF treatment time  $t_t = 0.384 \text{ s}$ . For the studies of the dehydration kinetics and the effect of PEF treatment on the freeze-dried strawberries, different number of series were applied ( $N = 0.5, 1, 2, 3, 4$  series) correspondent to various PEF treatment times ( $t_t = 0.012 \text{ s}, 0.024 \text{ s}, 0.036 \text{ s}, 0.048 \text{ s}$  and  $0.096 \text{ s}$ ). After the PEF pre-treatment, the samples were frozen and stored in a freezer (Fryka Kältetechnik, Esslingen am Neckar, Germany) at  $-80^\circ\text{C}$  until needed.

The degree of tissues damage was assessed from the conductivity disintegration index  $Z$  (-), calculated as  $Z = \sigma - \sigma_i / \sigma_d - \sigma_i$ .<sup>[7]</sup>  $\sigma$  is the electrical conductivity measured at time  $t$  ( $\text{S cm}^{-1}$ ),  $\sigma_i$  the conductivity of the intact sample ( $\text{S cm}^{-1}$ ) and  $\sigma_d$  the conductivity of the totally damaged sample ( $\text{S cm}^{-1}$ ).  $\sigma_d$  was determined from the measurements of the electrical conductivity of a tissue after a freeze-thaw cycle.

### 2.3 Freeze-drying experiments

The freeze-drying experiments were carried out using a VirTis Advantage XL-70 freeze-dryer (Sp Scientific, Warminster, USA). The frozen samples ( $-80^\circ\text{C}$ ) were introduced in the freeze-dryer on a pre-cooled heating shelf fixed at  $-50^\circ\text{C}$ . For both products investigated, the temperature inside the freeze-dryer chamber was set at  $-17^\circ\text{C}$ . The pressure inside the freeze-dryer chamber was kept at 18.4 Pa and 30 Pa for potato and strawberry tissues respectively. During the secondary drying, the plate temperature was risen to  $45^\circ\text{C}$ . Triplicate samples were weighted using a precision balance (Acculab ALC-110.4, accuracy  $10^{-4} \text{ g}$ , Sartorius, Goettingen, Germany). The relative mass,  $(m/m_i)$  was calculated by dividing  $m$ , which is the measured mass at time  $t$  (g) by  $m_i$ , the initial mass (g).

## **2.4 Quality analysis**

### *2.4.1 Rehydration ratio*

The rehydration ratio was determined by weighing a sample before and after soaking it in distilled water at room temperature ( $24 \pm 1$ ) °C for one minute. These measurements were done for triplicate samples.

### *2.4.2 Electrolyte release during rehydration*

The amount of electrolytes released during rehydration was determined by measuring the changes in electrical conductivity of the rehydration solution. These experiments were carried out with intact and PEF pre-treated samples with different treatment times ( $t_t = 0.012$  s, 0.024 s, 0.048 s, 0.072 s and 0.096 s). The electric resistance of the solution was measured using an impedance meter (Agilent U1733C, Keysight Technologies, USA) at 100 KHz frequency. The samples were first weighted and placed inside a small beaker filled with distilled water (conductivity of  $0.001 \text{ S m}^{-1}$ ). The liquid-solid ratio was fixed at 80. A magnetic stirrer was used to carefully agitate the mixture ( $100 \text{ tr min}^{-1}$ ). A small quantity of the solution (800  $\mu\text{L}$ ) was taken at different times during 2 h and was placed inside a cuvette electrodes (Eppendorf 800  $\mu\text{L}$ ), then it was connected to the impedance meter. The electrolyte release during rehydration was determined at room temperature ( $24 \pm 1$ ) °C. These measurements were done for triplicate samples.

### *2.4.3 Texture analysis*

The textural properties were determined through a Texture Analyser (MTS Synergie 200 H, Helmut Singer Elektronik, Aachen, Germany). Texture profile analysis TPA was carried out for freeze-dried slices of strawberry of 20 mm diameter. These textural measurements were performed with intact and PEF pre-treated samples with different treatment times (0.024 s, 0.048 s, 0.072 s and 0.096 s). For each condition, twenty five replicates were analysed. The trials were done using a cylindrical probe of 25 mm diameter. Two compressions were realized with an interval of 5 s between cycles. The samples were compressed to 50% of their original height, using a load cell 1 kN and the compression rate was  $30 \text{ mm min}^{-1}$ . From the force-time curves, the hardness, the cohesiveness and the springiness were determined.<sup>[8]</sup>

## **3 Results and discussion**

Fig. 1 presents the electrical conductivity disintegration index,  $Z$ , versus the total PEF treatment time for potato and strawberry tissues.

Fig. 1 Electrical conductivity disintegration index,  $Z$ , versus the total PEF treatment time for potato and strawberry tissues.

The disintegration index,  $Z$ , increases continuously during the PEF treatment. However, the evolution is not identical for potato and strawberry tissues. From Fig. 1, the half-permeabilization, defined as the time for which the disintegration degree  $Z = 0.5$  is reached, was determined.

Strawberry is more sensitive to PEF treatment with a half-permeabilization happened after less than 0.024 s of treatment time compared to potato tissue which required a two-fold treatment time (0.05 s).

In order to investigate the benefits of PEF pre-treatment on the freeze-drying process, potato and strawberry were prepared, frozen at  $-80^{\circ}\text{C}$  and freeze-dried.

Fig. 2 depicts the relative mass of the sample,  $m/m_i$ , as a function of the freeze-drying time for strawberry samples.

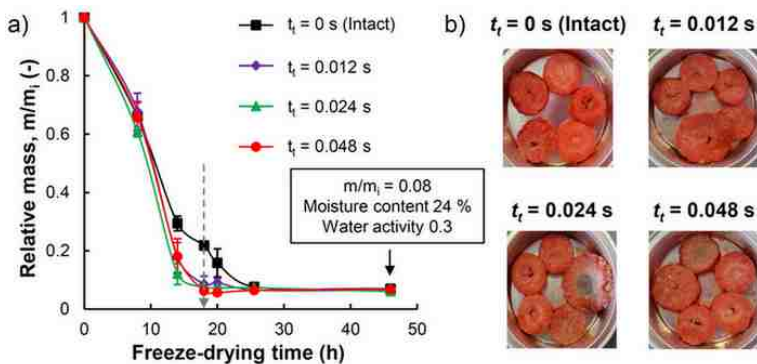

Fig. 2 a) Relative mass of the sample,  $m/m_i$ , as a function of the freeze-drying time for intact and PEF pre-treated strawberry samples with different treatment times; b) Photographies of samples.

PEF pre-treatment accelerates the freeze-drying process and no difference is observable between the pre-treated samples with different treatment times (Fig. 2a). Eighteen hours are sufficient to dry the pre-treated samples, against 46 h for intact ones. Thus, the PEF pre-treatment is able to reduce the drying time of strawberry by 30%. Visually, the appearance of PEF pre-treated samples after freeze-drying is slightly damaged compared with intact ones (Fig. 2b). For potato samples, the positive effect of the PEF pre-treatment on the freeze-drying rate is also obtained and the drying time is shortened by 35% (not shown).

The rehydration ratio is almost doubled for PEF pre-treated freeze-dried strawberries compared with intact ones. Moreover, the electrolyte release during the rehydration process increases with the PEF treatment time (Fig. 3).

Fig. 3 Relative conductivity,  $\sigma/\sigma_i$  as a function of time during the rehydration of freeze-dried strawberries at different PEF treatment times.

These results come from the fact that PEF pre-treatment causes breaks in the cell membrane which facilitates the release of the cell components towards the extracellular medium.<sup>[9,3]</sup> The concentration of the ionic components increases with the PEF treatment time as a consequence of a greater damage in the cell membrane. The statistical analysis indicated that PEF pre-treatment has a significant effect on the rehydration ratio (p-value < 0.05).

Fig. 4 shows the average values of the hardness and the springiness for intact and pre-treated freeze-dried strawberry slices for different PEF treatment times.

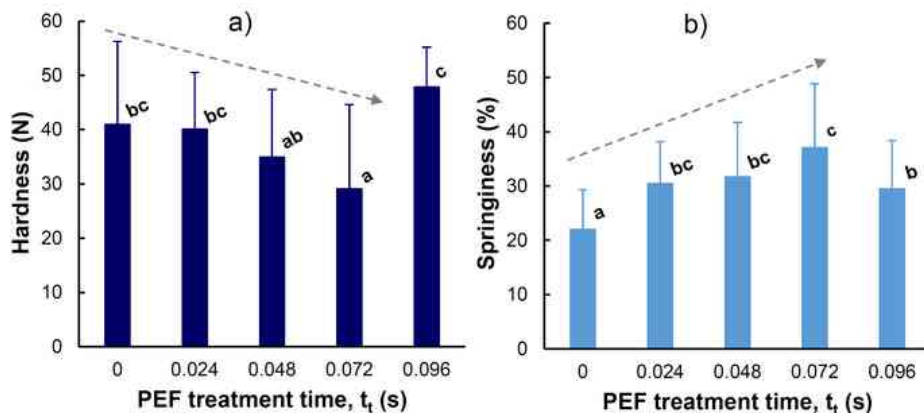

Fig. 4 Hardness and springiness for intact and pre-treated freeze-dried strawberry slices for different PEF treatment times.

The hardness represents the maximal force required to deform the sample in mastication during the first compression and the springiness characterizes the product elasticity. After the PEF pre-treatment, the strawberry tissues have lost a part of their initial strength. Thus, the hardness values decrease for increasing PEF treatment times until the time reaches 0.096 s (Fig. 4a). Both springiness and cohesiveness of pre-treated samples increase compared with the intact ones and this increase becomes all the more important as the PEF treatment time is high (springiness: Fig. 4b and cohesiveness: not shown). All these results can be explained by the irreversible damage in the cell membrane caused by the PEF pre-treatment.<sup>[10]</sup> However, after an intensive PEF pre-treatment (0.096 s) the cells have lost their cellular turgor components and we assume that all the residues from the cells aggregate and form a tougher structure.

#### 4 Conclusions

The influence of coupling PEF treatment and freeze-drying process for potato and strawberry tissues was investigated. PEF pre-treatment was able to reduce the drying time of 35% and 30% for potato and strawberry, respectively. A significant rehydration capacity was found for pre-treated and freeze-dried strawberries. Strawberries texture was characterized by the hardness, the cohesiveness and the springiness.

#### 5 Acknowledgements

Our gratitude goes to E. Mehinagic and E. Madieta who supervised the texture analysis.

### **Abstract**

*Apricot pretreated with RF and then dried with convective hot air at 65°C, 3.0m/s in this research. RF pretreatment time of 20, 30, 40 and 50min were chosen. Results showed that, there is only falling rate period during apricot hot air drying, and the drying rate of apricot is improved significantly; Herdenson and Pabis model is suitable for apricot hot air drying; retentions of flavonoids, polyphenols and Vc in dried apricot were higher than those of fresh apricot; when RF treating time was chosen 30mins, nutrients retentions of Vc, flavonoid and polyphenols were 0.9543mg/100g, 5.4089mg/100g and 7.3382mg/100g, separately.*

**Keywords:** *apricot fruit, hot air drying, drying rate, nutrients, radio frequency*

## 1. Introduction

Apricot originated in China. It has a wide distribution, high yield, good quality and unique flavor. However, fresh apricot fruit with high moisture content above 80% is easy to corrupt at normal temperature even cold storage<sup>[1]</sup>. Drying is an effective method to extend self life of apricot. Half dried preserved apricot fruits are popular to Chinese. So, there are several literatures about drying of apricot fruits. Wang studied on thin layer drying of apricot at low temperature and different air velocities, and temperature is the main factor affecting drying rate<sup>[2]</sup>. Natural air drying of apricot is time consuming and induces serious browning which affects the quality of dried apricot<sup>[3]</sup>. In order to prevent browning, blanching before drying or sulphur treated during drying is usual applied. And these treatments either high temperature, nutrients loss<sup>[4]</sup> or unsafe for health. New type of heating method, RF receives more and more attentions in recent years for lots of advantages such as selective heating, self-balancing effect of moisture content, large energy penetration depth and fast heating rate<sup>[5]</sup>, etc. There are several literatures on RF used in drying of agricultural products, deinfestation, sterilization<sup>[6,8]</sup>. Zhang and others<sup>[9]</sup> investigated RF combined with hot air drying red jujube, drying time was shortened by 2/3. In order to reduce drying time and improve the quality of dried apricot, RF technique was applied in this paper, and then convective hot air drying at 65°C was conducted.

## 2. Materials and Methods

### 2.1. Samples preparation

Apricot *armeniaca vulgaris lam* was provided by the institute of plum and apricot, Xi'an, in May to July, 2017. Fresh apricots were stored at 3-4°C and must be used within one week. The initial moisture of fresh apricot ranged from 85% to 86% wet basis which was determined by oven drying at 103°C. Samples were cut in half and the cores were removed, and then immersed in 2% sodium bisulfite solution for 1 hour to restrain browning.

### 2.2. RF pretreatment of apricot

Apricot fruits were moved into the RF equipment and the plate distance was set 60.0mm. The power of the radio frequency equipment is 6.0KW and the frequency is 27.1Hz. RF treated time was chosen for 20, 30, 40, and 50min.

### 2.3. Hot air drying experiment of apricot

After RF pretreatment, apricot was dried with convective hot air at 65°C and air velocity of 3.0m/s. During the drying period water content of apricot was declined from nearly 84% to about 20%. In order to analyze the drying characteristics of apricot pretreated with RF, the weights of samples were obtained by electronic balance with an accuracy of 0.001g every 60 minutes.

## 2.4. Nutrients assay

The flavonoid content of apricot fruit pulp was analyzed according the method described by Liang<sup>[10]</sup> with slight amendent. 1.0ml of filtrate was placed in a 25ml volumetric flask, and then 6ml of distilled water and 1.0ml of sodium nitrite (1:20) were added in turn and shaken well. After 6 minutes, 1.0ml of aluminium nitrate (1:10) was added and shaken well, and 6minutes later, 10.0ml of sodium hydroxide (1:10) was added and shake well. After 15 minutes' standing, the final volume was made up to 25ml with distilled water and shade well. And the sample was placed in colorimetric tube and the absorbance was measured at 510nm.

Phenolic content in apricot was determined by the Folin-Ciocalteau method<sup>[11]</sup>. 2,6-dichlorophenol indophenol method<sup>[12]</sup> was applied to assay vitamin C content of apricot in this study.

All measurements were conducted in triplicate.

## 3. Results and discussion

### 3.1. Drying characteristics of apricot preteated with RF

After RF pretreatment, the apricot fruit was dried with hot air at 65°C and on the velocity of 3.0m/s. There is only falling rate period during apricot hot air drying, shown in Figure 1. The drying rate of apricot preteated with RF was obviously higher than that of control sample, because RF treatment can improve the permeation of apricot, that would induce moisture migrate quickly. In the range of 20-50minutes RF treated, the drying rate of apricot fruit increased with the increase of RF treated time. And the drying rate of apricot fruit with 50 minutes' RF pretreatment was the highest, while that of apricot with 20minutes' RF treatment was the lowest. May be the longer RF treated time, the permeation of apricot tissue was better, which makes it easier for moisture migrate in subsequent drying process.

*Fig.1 Drying rate curves of apricot during hot air drying after different RF pretreatments*

In this paper, moisture ratio was applied to analyze the drying characteristics, shown in equation (1)<sup>[13,14]</sup>.

$$MR = \frac{M_t - M_e}{M_0 - M_e} \quad (1)$$

Where,  $M_0$ ,  $M_e$  and  $M_t$  stand for initial moisture content, equilibrium moisture content and moisture content at any time, respectively, dry basis, %. As  $M_e$  was difficult to determine at laboratory, it was neglected in this paper. So, equation (1) was simplified as equation (2).

$$MR = \frac{M_t}{M_0} \quad (2)$$

From the curves of moisture content of apricot pretreated with RF during hot air drying, as shown in figure 2, moisture content of apricot pretreated with RF declined more fast than that of control samples. And the drying time was shortened by 10% to 34%. That means RF pretreatment could save drying time and energy.

Fig.2 Curves of moisture ratio of apricot changing with drying time during hot air drying

### 3.2. Hot air drying model of apricot pretreated with RF

There are many mathematical models to describe drying characteristics of fruits and vegetables<sup>[15-19]</sup>. Through analysis of experiment data, it was found that, Henderson and Pabis model, Page model and Lemus model, showed in table 1, were better consistent with experiment data.  $R^2$ ,  $\chi^2$ , and RMSE of every model, as equations from (3) to (5), were used as indications to evaluate drying model. Henderson and Pabis model has the highest  $R^2$  ranging from 0.9715 to 0.9955, and has lower  $\chi^2$  and RMSE. So Henderson and Pabis model was better fit for experiment data.

$$R^2 = 1 - \frac{\sum_{i=1}^N (MR_{exp,i} - MR_{pre,i})^2}{\sum_{i=1}^N (\overline{MR}_{exp} - MR_{pre,i})^2} \quad (3)$$

$$\chi^2 = \frac{\sum_{i=1}^N (MR_{exp,i} - MR_{pre,i})^2}{N - n} \quad (4)$$

$$RMSE = \sqrt{\frac{\sum_{i=1}^N (MR_{exp,i} - MR_{pre,i})^2}{N}} \quad (5)$$

**Table 1**  $R^2$ , RMSE,  $\chi^2$  of hot air drying models for apricot pretreated with RF

RF treatment time/min	Model name	Model equation	Model parameters		$R^2$	RMSE	$\chi^2$
			$a$	$k$			
20	Henderson and Pabis	$MR=a\exp(-kt)$	1.0432	$-8.7\times 10^{-5}$	0.9900	0.0386	0.0016
30			0.9867	$-9.8\times 10^{-5}$	0.9715	0.0525	0.0031

### 3.3. Analyze of nutrients in dried apricot

#### 3.3.1. Flavonoids in apricot pretreated with RF

At the bigining of drying, total flavonoid content was the one of fresh apricot. From figure 3(a), it was known that, as moisture decrease, total flavonoid contents of apricots pretreated with RF were increased firstly and then declined, but higher than that of fresh apricot. The reason might be RF treatment induce fruits tissue collapsed that would favorable for testing nutrients. It also can be found that, when RF treatment time was chosen 40min, flavonoid contents of apricot maitaned highest level during the hole drying process, those of apricots pretreated with 30min and 50min were flowed by, and the last was 20minutes' RF pretreatment. The main reason might be tissue permeation of apricot would improve as the RF treetated time but there exists a limit level for permeation; and prolong RF pretreated time, nutrients were degraded or decomposed.

When dying was finished, flavonoid content in dried apricots also maintained higher than of fresh apricot (0.9075mg/100g). The main reason would be that RF destroyed internal structures of apricots, and flavones in tissue were easy to dissolve out.

#### 3.3.2. Polyphenol content in apricot pretreated with RF

It was obvious showed that, after 30 and 40 minutes' RF pretreatment, polyphenol contents of apricot during hot air drying maintained the highest level, and those of samples with 20 munites' RF pretreatment were follow by, and those of samples with 50 munites' RF

pretreatment were the lowest, showed in figure 3(b). The reason for this phenomenon as the above. But, longer time RF pretreatment may destroy polyphenol tissue and induced oxidation. The result from this study were consistent with that from Zhao et al<sup>[20]</sup>. During the hot air drying process, polyphenol contents maintain stable level and did not decline with the decrease of moisture content of apricot.

(a) Flavonoid contents

(b) Polyphenol Content

(c) Vc content

20 minutes' RF pretreatment    
  30 minutes' RF pretreatment  
 40 minutes' RF pretreatment    
  50 minutes' RF pretreatment

**Fig.3 Nutrients of apricot pretreated with RF changing with moisture content in hot air drying**

### 3.3.3. Vitamin C in apricot pretreated with RF

As soon as RF pretreated, Vc content in apricot were sharply increased compared to that of fresh sample, showed in figure 3(c). However, Vc is heat sensitive material, as drying

processing, it was decreased as the decrease of moisture content of apricot. And the 40 minutes' RF pretreatment could induce the better permeation of apricot tissue analyzed above, so more Vc in apricot was exposed on the surface of wet material, that meant more Vc would degrade when exposed in high temperature condition. When hot air drying was finished, Vc contents of dried apricot with different RF pretreated were slightly higher than that of fresh fruit (0.7817mg/100g).

From the above nutrients analyze, when RF treating time was chosen 30 minutes, nutrients retentions of flavonoid, polyphenols and Vc were 5.4089mg/100g, 7.3382mg/100g, and 0.9543mg/100g, separately.

#### **4. Conclusions**

RF treatment could improve the hot air drying rate of apricot, and saving time and energy. After RF pretreatment, nutrients of flavonoids and polyphenol in apricot were improved and maintain higher levels during hot air drying, although vitamin C was higher just after RF pretreatment, it was degraded during hot air drying. Overall, RF would be a new pretreatment technique for fruit and vegetables drying.

### **Abstract**

*Organic acids, sugar and colour define the quality and the taste of mangoes. The quality deteriorates during drying on a single-layer-dryer. Quality losses can be reduced by using drying parameters that influence the quality less. In this research, the contents of ascorbic acid, organic acids and sugar as well as colour changes and shrinkage are analysed. Analyses are carried out at different temperatures, dew point temperatures and air velocities using HPLC, IC and UV/Vis- spectrometry. The quality criteria showed the lowest changes at a temperature of 60°C, dew point temperature of 20°C and an air velocity of 0.9 m/s.*

**Keywords:** *organic acids; sugars; colour; shrinkage; thin-layer-dryer.*

---

## **1. Introduction**

The world's population is projected to reach nine billion by 2050. It is expected that the number of people suffering from chronic undernourishment (1 billion in 2010) will therefore increase significantly by 2050. Due to this fact, it is vital to make the food available more useful during production. In developing and transition countries, the main focus should be on reducing post-harvest losses [1]. These losses can be avoided if the shelf life of the products is extended. In order to extend the shelf life of the investigated products, it is necessary to influence the microbial population by changing the conditions in the products; so microorganisms cannot grow and reproduce. One method to make agricultural products more durable is drying [2]. During drying, the agricultural products lose water and the living conditions for microorganisms become increasingly harsher. But during drying, the products undergo a loss of quality, e.g. changes in taste, degradation of vitamins and temperature sensitive acids and change in colour. Optimal drying parameters can reduce such quality losses and preserve the essential quality criteria of the investigated agricultural products. In this study, the content of ascorbic-, citric- and malic acid as well as the sugar content of fresh and dried mangoes are analysed. Analyses are carried out on mangoes dried with an experimental single-layer-dryer described by ARENDT using HPLC, IC and UV/Vis instruments [3].

## **2. Materials and Methods**

The mango plant originates from the tropics of India and Burma. Its edible pulp is yellow to orange-red and is protected by a leathery shell, which in ripe state has a green to orange-red colour, depending on the variety. [4]

### **2.1. Quality Criteria of Mangoes**

Because humans and animals have lost their ability to synthesize ascorbic acid out of carbohydrates, it is essential to ingest ascorbic acid within their diet. Ascorbic acid is an important compound in all living organisms and maintains metabolic functions. The best way to reach the daily necessity of 250 to 300 mg is by consuming fruits and vegetables. Ascorbic acid acts like an antioxidant against free radicals and can reduce cancer risks and risk for arteriosclerosis [5, 6, 7]. Environmental conditions like light, temperature, oxygen, cations, trace elements and the pH-value can influence the ascorbic acid content in fruits [5, 7]. Therefore the content of ascorbic acid in mangoes can vary from one fruit to another. The stability of ascorbic acid in food products or an aqueous medium depends on different ambient conditions. Factors lowering the content of ascorbic acid include light, oxygen, high temperature, alkaline pH-values, enzymatic reactions and catalytically active metal ions [7, 8]. Citric acid is found in every living cell because it is produced as an intermediate in the citric acid cycle and is required for energy generation. Like other antioxidants, it is able to conserve fat, colours, flavors and vitamins in food. Furthermore, it is able to

complex heavy metals and acts like an important inhibitor against uroliths [9, 10, 11]. Together with malic acid, citric acid contributes significantly to the flavor of fruits and vegetables [12]. The riper the fruit is, the lower its content of malic acid [12]. Malic acid also has a supportive effect on antioxidants and therefore inhibits enzymatic browning in truncated or injured fruits and vegetables [13]. Malic acid occurs in L- and D-form, but only L-malic acid is present in nature. Malic acid is found in all living cells because it also appears as an intermediate in the citric acid cycle and is required for energy generation [13]. The primary sugars available in mangoes are sucrose, glucose and fructose. Together with polyphenols and the organic acid content, the sugar content defines the taste of fruits and vegetables [14, 15]. The carbohydrates are the energy providers for the human body and also serve as construction material of cells. [7, 16]

## 2.2. Sample Preparation and Experimental Set-up

Mangoes were purchased at a local supplier in Konstanz, Germany. For analysis fresh and dried mangoes were frozen in liquid nitrogen and pulverized in a Moulinex mill. In each series of experiments, the mangoes were dried in a laboratory single-layer-dryer. For the drying process, the through flow principle was applied with air temperatures of 40°C, 60°C, 80°C and 94°C, dew point temperatures of 5°C, 10°C, 20°C, 30°C and 37°C and air velocities of 0.6 m/s, 0.9 m/s, 1.2 m/s and 1.4 m/s. The homogenized samples were extracted for measuring quality criteria.

### 2.2.1. Ascorbic Acid Extraction

The fresh and dried mangoes were prepared according to the European Standard EN 14130 [18]; diluted meta-phosphoric acid was used to extract the samples. This suspension was then filtered. A certain amount of the filtrate was diluted with an L-cysteine solution, and adjusted to a pH-value between 7.0 and 7.2. The solution was then stirred for a defined time and set to a value between 2.5 and 2.8 on the pH-scale. Prior to injection to the HPLC ultrapure water was added to the solution until a defined volume was reached. Furthermore, the samples were filtered with a 0.45 µm filter to prevent pollution of the RP- (reversed phase-) column [18] before the injection to the HPLC.

### 2.2.2. Organic Acid Extraction

The fresh and dried mangoes were diluted in ultrapure water and extracted for 30 minutes in an ultrasonic bath. Then the samples were filtered and subsequently injected to the IC-system. Prior to IC analysis the filtrates were filtered through a 0.45 µm filter to prevent the organic acid column (ion-exclusion chromatography (IEC)) from pollution.

### 2.2.3. Sugar Extraction

For sugar extraction, fresh and dried mango samples were diluted with ultrapure water. The samples were extracted for 10 minutes on a magnetic stirrer. Then the diluted samples were

filtered and processed like described in the manual of the enzymatic test of R-BIOPHARM AG. Following this enzyme kit, the content of sucrose, D-glucose and D-fructose were measured using an UV/Vis-spectrometer. Samples were prepared in a way that enables the determination of D-glucose content before and after the enzymatic hydrolysis of sucrose. Subsequently, the content of D-fructose was determined. [19]

#### 2.2.4. Experimental

The ascorbic acid extracts of fresh and dried mango samples were analysed by an HPLC System (1260 Infinity, AGILENT TECHNOLOGIES, INC.). The used column was a LiChrospher (5  $\mu$  C18 100A; 4.0 x 250 mm). The ascorbic acid (L(+)-ascorbic acid) was analysed by isocratic elution using an eluent consisting of ultrapure water with  $\text{KH}_2\text{PO}_4$  and methanol with N-cetyl-N,N,N-trimethyl-ammonium bromide according to the European Standard EN 14130. Detection of the ascorbic acid was carried out with a diode-array-detector at a wavelength of 254 nm. [18] The extracts of the organic acids were analysed using the METROHM ion chromatograph 883 Basic IC plus. The sample components were separated on a chromatographic ion-exclusion chromatography (IEC) column, Organic Acid 6.1005.200 from METROHM GmbH & Co. KG (particle size of 9  $\mu\text{m}$ , length of 250 mm, diameter of 7.8 mm). As mobile phase acetone diluted with 0.5 mmol/L  $\text{H}_2\text{SO}_4$  was used (standard eluent) [20]. A suppressor cell was placed prior to the conductivity detector. Sugar content analysis of the extracted and prepared mangoes was done using an UV/Vis spectrometer at a fixed wavelength of 340 nm [19].

### 3. Results and Discussion

The drying process was carried out using an experimental approach, which was developed by a Design of Experiment (DoE) software. A response surface plan with central composite design was created. Air temperatures (40°C, 60°C, 80°C, 94°C), dew point temperatures (5°C, 10°C, 20°C, 30°C, 37°C) and air velocities (0.6 m/s, 0.9 m/s, 1.2 m/s, 1.4 m/s) were used as variable parameters. The aim was to determine the influence of these factors on the quality of the dried samples (mango slices with an initial thickness of 0.4 cm). For fresh mangoes, almost constant ascorbic acid contents were detected. Small variations in the contents would be due to natural variations of the fresh product. Fig. 1 shows the retention of ascorbic acid in dried mangoes plotted against the drying temperature.

Fig. 1 Retention of ascorbic acid in mangoes

As shown in fig. 1, the content of ascorbic acid decreases due to drying (retention < 100%). The degradation level increases with increasing drying temperatures. This was expected because the ascorbic acid decomposes during drying at high temperatures and in the presence of oxygen [8]. The concentration of citric acid in dried mangoes (fig. 2) shows nearly the same tendency as the concentration of ascorbic acid. It decreases as the drying temperature increases, and thus, during shorter periods of drying times.

*Fig. 2 Retention of organic acids in mangoes*

In the case of the malic acid (fig. 2) in dried mangoes, the results showed some variations when compared to those of ascorbic and citric acid. The trend of degradation with increasing drying temperatures can only be slightly noticed. It can be concluded that malic acid is reduced during drying, but remains nearly independent of the drying temperature. Fig. 3 shows the content of the three main sugars (glucose, fructose, sucrose) in mangoes. As shown in fig. 3 (left), the content of glucose increases during drying.

*Fig. 3 Retention of sugar in mangoes*

The contents of fructose (fig. 3, center) and sucrose (fig. 3, right) decrease as the drying temperatures increase. The content of glucose seems to be nearly independent of the drying temperature or increases slightly. This increase of glucose and at the same time degradation of sucrose is due to the fact that sucrose is a disaccharide consisting of two molecules: one fructose and one glucose [21]. During drying, it seems that sucrose divides back into its two constituting molecules. The rate at which the sucrose molecules split is higher at high drying temperatures, which in turn means that the contents of fructose and glucose increase. As shown in fig. 3, the content of glucose rises slightly with increasing drying temperature compared to fructose which decreases, because fructose and glucose are also degraded

during drying. Nevertheless, the degradation especially for glucose seems to be muffled because of the continuous splitting of sucrose [16, 21].

The colour of the dried samples was also compared with the colour of the fresh fruit. For an easy comparison, the *CIE L\*, a\*, b\** colour space is used. *a\** represents the colour space from green to red; *b\** from blue to yellow and *L\** represents the brightness (white to black). The total colour difference *TCD* is calculated out of these values using equation (1):

$$TCD = \sqrt{(\Delta L^*)^2 * (\Delta a^*)^2 * (\Delta b^*)^2} \tag{1}$$

Fig. 4 Colour changes in mangoes

As it can be seen in fig. 4, the *TCD* increases as the drying temperatures increase. This is not only recognizable from fig. 4, but also from fig. 5, which shows, that the mango powder gets darker as the temperature increases.

Fig. 5 Colour changes in mangoes (photo)

At last the retention of the surface area (shrinkage *S*) of mango samples before and after drying was compared. The retention of surface is calculated using equation (2), where *P<sub>0</sub>* and *P* represent the amount of pixels before and after drying, respectively.

$$s = 100 - \left( \frac{P}{P_0} * 100 \right) \tag{2}$$

As it can be seen in fig. 6, the retention of the surface decreases as the drying temperatures increase. This is due to the fact that mangoes loose water during drying and become smaller.

Fig. 6 Surface retention of mangoes

#### 4. Conclusions

It can be concluded that the drying temperature has the largest influence on changing the quality criteria during the drying process of mangoes. The evaluation according to DoE revealed that dew point temperature as well as air velocity have a slight effect on the changing of the quality criteria. Furthermore, it was found that dew point temperature should be kept at 20°C and air velocity at 0.9 m/s. It could be shown that concentrations of ascorbic and citric acid in dried mangoes decrease with increasing drying temperatures. The content of malic acid as well as that of glucose seem to be nearly independent of the drying temperature. The contents of sucrose and fructose decreased during drying. The degradation of sucrose can be explained with the splitting of this molecule into fructose and glucose. Fructose seems to be more instable towards heat so it decreases more than glucose. This is due to the fact that sucrose consists of molecules of fructose and glucose and is divided into these two substances during drying [16, 21]. An optimal air temperature for the drying of mangoes could be found at around 60°C, because all of the mentioned components show a low or the lowest change/degradation values. The changes in the mentioned quality criteria should be kept as low as possible because organic acids as well as the different sugars are responsible for the taste of the mangoes and possesses health promoting qualities.

### Abstract

*Pirarucu (Arapaima gigas Schinz) farming has been encouraged and, among meat preservation techniques, the salting process is a relatively simple and low-cost method. The objective of this work was to study the sodium chloride diffusion kinetics in Pirarucu during wet salting. Limited volumes of brine (20% w/w) were employed with wet salting assays carried at 3, 4 and 5 brine/muscle ratios, and brine temperatures of 10, 15 and 20 °C. The analytical solution of Fick's second law considering one-dimensional diffusion through an infinite slab in contact with a well-stirred solution of limited volume was used to calculate the effective salt diffusion coefficients. Salt diffusivities in muscle were found to be in the range of 2.07 and 8.80 × 10<sup>-10</sup> m<sup>2</sup>/s. The wet salting of Pirarucu is greatly influenced by temperature and by the brine/muscle ratio by volume.*

**Keywords:** Pirarucu; Arapaima gigas Schinz; salt diffusion coefficients; brine.

---

## 1. Introduction

The pirarucu (*Arapaima gigas Schinz*) is one of the largest freshwater fish in the world, reaching approximately 2 to 3 meters in length and up to 200kg in weight in its natural habitat. The fish inhabits the Amazon River basin in South America and is one of the five most widely cultivated and marketed species in the region [1, 2, 3, 4]. It is economically and ecologically important to the riverside population due to its high commercial and nutritional value [3, 5]. Due to its great adaptability, high market value, good sensory characteristics, expressive size and rapid development, the pirarucu has been a focus of several studies, mainly in relation to its captive breeding [6].

The increase in the pirarucu farming in aquaculture production systems has highlighted the economic significance of this species in recent years, mainly due to its nutritional quality. However, its marketing and consumption throughout the year faces some barriers due to the many changes occurring in the product because of enzyme and microbiological activities, which can affect the flavor, odor, color and texture and lead to rapid deterioration, resulting in fish of lower quality [7, 8].

Studies on shelf-life of food products depend on the knowledge of internal and external characteristics that can affect the speed of deterioration, such as packaging technologies, storage conditions, formulation and conservation among others [8]. Salting is one of the oldest food conservation processes [9, 10]. The concentration of sodium chloride influences the technological properties of the food, such as water retention capacity, viscosity, texture, emulsification, influences the properties of proteins and promotes sensory acceptance [11, 12].

Salting is a good alternative for producing processed food because it is a relatively simple, low-cost technique and can be carried out in places with little infrastructure. Brining is a specific process of osmotic dehydration that is conducted by immersing the product in concentrated saline solution [13]. In this operation, two main mass transfer processes occur. The water migrates from the meat to the brine and solutes from the brine transfer to the meat. Consequently, changes in the composition of solids produce a decrease in the amount of water available for degradation reactions by enzymes and microorganisms [14, 15].

The diffusion of salt in meats and meat products has been the objective of some studies [16]. Diffusion is an important mass transfer phenomenon, responsible for the transport of sodium and chloride [17]. The mass transfer between the brine and the product is usually controlled by the diffusion rate of the solutes. Diffusion rates are calculated using solution diffusion coefficients for solids [18]. Food and foodstuffs present irregular shapes and have regions of different compositions that make the mathematical modeling difficult and some alternatives should be considered to deal with the heterogeneity of materials [16, 19, 20].

Water loss and absorption of solids during osmotic dehydration have been modeled using Fick's second law. Some studies use analytical solutions for transfer of one-dimensional mass based on laboratory studies carried out with a great excess of agitated solution, in order to ensure a variation in the composition of the solution and simplify the calculations involved [21]. To determine the effective diffusivity of salt in caiman meat, Romanelli & Felício [22] used the same approach. However, the management of large volumes of solution is an obstacle to the process at an industrial scale, leading to an increase in production costs.

The knowledge of the diffusion rates is important, as it allows the correct determination of the necessary processing time, having control over the exact final concentration of salt and its distribution in the product. Several articles have been published on mass transfer and diffusion of salt in meat and fish products [23, 24]. So, the aim of this study was to evaluate the proximate composition of the pirarucu raw material and investigate the sodium chloride diffusion kinetics in pirarucu muscle during wet salting.

## 2. Materials and Methods

This study focused on the sodium chloride diffusion in pirarucu muscle during the wet salting process using a limited volume of brine (20% w/w). The experiments were developed and done in the meat and meat products laboratory of the Department of Engineering and Food Technology of the Sao Paulo State University – UNESP-IBILCE.

The material used in this study consisted of a frozen Pirarucu fillets (*Arapaima gigas Schinz*) purchased from a single supplier, in a local supermarket in the city of Manaus (Brazil). The fillets were transported to UNESP-IBILCE (São José do Rio Preto, Brazil), stored under freezing and thawed under refrigeration temperature for 24 hours for evaluation of its physical characteristics, such as size and weight, and also the proximate composition, before salting. Moisture, ash and protein contents were determined according to the AOAC [25] method. The lipid content was determined, following the method described by Bligh & Dyer [26].

Sodium chloride solution was used as the osmotic agent. The sodium chloride used was of food grade, the other chemical compounds used for the determinations of sodium chloride, proteins and lipids were of analytical grade.

Experiments were carried out with a brine concentration of 20% (w/w), at temperatures of 10, 15 and 20 °C and volume ratios of brine/muscle ( $V^L / V^S$ ) of 3, 4 and 5.

Fillet densities before salting and at different periods after salting were measured according to the liquid displacement method [13]. Brine densities were measured by means of a pycnometer at 25 °C.

Fillets were weighed and placed inside flasks of 500 ml containing brine at a pre-determined volume, temperature and salt concentration. The flasks were then maintained in a refrigerated orbital agitator, being removed at different time intervals, when the brine was drained and weighed and the fillets were dried with absorbent paper, weighed and ground. Two aliquots for salt content, estimated as the ash contents in a muffle furnace at 550 °C. Two aliquots of brine were taken to measure the salt content. The salt content was obtained according to the Mohr method [27].

The governing equation for the unsteady-state one-dimensional diffusion in a plane slab was given by Fick's second law, also called the diffusion equation, and the analytical solution of the stated problem was given by Crank [28] as:

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=1}^{\infty} \frac{2\alpha(1+\alpha)}{1+\alpha+\alpha^2q_n^2} \exp\left(\frac{-D_{\text{eff}}q_n^2t}{L^2}\right) \quad (1)$$

where  $M_t$  is the total amount of solute in the solid at time  $t$ ,  $M_\infty$  is the corresponding quantity at equilibrium,  $L$  is half of the slab thickness and  $q_n$  are the non zero positive roots of the equation

$$\tan q_n = -\alpha q_n \quad (2)$$

In order to adjust equation (1) to the experimental data and obtain the effective diffusivity values, parameters  $m$ ,  $\alpha$ , and  $q_n$  were determined according to Telis et al. [13].

The effective diffusivities were obtained by a non-linear adjustment of the first six terms of the series corresponding to equation (1), which was performed using the Statistica software (StatSoft Inc., V.7.0).

### 3. Results and discussion

The proximate composition of Pirarucu muscle is shown in Table 1. Similar results were found by Martins et al. [29], when analyzing the proximal composition of pirarucu muscle.

**Table 1. Proximal composition of the Pirarucu muscle (n=3).**

	<b>Proximate composition (%) (mean ± standard deviation)</b>
Moisture	78.99 ± 0.07
Protein	20.30 ± 0.21
Lipid	0.41 ± 0.17
Ash	1.08 ± 0.07

The results for the effective diffusivity of salt at each temperature studied in the three brine/muscle ratios are shown in Table 2.

**Table 2. Effective diffusivity at different brine/muscle ratios and temperatures during wet salting of Pirarucu.**

<b>Brine/muscle ratio</b>	<b>Temperature (°C)</b>	<b>Effective diffusivity x 10<sup>10</sup></b>
		<b>(m<sup>2</sup>/s)</b>
3	20	8,79
	15	5,30
	10	2,07
4	20	8,67
	15	5,62
	10	2,77
5	20	8,80
	15	5,71
	10	3,17

Table 2 shows that the brine/muscle ratio has a low effect, since effective diffusivities were very similar for the different ratios at the same temperatures. Similar behavior was observed by Medina-Vivanco et al. [30] when they studied tilapia muscle.

Effective diffusivities increased with increasing temperatures (Table 2) for all brine/muscle ratios. Similar results were observed by Telis et al. [13] who studied salting diffusivities in caiman muscle. Low temperatures are recommended because fish is a very perishable food. Brás & Costa [31] used salting temperatures from 12 °C to 18 °C for salting different fishes. According to Chiralt et al. [32], higher temperatures not only affect the rate of diffusion

phenomenon but also may affect the viscoelastic properties of the solid matrix, with a softening of the structure accompanying the temperature increase. An additional effect in salt gain rates could arise from the reduction in brine viscosity at higher temperatures.

Salted fish products have a long shelf life due to their low water activity and the flora selection that a high salt content media implies [31].

#### **4. Conclusions**

Salt effective diffusion coefficients are in the range from 2.07 to  $8.80 \times 10^{-10}$  m<sup>2</sup>/s.

The wet salting process of pirarucu is great influenced by temperature: the higher the temperature in the wet salting process, the higher the effective diffusion coefficients; and, to a lesser extent, by the brine/muscle volume ratio though lower temperatures are better because fish is a perishable food.

### **Abstract**

*The aim of this study was to evaluate the influence of fat reduction in the drying process of Italian salami. Two Italian salami formulations: HFS (High Fat Sausage) with 20g/100g of pork back fat and LFS (Low Fat Sausage) with 11.2g/100g of pork back fat were analyzed as water activity, weight loss, proximate composition and pH. The evaluation times were 0, 3, 7, 10 and 13 days of drying. The reduction of more than 25% in the fat content of Italian salami affected the weight loss in the drying process, but did not affect the moisture, pH and water activity.*

**Keywords:** *Low-fat; fermented sausage; weight loss; healthier meat products; ripening time.*

---

## **1. Introduction**

Currently, there is an increase in consumer demand for healthier food products that have low calorie and low fat content. Because of this trend, the meat product manufacturers are seeking to develop new formulations of traditional products, reducing fat content and using fat substitutes on the aim of producing healthier meat products [1].

The high fat content in fermented sausages contributes to the sensory characteristics, such as taste, texture, juiciness, mouthfeel, lubricity and appearance, and its reduction can directly affect the acceptability of the product [2, 3]. However, there is an association between excessive consumption of saturated fat and increased risk of heart disease and some cancers [4, 5].

The drying stage of the fermented sausage represents an important factor for determining the physicochemical and sensorial properties of the final product. The duration of the drying step of the sausage is related to the diameter. This stage of the process should always be performed at temperatures, between 12°C and 15°C. The sausage can lose up to 40% of its weight during the drying and this loss must be gradual to avoid deformation of the final product [6].

Fat reduction in dry fermented sausages is one of the most difficult because the excessive reduction of fat can lead to harder products and can increase the weight loss. But according to Olivares et al [2], those defects can be avoided if appropriate processing and climatic conditions of the drying process are applied correctly. So, the aim of this study was to evaluate the influence of fat reduction level on the drying process of Italian type salami.

## **2. Materials and Methods**

### **2.1. Italian type Salami drying process**

The samples were manufactured in the Laboratory of Meat and Derivatives at the Faculty of Food Engineering, University of Campinas (São Paulo, Brazil). Two levels of pork back fat were added in the Italian type salami formulation: HFS (High Fat Sausage) with 20g/100g of pork back fat added and 80g/100g of lean pork / LFC (Low Fat Sausage) with 11.2g/100g of pork back fat added and 88g/100g of lean pork. The other ingredients of the formulation were: sucrose (2g/100g), sodium chloride (2.5g/100g), sodium erythorbate (0.5g/100g), sodium nitrite (0.015g/100g), sodium nitrate (0.015g/100g), white pepper (0.5g/100g), garlic (0.2g/100g), nutmeg (0.2g/100g) and a starter culture (0.25 g/kg; SPX Floracarn, Chr Hansen).

All ingredients were mixed with the raw material using a blender for approximately 5 minutes. After, the treatments were stuffed in cellulose cases (diameter of 50 mm) and they were cut into pieces 15 cm in length. For each treatment 25 pieces (approximately 250 g

each) were made and each sample was soaked in a solution of potassium sorbate (20%). The temperature and relative humidity parameters (T °C/RH %) were: 25 °C/95% (first day), 24 °C/93% (second day), 23 °C/91% (third day), 22 °C/89% (fourth day), 21 °C/87% (fifth day), 20 °C/85% (sixth day), 18 °C/85% (seventh day), 15 °C/75% (until the end of ripening process). The air velocity during all the process was 0.5 m/s. The processing was performed twice.

## **2.2. Ripening analysis**

Water activity was measured in triplicate using Aqualab Decagon equipment (Decagon Devices Inc., Pullman, USA).

The moisture, ash and protein content quantification was performed according to AOAC [7]. Fat content was measured using the Bligh & Dyer method [8]. This analysis was performed in triplicate.

The pH was measured using a digital pH meter with penetration probe, in triplicate, in the same piece of salami.

To calculate the weight loss, the same samples were weighed throughout the drying process and the loss was determined by the difference calculation between the initial weight and the final weight (n=5).

## **2.3. Statistical analysis**

The data obtained were analyzed by analysis of variance (ANOVA), and the differences between the means of the results were evaluated by the Fisher test ( $P \leq 0.05$ ) at a significance level of 5%. The software used was MiniTab 16.

# **3. Results and discussion**

## **3.1. Proximate composition**

The moisture content of Italian type salami was different between batches only after the drying process (Table 1).

**Table 1. Proximate composition of Italian type salami high fat content (HFS) and low fat content (LFS) after 0 and 13 days of dry process.**

Analysis	Days of drying	HFS	LFS	SEM <sup>1</sup>	<i>p</i> value
<b>Moisture (%)</b>	<i>0</i>	65.17 <sup>A</sup>	64.13 <sup>A</sup>	0.245	0.066

	<i>13</i>	26.14 <sup>A</sup>	28.94 <sup>A</sup>	0.956	0.075

<sup>AB</sup>Different letters in the same line differ significantly ( $P < 0.05$ ) by the Fisher's test. \*Significant.

<sup>1</sup>SEM: Standart error of the mean.

LFS had higher moisture content because of the fat reduction. Similar results were reported by Olivares et al [2] that manufacture dry sausage using different pork back fat content and the lowest (13.2%) had the highest moisture at the end of the dryng process.

The results for ash and protein did not show differences at the end of the drying process. The reduction of fat level achieved was approximately 25%. So, it is possible to classify this product as an Italian type Salami with reduced saturated fat content (light), according to the corresponding legislation [9].

## 2.2. Ripening analysis

The results for the water activity, pH and weight loss during the drying proceso of salami type Italian are presented in Figure 1.

**Fig. 1. Evolution of water actvity (A), pH (B) and weight loss (C) during the drying process of Italian type salami.**

<sup>ab</sup>Different letters in the graphic differ significantly ( $P < 0.05$ ) by the Fisher's test

The water activity (Fig.1A) of the treatments was reduced during processing (13 days), starting at 0.96 and reducing to 0.9. The high fat sausage (HFS) didn't show difference water activity from the low fat sausage (LFS) at the end of the drying processing. So the reduction in the pork fat of Italian type salami did not affect this technological parameter. This result is in agreement with Fonseca et al [10] that reported that the reduction in fat content (10%, 20% and 30% fat) in fermented dry salsichon had no significant effect on the water activity of the final product.

The initial pH (Fig.1B) of the batch was 5.6. After 3 days of processing, the pH value was near 4.6 for all treatments, indicating that micro-organisms present in the fermenting starter culture produced lactic acid from the sugars present in the formulation, reducing the pH. Othes authors also reported a significant reduction of pH from day 0 to day 3 in the production of fermented sausage [11, 12].

To ensure the loss of water during the drying process, the pH should reach values close to the isoelectric point of the meat (pH 5.0). According to Price and Schiweigert [13] acidification contributes to the texture of the product, as well as in the formation of

aromatic compounds and the typical salami flavor. This rapid drop in pH value, close to 4.6 ensures product stability and provides microbiological protection against gram negative bacteria. The reduction in the pork fat content did not affect the pH value during the drying of the fermented sausage.

HFS showed the lowest ( $p>0.05$ ) weight loss (Fig.1.C) (%) compared to the other treatments (LFS), showing that fat level may influence yield. This result is in agreement with the results presented by Ham et al [14], who observed that the fermented salami with fat reduction had the lowest yield when compared to the control treatment (with no reduction in fat content).

#### **4. Conclusions**

The reduction of 25% in the fat content of Italian type salami can be used to produce a healthier dry fermented meat product without affected the technological parametrs such as moisture, pH and water activity durind the drying process.

### **Abstract**

*In this work the new process of producing parboiled rice (PB) by combination of microwave and hot air fluidized bed (MWFB) was proposed and investigated. Results showed that the drying time was shorter with smaller bed depth, higher drying temperature and higher microwave power. The initial grain temperature, drying temperature, bed depth and microwave power strongly affected the gelatinization of rice starch. The PB produced by MWFB caused a very small broken kernel (1-2%). The whiteness was decreased with increase in drying time, initial grain temperature, drying temperature and microwave power. The specific energy consumption was increased with increasing such operating parameters.*

**Keywords:** *Drying; Parboiled rice; Fluidized bed; Microwave.*

---

## **1. Introduction**

PB production in the industrial scale around the world can normally be done by wet-heat process. This process mainly consists of soaking, steaming and drying step. In the steaming step, the saturated steam, normally produced by high pressure boiler, is used to gelatinize the rice starch [1]. After stemming, the rice starch appears translucent. In addition to the wet heat process, the dry heat process is also used in a small scale factory. By the dry-heat process, hot air or roasting with or without sand is practically utilized. The later process involves conduction heating of moisten paddy at a higher temperature with shorter drying duration. The starch gelatinization with no retrogradation is specifically found, unlike to the wet heat process, because of the simultaneous rapid loss of water from the paddy during conduction heating was studied by Mahanta and Bhattachaya [2]. Pillaiyar et al. [3] reported that the roasting sand at temperature of 125°C could get the fully PB but with mild effect. The parboiling became severe at high temperatures. Roasting the soaked paddy at 250°C could reduce the cooking time of the PB. A sand temperature of 125-150°C is considered as suitable condition for producing PB by this technique

The wet-heat PB production requires many components such as the boiler, steam pipe and auxiliary devices, while the dry-heat PB process using sand roasting [4] needs to separate the paddy-sand mixture after parboiling. To eliminate the restrictions on the steaming and sand separation in PB production, the MWFB was proposed and investigated. The microwave (MW) drying has been studied by many researchers and applied with many products. But, the work involving with parboiling rice is still limited in the literature. It appears only work reported by Kahyaoglu et al. [5] for parboiling wheat using MW-assisted spouted bed drying. They found that the MW-assisted spouted bed drying at the MW power of 3.5 and 7.5 W/g reduced drying time by at least 60% and 85%, respectively compared to spouted bed drying. As mentioned above, in this work, the new process of producing PB by MWFB was proposed and investigated. In the experiment, the drying kinetics and quality of head rice yield (HRY), the degree of starch gelatinization (DSG), morphology, whiteness value and specific energy consumption (SEC) were investigated.

## **2. Materials and Methods**

### **2.1. Materials**

The Suphanburi 1 paddy variety was stored at ambient air temperature for 6 months. Paddy was soaked at the temperature of 69±1°C for 5 h (47±1% d.b.) and different initial grain temperatures of 32, 55 and 65°C was dried by MWFB and FB dryers.

### **2.2. MWFB dryer**

Fig. 1 shows the MWFB dryer. The system consists of a stainless steel cylindrical drying chamber with an inner diameter of 21 cm and height of 80 cm, a 19 kW electric heaters, a backward-curved blade centrifugal fan driven by a 2.2 kW (3 HP) motor and 5 MW magnetrons with each rated at 800 W (2.45 GHz). The magnetrons were installed at 5.5, 11.5, 17.5, 23.5 and 30.0 cm above distributor plate of the drying chamber.

Fig. 1 A schematic diagram of a MWFB dryer.

### 2.3. Experimental design

The soaked paddy was dried by MWFB and FB at temperatures of 130, 150 and 170°C with a MW power of 1.6, 2.4 and 4.0 kW. Bed depth of 5 and 10 cm, as well as an inlet superficial air velocity of 4.6 m/s and recycled exhaust air fraction of 0.8 were used. After reaching predetermined drying time, the paddy was taken out from the dryer and the samples were gently dried in shade to obtain a final moisture content of 15±1% d.b. The experiment was performed in duplication. The MC of paddy was determined according to AACC 1995 [6] method at a temperature of 103±2°C for 72 h. It was done in triplicate and the mean value was reported.

The dried paddy sample (150±1 g) was dehulled using a rubber roll hulling machine (Ngeksenghuat, model P-1, Thailand) and milled rice to remove bran using a miller (Ngeksenghuat, model K-1, Thailand). Whole and broken grains were graded automatically using a cylindrical rice separator (Ngeksenghuat, model I-1, Thailand). The milling test was performed in duplicate and the HRY was calculated by the following equation.

$$\%HRY = \frac{W_{hr}}{W_p} \times 100 \quad (1)$$

where  $W_{hr}$  is mass of head rice sample (g) and  $W_p$  is mass of paddy sample (g).

The DSG of the rice samples was characterized by the Differential Scanning Calorimeter (DSC) (Perkin Elmer, model DSC-7, USA). A sample was ground into powder and 3 mg rice flour sample was put into an aluminium pan and mixed with 10 mL distilled water. The pan was sealed and kept to equilibrate at room temperature for 1 h. After that, the sample was heated from 40 to 110°C at a scanning rate of 10°C/min. The determinations were done duplication and the DSG was calculated by the following equation.

$$\%DSG = \left[ 1 - \frac{\Delta H}{\Delta H_c} \right] \times 100 \quad (2)$$

where  $\Delta H$  is the enthalpy change of starch in dried rice (J/g dry matter) and  $\Delta H_c$  is the enthalpy change of reference rice starch (J/g dry matter).

The scanning electron microscope (SEM) (JEOL, model JSM-6610LV, Japan) with accelerating voltage 5 kV was used to examine the starch granules morphology. Before test, the sample was attached to an SEM stub and coated by sputter coater (Cressington, model 108 Auto, UK) with a pure copper 99.99% layer. While, the whiteness of rice samples was determined by a Kett digital whiteness meter (model C-300, Japan). Before measuring, the whiteness meter was calibrated with a white colored reference that has a standard value of 86.3. Each measurement was performed in 10 replicates and the mean value was reported.

### **3. Results and Discussion**

#### **3.1 Drying characteristics**

The experimental results showed that the bed depth of 5 cm, the grain temperature was significantly higher than that at the bed depth of 10 cm approximated by 5-15°C. With the MWFB drying, it could reduce MC faster than the FB drying by approximately 2-5% d.b. When the grain gets the MW, the water molecules are rapidly rotated by MW frequencies (2.45 GHz). The heat is rapidly generated, especially in the middle of the paddy grain. As a result, the grain temperature in the MWFB was significantly higher than that of FB about 5-10°C. The higher grain temperature in the MWFB can accelerate the travel of moisture from the inside to the external, resulting in higher rate of drying [8].

At the same time, the drying time to reach an intermediate MC of 20±2% d.b. was shorter with smaller bed depth, higher drying temperature and higher MW power, as shown in Fig. 2(a). Considering the effect of initial grain temperature as shown in Fig. 2(b), the drying rate for the grain temperature of the paddy sample that had higher initial grain temperature was insignificantly different from that of the sample with lower initial grain temperature although the grain temperature at higher initial grain temperature was higher during drying. This is possibly due to the fact that the moisture movement during drying might be in the liquid form and controlled by liquid diffusion. In the liquid diffusion, the variation of temperature between 32 and 65°C does not provide a big difference of effective diffusion coefficient of water (only 1-2% d.b. moisture difference).

Fig. 2 Evolution of MC and grain temperature of soaked paddy dried by FB and MWFB.

$T_{gi}=32^{\circ}\text{C}/\text{FB}(170^{\circ}\text{C})\text{MW}(2.4\text{kW})/\text{DSG}=70\%$

$T_{gi}=55^{\circ}\text{C}/\text{FB}(170^{\circ}\text{C})\text{MW}(2.4\text{kW})/\text{DSG}=96\%$

Fig. 3 SEM images at the interior area of soaked paddy dried by FB and MWFB (Bed=10 cm)

### 3.2 Degree of starch gelatinization

The use of FB drying at the temperature of 130-170°C allowed starch to be gelatinized in a range of 41-65% for initial grain temperatures of 32°C and 10 cm bed depth. At this DSG range, the PB is classified as the mildly PB [8] and the kernel that appeared white belly was not found although the starch gelatinization was incomplete. As the soaked paddy was dried at the bed depth of 5 cm, the rice starch was gelatinized in a range of 48-100%, depending on the drying temperature. The FB drying at 170°C could produce the severely PB.

As the MW(4.0kW) was combined with FB, the PB dried at the temperature of 150°C or higher was designated as severely PB. The complete gelatinization of rice starch was found

with the soaked paddy dried by FB(170°C)MW(4.0kW), FB(150°C)MW(4.0kW), FB(170°C)MW(2.4kW) when the initial grain temperatures of 32, 65 and 65°C, respectively, was employed at the bed depth of 10 cm. Also the soaked paddy dried by FB(170°C) and FB(170°C)MW(4.0kW) at initial grain temperature of 32°C and bed depth of 5 cm had complete gelatinization of rice starch as shown in Table 1.

### **3.3 Morphology**

Fig. 3 show the starch granules of the soaked paddy dried by FB(150°C) and MW(4.0 kW)FB(150°C) with initial grain temperature of 32°C, it seem that some starch granules still appeared at the interior of the rice kernel when the soaked paddy dried by FB only whereas the starch granules of the soaked paddy dried by MWFB were smooth with the complete loss of granular morphology of the rice.

In case of soaked paddy at the initial grain temperatures of 32 and 55°C dried by MW(2.4 kW)FB(170°C), some starch granules still appeared at the at the interior of the rice kernel when the soaked paddy dried at initial grain temperature of 32°C whereas the starch granules of the soaked paddy dried at initial grain temperature of 55°C were smoothest with the complete loss of granular morphology of the rice, indicating the complete starch gelatinization. This is consistent with the result of degree of starch gelatinization.

### **3.4 Head rice yield**

Table 1 shows the HRY of PB produced by MWFB yielded a very small broken kernel (1-2%) after drying with including tempering at the drying temperature above 130°C for MW powers of 2.4 and 4.0 kW. The small broken kernel can be attributed to the higher DSG. However, considering the initial grain temperature effect, this parameter did not much effect on the HRY, the value laying between 68 and 70%. However, the operation of MW(4.0 kW)FB(170°C) must be avoided although the starch gelatinization was completed. This is because the grain temperature dried at this condition was raised to 150°C causing the grains to be puffed and resulting lower HRY.

### **3.5 Colour**

The whiteness value of PB was decreased with increase in initial grain temperature, drying temperature and MW power and with decreasing bed depth as shown in Table 1 for both tempering and no tempering. The whiteness value of MWFB drying was significantly lower than that of FB drying at the same initial grain temperature, drying temperature and MW power because the paddy grain temperature in the MWFB drying is higher than that of FB drying. The higher grain temperature time more accelerates a higher rate of Maillard reaction [9]. The PB samples that fallled in the severely PB category (DSG>70) had yellowish brown colour (Gold parboiled rice), which corresponded to the whiteness value of 22-24. When the soaked paddy was dried by at 170°C, MW power of 4.0 kW and at a bed depth of 5 cm, the product colour was reddish, which was unacceptable in the market.

### 3.6 Specific energy consumption

Considering in Table 1, it was found that drying the soaked paddy at the initial grain temperature 32°C at 170°C and at bed depth of 5 cm spent the SEC of 4.6 MJ/kg<sub>water evap.</sub>

**Table 1. DSG, HRY, SEC and whiteness of soaked paddy dried by FB and MWFB.**

Drying conditions		DSG (%)	HRY (%)		Whiteness		SEC (MJ/kg <sub>water evap.</sub> )	
			T	NT	T	NT

	FB(170°C)MW(1.6kW)	92.9	69.6	67.7	21.3	23.5	-	
	FB(170°C)MW(2.4kW)	100.0	70.5	68.9	20.3	22.8	5.1	
	Bed = 5 cm	<i>Initial grain temperature of 32°C</i>						
		FB(130°C)	48.6	69.7	65.5	24.0	25.6	-
FB(150°C)		80.4	71.5	69.7	21.1	24.3	-	
FB(170°C)		100.0	69.2	68.4	16.4	22.9	4.6	
FB(130°C)MW(4.0kW)		70.2	68.9	65.5	18.7	23.2	-	
FB(150°C)MW(4.0kW)		91.2	70.6	69.8	17.8	23.5	-	
FB(170°C)MW(4.0kW)		100.0	65.6	59.4	12.5	17.8	10.8	
Traditional method		100.0	70.0-71.5		21.5-26.2		6.4-7.5	
Raw rice	0.0	-	50.3	-	45.2	-		
Soaked rice	7.8	-	52.8	-	37.0	-		

Bed = Bed depth, T = Tempering, NT = No tempering

This SEC was significantly lower than that dried by FB(170°C)MW(4.0kW) by 57% and less than the SEC from the traditional PB production by 32%. The use of higher initial grain

temperature (65°C) could reduce the MW power to 2.4 kW and the SEC was reduced by 27% as compared to the traditional method

#### **4. Conclusions**

The MWFB could produce PB with a complete degree of starch gelatinization without the need of steam for parboiling rice. This makes it easier to produce PB and reduces the complexity and size of the plant. The production of PB with FB(170°C) alone at initial grain temperature of 32°C and bed depth of 5 cm have lower SEC than the traditional PB production by 32%. The increasing initial grain temperature up to 55 and 65°C for soaked paddy dried by FB(170°C)MW(2.4kW) at the bed depth of 10 cm could reduce the SEC in the production of PB by 27% as compared to the traditional method.

## **1. Introduction**

Although numerous studies on drying have been reported in the literature concerning spouted beds, there are few ones approaching process modelling, which is due to the complexity involving the mathematical description of the phenomena occurring in the drying chamber, i.e., aspects involving thermodynamics, hydrodynamics, and heat and mass transfer. Therefore, the most common procedure is to perform approximations, which, depending on the rigor of the model, simplify the system behaviour in any of the mentioned aspects.

Most of the studies published are based on developing a macroscopic bed model that considers the mass and energy balances and the dynamics of the drying process. The drying mechanisms for the spout and annular zones are considered in these models. Becker and Sallans [1] made the first rigorous analysis of the continuous drying process of wheat in a conventional spouted bed, based on the assumption that bed height is enough to reach thermal equilibrium between exiting gas and the upper surface of the bed. In this way, diffusion of water from the solid inside to the surface limits the drying process. Later, Becker and Isaacson [2] and Viswanathan et al. [3] applied the same model to discontinuous drying, assuming an effective surface moisture content calculated from the dynamic equilibrium moisture content. The latter is obtained experimentally and, unfortunately, there is no data published in the literature. Chu and Hustrulid [4] demonstrated that even being convenient to assume that moisture content at the surface takes a constant value to facilitate calculation, computer problems are generated [2].

For discontinuous operation, Zuritz and Singh [5] proposed to calculate the moisture content on the surface by means of the variation of outlet air temperature and relative humidity. The authors tested an empirical equation that describes the desorption isotherms of equilibrium moisture. Later, Zahed and Epstein [6] deepened in this question using an empirical equation that relates the diffusion coefficient with temperature and solid moisture content. In addition, these authors propose that for continuous operation residence time distribution can be applied to the solids that make up the bed. With these two contributions, thermal equilibrium model with internal diffusion control has demonstrated its capacity to provide a good representation of wheat drying both for discontinuous and continuous operation.

Furthermore, Jumah et al. [7] developed a model for discontinuous corn drying using a novel jet spouted bed under constant and intermittent drying conditions. Unlike previous works, they do not assume thermal equilibrium at the end of the bed and also take into account temperature gradient within the bed. Kalwar and Raghavan [8] worked on drying of husked corn under minimum spouting velocity and found that there is no constant drying period. However, Wetchacama et al. [9] and Nguyen [10,11] found that moisture reduction rate remains constant.

Madhiyanon et al. [12] proposed a batch drying model for vegetable grains. They assumed the process was neither in thermal equilibrium nor in isothermal regime, and it was validated with the experimental results for corn discontinuous drying in a two dimension spouted bed dryer. Unlike the previous studies, the modelling of spout and annular zones was made separately for a better description of drying thermodynamics. The model results agree with those predicted by grain circulation model, empirically formulated by Kalwar and Raghavan [8].

Recently, Markowski et al. [13] published a study of drying dynamics of barley in a spouted bed and determined the influence of grain shape, which is considered in the model by the value of the effective diffusivity of moisture. Significant differences were observed when starting from an ellipsoidal or spherical geometry, so these results show that the proper definition of the solid geometry is essential for moisture diffusivity determination. They also demonstrated that assumption of spherical geometry is not a correct assumption when a great accuracy is desired in the predictions.

Although there is a relatively large amount of studies on drying in spouted beds, very few use conical spouted beds for drying solids [14-17]. Olazar et al. [18] proposed a model to predict the evolution of sand moisture in a conical spouted bed with nonporous draft tube. In this model, three regions (spout, annular zone and fountain) were considered and mass balances were described for water in solid and gaseous phases. The model was validated with experimental results. Based on these studies, this paper proposes a rigorous model for the batch drying in conical spouted beds, which is based on mass and energy balances and has only one adjustable parameter.

## **2. Materials and Methods**

Drying of solids was carried out in a pilot plant consisting of a stainless steel conical vessel (1.62 m height,  $D_c=0.36$  m column diameter,  $D_0=0.05$  m inlet diameter and  $\gamma=32^\circ$  base angle) provided with an open-sided draft tube ( $A_0/A_T$  ratio of 60%) and a new fountain confinement device, which consists of a stainless steel pipe with the upper end closed. This device is under patent, and its dimensions are therefore confidential. Experiments were carried out at four temperatures (30, 50, 100 and 150 °C), three air velocities ( $u/u_0= 1.2, 2$  and 3) and four wet sand pulses (0.5, 1, 1.5 and 2 kg).

Modelling of drying is based on the assumption that the spouted bed behaves like a perfect mixing ideal vessel. Therefore, it is considered that all particles have the same moisture content and temperature at any time, and also that air humidity and temperature is the same at the drying chamber and the outlet. In addition, the model considers the humidity content of the gas at the inlet and exit, and the fact that the solid remains in the bed during the run.

The procedure for the simulation is similar to that followed in the experimentation. A bed of dry sand is being spouted at a temperature corresponding to the outlet gas and a given mass of wet sand ( $x_{s0}=15\%$  w/w) is added at  $t=0$  as a pulse injection.

Based on these assumptions, the following mass and energy balances are considered: 1) Water mass balance for the wet sand added, 2) water mass balance for the gas phase, 3) energy balance for the wet sand added, 4) energy balance for dry sand (initial bed) and 5) energy balance for the gas phase, which should take into account heat losses from the drying chamber to the atmosphere.

Given that the experimental study showed that both gas and solid temperatures do not remain constant during the process, air, liquid water and steam properties are calculated at the corresponding temperature at each time and position. This includes air viscosity and density ( $\mu$  and  $\rho_g$ , respectively), water vapor pressure ( $P_{vw}$ ), diffusivity of water into air ( $D_{AB}$ ), volumetric gas flow and velocity ( $u$ ), mass transfer coefficient ( $K$ ), heat capacity of water, steam and air ( $C_{pw}$ ,  $C_{pv}$  and  $C_{pg}$ , respectively), thermal conductivity of the air ( $kg$ ), heat transfer coefficient of the gas ( $h$ ) and latent heat of water vaporization ( $\lambda$ ).

Drying rate,  $R_w$ , is defined as:

$$R_w = Ka(y_{sat} - y_g)|\rho_g|_{T_g} \quad (1)$$

where  $K$  is the mass transfer coefficient,  $a$  the gas-solid interface area or wet area,  $y_{sat}$  the equilibrium moisture at the gas-liquid interface (or saturation humidity),  $y_g$  the gas moisture in the drying chamber (and at the exit) and  $|\rho_g|_{T_0}$  the density of the gas at the inlet temperature.

The gas-liquid interface area or wet area,  $a$ , depends on the moisture content of the particle. When moisture content of sand is high, the water covers the entire surface of the particle and, as explained above,  $R_w$  is constant. When humidity drops to the value corresponding to the critical humidity,  $x_{s,c}$ , the water cannot cover the entire surface of the particle, and therefore the interface area causes a gradual decrease in the drying rate. These two stages are described by Eq. 2 and 3:

$$x_s > x_{s,c} \rightarrow a = A \quad (2)$$

$$x_s \leq x_{s,c} \rightarrow a = A \frac{x_s}{x_{s,c}} \quad (3)$$

In addition, runs have been carried out assuming a time depending exchange area, even during the drying step at constant rate. This assumption is based on the fact that sand agglomerates are formed at the beginning, but their diameter decrease during the drying process, and therefore the mass transfer surface increases. Accordingly, in addition to Eqs. 2 and 3, various mathematical functions have been tested to monitor this surface change over time (straight line, vertical parabola, hyperbolic tangent and exponential).

The critical humidity point,  $x_{s,c}$ , is determined based on the experimental results. The equilibrium moisture at the gas-liquid interface,  $y_{sat}$ , expressed as a percentage by weight on a dry basis, is calculated from the vapour pressure of the water at the temperature of the solid.

### 3. Results and discussion

Once the value of best fit has been determined for the single adjustable parameter (mass transfer coefficient,  $K$ ) the model suitably predicts the reduction in sand moisture content, as shown in the parity plot in Fig. 1, in which the experimental values of  $x_c$  have been plotted versus the calculated ones. As observed, the model underestimates the drying rate in the first half of the drying period (for high values of  $x_s$ ), whereas in the second half (low values of  $x_s$ ) the model predicts a faster drying than that measured experimentally.

*Fig. 1 Experimental and calculated values of water content in the added sand.*

Fig. 2 shows the evolution with time of the experimental and calculated values of bed moisture content,  $x_s$ , and the absolute humidity of the air at the outlet gas,  $y_g$ . It is observed that calculated values of  $x_s$  are very close to the experimental ones, but there is a considerable difference between calculated and experimental values of  $y_g$ . The model is not able to predict the typical curve in drying processes, in which humidity peaks at a very short time, it then decreases smoothly until a constant value is reached, and finally undergoes a sharp decrease to reach the critical moisture content. The calculated values show an evolution without the initial peak, and the absolute humidity of the air remains approximately constant with a higher value than the experimental one.

Fig. 2 Evolution with time of the solid moisture content and the air absolute humidity. Points, experimental values, lines, calculated with the proposed model.

To correct these differences, the heat transfer estimation should be improved in the model, since the predictions of the outlet gas temperature by the model do not match the experimental results, and this fact has a great impact on the value of  $y_g$ . Accordingly, we are at present involved in the analysis of several options for the estimation of the parameters involving heat transfer, such as the heat transfer coefficients in the bed and those related to heat losses.

#### 4. Conclusions

The proposed model predicts acceptably the evolution with time of moisture content in the solid and the final moisture for the different operating conditions, with the mass transfer coefficient being the only adjustable parameter.

The model underestimates the drying rate in the first half of the process, whereas overestimates in the second half. In order to overcome these shortcomings, heat transfer description should be improved by means of a more detailed definition of convective coefficients and global transfer coefficients for heat loss.

#### 5. Nomenclature

$a$	Gas-liquid interface area	$m^2kg^{-1}$
$A$	Surface area of the solid	$m^2kg^{-1}$
$x_s$	Moisture content by solid mass unit	

$x_{s0}$	Initial moisture content by solid mass unit	-
$x_{s,c}$	Critical moisture content by solid mass unit	-
$y_g$	Moisture content by air mass unit	-

### **Abstract**

*We study the behavior of a multi-stage fluidized bed dryer operated continuously with downcomers. With the kinetics of silica gel drying depending on the mass of solids in the dryer and the gas feeding temperature,  $E = 14.5$  KJ/mol, and the distribution of residence times of solids through the dryer, modeling by  $N$  tanks agitated in series, the experimental moisture content of the solids coming out of the dryer is compared with the predicted by the Vanecsek model.*

**Keywords:** *fluidization; gel of sílice; continuous multistage dryer.*

---

## 1. Introduction

Drying is one of the most important operations in the chemical, metallurgical, pharmaceutical and food industry, among others, being the drying in fluidised beds, one of the most successful techniques in the drying of solids such as seeds, fertilizers, polymers, minerals and other important chemicals [1, 2, 3].

In general, fluidised solids can be considered perfectly mixed, therefore, in a batch-operated dryer, a uniform treatment of the solids being dried is guaranteed; However, when the equipment is operated continuously, the solids that come out of the dryer present distribution of residence times and therefore different degrees of drying [4]. An option to overcome these disadvantages is the use of multi-stage fluidized bed columns [5]. By passing the solids through several stages connected in series, either in vertical or horizontal arrangement tends to reach a piston flow pattern, which is tantamount to narrowing the distribution of residence times. It can be stated therefore that as long as the flow of solids deviate from the perfect mixing and tend to the piston flow, the particle population coming out of the dryer will have a more uniform moisture content. In the operation of multi-stage fluidized bed columns with downcomers, one of the difficulties presented is to keep the flow of solids from stage to stage stable [4,6,7,8] It has been established that the zone of stable operation of these equipment is function of the fluxes of solid and gas through the column, as well as of the employment or not of a reduction in the inferior cross-section of the downcomer. This considerably decreases the treatment capacity of the solids, which may represent a limitation for the application of this technology.

This research evaluates the influence of the number of stages, the relation between the length of the downcomer to diameter of the dryer (L/D) and the air supply temperature on the final moisture content in silica gel particles. The continuous operation is modelled through an integral type model derived from the equation proposed by Vanecek[9].

### 1.1. Mathematical model of continuous dryer

The performance of a continuous fluidized bed dryer can be evaluated from the drying kinetics obtained experimentally in a batch dryer and by the use of the corresponding function of the residence time distribution of solids (E(t)) in the continuous operation of the dryer. This is expressed mathematically by Eq. (1) [9].

$$X_e = \int_0^{\infty} X(t)E(t)d\tau \quad (1)$$

#### 1.1.1. Drying kinetics

Considering that the drying kinetics of silica gel can be represented by an exponential model similar to Newton's second law of cooling, the following expression is proposed, Eq. (2):

$$-\frac{dX}{dt} = kX \quad (2)$$

This expression is integrated, considering that at  $t = 0$ ,  $X = X_0$ , thus obtaining Eq. (3)

$$X = X_0 \times \text{EXP}(-kt) \quad (3)$$

where  $k$ , is a coefficient that considers the effects of the air supply temperature, according to an Arrhenius type equation and that is represented by the following relationship:

$$k = A \times \text{EXP}\left(-\frac{E}{RT}\right) \quad (4)$$

Where,  $A$  is the preexponential factor,  $E$  the activation energy and  $R$  the universal constant of the gases. Substituting Eq. (4) in Eq. (3), the drying kinetics is obtained as a function of temperature and time, Eq. (5):

$$X = X_0 \times \text{EXP}\left[-A \times \text{EXP}\left(-\frac{E}{RT}\right)t\right] \quad (5)$$

### 1.1.2. Resident Time Distribution (RTD)

To establish the residence time distribution function of the solids ( $E(t)$ ) that go through the multi-stage dryer, the series of stirred tanks model<sup>[10]</sup> was used.

Thus the DTR as a function of time is given by Eq. (6), for  $N$  geometrically identical stages<sup>[2]</sup>

$$E(t) = \frac{1}{\tau_i} \left(\frac{t}{\tau_i}\right)^{N-1} \times \frac{1}{(N-1)!} * e^{-t/\tau_i} \quad (6)$$

Where  $\tau_i$  is the residence time of the solids in stage  $i$ .

### 1.1.3. Moisture content of the solids at the exit of the multi-stage dryer.

Finally, substituting the equations (5) and (6) in (1), we obtain the equation for the calculation of the moisture content of the solids at the exit of the multistage dryer as a function of the temperature and the number of stages:

$$X_e = \int_0^\infty \left\{ X_0 * \text{EXP}\left[-A \times \text{EXP}\left(-\frac{E}{RT}\right)t\right] \times \left[ \frac{1}{\tau_i} \left(\frac{t}{\tau_i}\right)^{N-1} \times \frac{\exp\left(-\frac{t}{\tau_i}\right)}{(N-1)!} \right] \right\} dt \quad (7)$$

## 2. Materials and Methods

### 2.1. Materials

Silica gel was used:  $d_p = 1.8 \times 10^{-3}$  m,  $\rho_p = 2.1 \times 10^3$  Kg / m<sup>3</sup>,  $\epsilon_{mf} = 0.67$ ,  $\phi = 1$ ,  $U_{mf} = 1.4$  m/s, solid type D of the Geldart classification.

## 2.2. Methods

### 2.2.1. Experimental Dryer

Fig. 1 shows the equipment used in this study and that served to perform the hydrodynamic study of the column, stable operation and distribution of residence times of the solids, the kinetics of drying of the silica gel and the continuous operation of the multistage dryer.

### 2.2.2. Drying Kinetics

The fluid bed dryer operated in batch with a single stage, is thermally stabilized at one of the previously established temperatures (T), 50, 60 or 70 °C and one of the loads of solids in the dryer ( $W_i$ ), 0.360, 0.720 or 1.080 Kg of gel of silica, corresponding to the height (L) to bed diameter (D) ratio of 0.5, 1.0 and 1.5, respectively. The air velocity remained constant at 2.24 m / s (1.6 Umf). During each experimental run, samples of approximately  $2.0 \times 10^{-3}$  Kg are taken and stored hermetically to later determine their moisture content. At the same time the temperatures in the bed are monitored. This routine is repeated for all temperatures and solids loads contemplated in the experimental domain.

### 2.2.3. Residence Time Distribution of solids

The "pulse" type of stimulus-response technique was used. Once the dryer operates continuously and in a steady state, an amount of tracer (silica gel with blue indicator) is "injected" into the feed stream (approximately 0.025 Kg), once this is done the valve is opened again so that the fresh solid continues to feed continuously. When the tracer enters the bed, the time starts to be taken and from this point samples of the concentration of tracer

are taken at the exit of the column in 30 seconds lapses. The function of RTD is obtained from the methodology reported by Levenspiel<sup>[2]</sup>. The tracer injection is done quickly enough to avoid that the downcomer is left without solids and thus avoid a possible destabilization in the column.

### 3. Results and discussion

From a previous study, the stable operation area of the multistage column was determined by operating the downcomers with a conical reduction, in its lower part equivalent to 45% of free area <sup>[1]</sup>. In this way, the solid and air fluxes were fixed respectively, in  $5.3 \times 10^{-4} \text{ Kg}_{\text{ds}} / \text{s}$  and  $5.2 \times 10^{-3} \text{ Kg}_{\text{dg}} / \text{s}$ , which remain constant during the experiments.

#### 3.1. Drying Kinetics

In Fig. 2 are shown the moisture profiles in the solid as it dries for the different air feed temperatures to the dryer. It can be seen that the constant drying period ranges from  $X_0 = 0.37 \text{ KgH}_2\text{O} / \text{Kg}_{\text{ds}}$  to a critical point that oscillates between 0.15 and 0.20  $\text{KgH}_2\text{O} / \text{Kg}_{\text{ds}}$ . It is observed that all the curves present period of constant drying speed and that as the load of solids in the dryer increases, the temperature of the bed takes longer to reach the air inlet temperature. In the same way, the higher the load of solids in the bed, the drying is slower, because there is more moisture to remove for a constant flow of air.

Fig. 2.- Drying kinetics of the silica gel in the period of constant drying as a function of the charge of solids in the dryer. a) 50°C; b) 60°C; c) 70 °C

When plotting the linearized form of Eq. 3, applied to the constant drying period, we obtain the value of the constant  $k$ , which is presented in table 1 for the different experimental conditions.

**Table 1.- Values of the silica gel drying constant**

T (°K)	W (kg)	$k \times 10^3$ (s <sup>-1</sup> )	E (KJ/mol)	A (s <sup>-1</sup> )
323	0.36	1.330		
333	0.36	1.720	14.78	0.337
343	0.36	1.830		
323	0.72	0.622		
333	0.72	0.758	14.42	0.135
343	0.72	0.850		
323	1.08	0.434		
333	1.08	0.500	14.51	0.096
343	1.08	0.595		

It can be seen that practically the loading of solids in the dryer does not appreciably affect the value of the activation energy, however this parameter affects the value of the pre-exponential factor, as can be seen in Fig. 3.

**Figure 3.- Activation Energy and Pre-exponential Factor.**

### 3.2. Residence Time Distribution

The table 2 shows the values corresponding to the residence time that the solids remain in a stage at the different L / D ratios.

**Table 2. RTD of the solids in the multi-stage fluidized bed dryer**

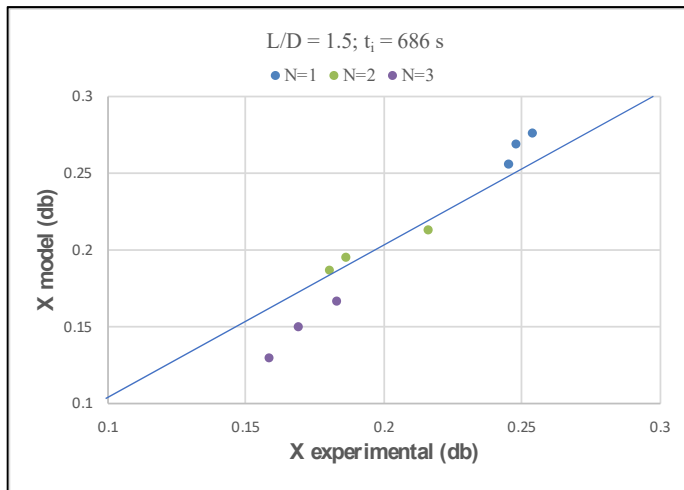

L/D	W (kg)	$\tau$ (s)
0.5	0.120	226
1.0	0.240	453
1.5	0.360	680

### 3.3. Continuous operation of the multistage dryer.

For  $N = 3$ ,  $\tau_i = 680$  s,  $(L/D)_i = 1.5$  (0.360 Kg), Eq. (7) left:

$$X_e = \frac{X_0}{2\tau_i^3} \int_0^\infty \left[ t^2 \text{EXP} - \left( (0.096 * \text{EXP}(-\frac{1750}{T}) + \frac{1}{\tau_i}) t \right) \right] dt \quad (8)$$

The results obtained by comparing the experimental humidity of the output of the dryer solids with those calculated with the Eq. (7) are presented in Fig. 4

**Fig. 4 Prediction of moisture content at the dryer outlet at different temperatures**

## 4. Conclusion

In this paper we show that the equation proposed by Vanecek, 1966, reasonably well predicts the humidity of the solids that come out of a multistage dryer.

It was found that the activation energy related to the drying process is independent of the load of solids in the dryer, but not for the pre-exponential factor.

Finally, it was found that the drying kinetics can be reasonably well represented by a first order power law model

### Abstract

*1-cm strawberry slices were partially airflow-dried at 50 °C, to reach 0.25 g H<sub>2</sub>O/g db. Optimized DIC treatment was performed at 350 kPa for 10 s. The final drying stage of these DIC-expanded slices was achieved from 0.25 to 0.1 g H<sub>2</sub>O/g db (dry basis) using intermittent Pulsed Micro-Wave Drying PMWD to prevent from the paradoxical step of coupled conduction heat transfer with deep generation and transfer of vapor. PMWD was defined at constant 100 W for 3.25±0.05 g with constant active time  $t_{on}$  maintained at 2 s, and tempering time  $t_{off}$  ranged between 2 and 10 s, or with a continuous way. By decreasing both energy consumption and total drying time of DIC-expanded slices using intermittent microwave, the whole cost significantly decreased to be much lower than the conventional MWD drying, with a great increasing of the quality.*

## 1. Introduction

Dehydration of strawberry aims at extending product availability while preserving nutritional components, and gains a noticeable increase [1]. Major disadvantages of airflow drying of strawberry are lengthy drying time and low energy efficiency [2, 3]. The three most crucial aspects of airflow drying resides in 1/ a first stage of superficial evaporation of water allowing the material core to have low temperature (Wet-bulb temperature), which implies ample preservation of nutritional contents (color, antioxidants...), 2/ a shrinkage of the low-temperature glass-transition polymers; this leads to a weaker effective diffusivity of water, and 3/ a final paradoxical stage of coupled heat conduction and Fick vapor diffusion transfer. This last generates a high-temperature/long-time stage source of the most part of degradation of the active molecules. The quality of the final dried product and its cost mainly depend on the final stage of drying [4].

The swell-drying of strawberry for crispy, high nutritional quality was defined by Alonzo-Macias et al. (2012) [5] as an Instant Controlled Pressure Drop DIC texturing treatment following a first stage of airflow drying. DIC targets at remedying the product shrinkage via a controlled expansion improving process kinetics and final quality of dried products. This operation doesn't reduce the famous final paradoxical stage of airflow drying, which occurs when the main evaporation process occurs within the matrix. Al Haddad et al. 2008 [4] were the first researchers to propose to remedy such a paradoxical stage drying through a distinct final stage of drying using Darcy process issued from Micro-Wave drying, overheated steam drying, or Multi-Flash Autovaporization MFA drying.

Thus Al Haddad et al. 2008 [4] were the only researchers who experimentally defined for green apple strips and sweet potato slices an efficient and economic three-stage drying process of hot air drying combined to a DIC texturing stage, and finally using microwave assisted ambient temperature airflow dehydration. In their study, each drying kinetic was carried out through 720 W power and different number of cycles. Each cycle consisted in subjecting the products to microwave assisted by ambient temperature air for 30 seconds and then sweeping the products with only air at ambient temperature for one minute. The use of MW may ensures a deep and almost uniform heating way implying the same required orientation of the both gradients of temperature ( $T_i > T_s$  for heating) and vapor pressure ( $p_{vi} > p_{vs}$ ) between the core and the superficial zone of the product. It should be an effective manner to overcome the paradoxical stage improving thus the drying kinetics.

Microwaves are an attractive source of thermal energy, generate volumetric internal heating within the product, increasing the internal total pressure (air+vapor) [6]. Microwave drying using continuous microwave energy is rapid and energy-efficient compared to conventional airflow drying [7]. However, the too rapid mass transport caused by MW power and uneven temperature and moisture distribution may cause overheat in the sample, provoking deep dark-point tissue damage, and/or undesirable changes in the food texture [8]. Some of the limitations of single MW drying can be overcome by combining MW energy with conventional heating or by using microwave energy in a pulsed manner in order to maximize drying efficiency possibly improving the product quality [7].

Moreover, intermittent Pulsed Microwave Drying PMWD operation has proven itself a good method to avoid uneven over-heating by allowing redistribution of temperature and water to diffuse through

the sample during power-off time [9]. PMWD has to be defined and performed in order to improve both drying process performance (kinetics, etc.) and preserve swell-dried strawberry quality attributes (color, antioxidant content, etc.). This study would be a basis to extend this operation to other fragile fruits, and technically support the industrial scale of final products for various applications (baby foods, nutraceuticals...) to make them commercially available.

To define an efficient and economic hybrid drying process, this work compiled 1/ a first conventional stage airflow drying AFD, 2/ a second stage of well-controlled texturing process of Instant Controlled Pressure-Drop DIC, and 3/ a microwave dehydration (MWD) whose driving force is the gradient of the total pressure of Darcy's permeability, which advantageously replaces Fick's diffusion mass-transfer. Two features prevent thermal MW energy from accumulating in the material through the removal of the generated vapor, by 1/ replacing the too compact AFD structure by porous swell-dried materials; the high porosity induces a high permeability of the vapor, and 2/ using a pulsed PMWD.

Therefore, using the intermittent microwave drying after SD, this current work aimed to 1/ examine the effectiveness and optimize the PMWD applied in early stage of drying from the point of view of overall final quality of dried slices of strawberry, a heat sensitive fruit, and 2/ evaluate the effectiveness of intermittent PMWD drying at optimized conditions ( $t_{on}$ ;  $t_{off}$ ) compared with continuous microwave, airflow drying and freeze-drying (FD) in terms of drying kinetics and visual attributes of dried rehydrated SD strawberries.

## 2. Materials and Methods

### 2.1 Fresh materials

Fresh strawberries camarosa cultivar were purchased from a local market in La Rochelle (France). The strawberries were manually cut parallel to the main axis into halves (for FD) or 1cm slices (AFD and CMWD) of average  $37 \pm 2$  mm length,  $18 \pm 1$  mm width and  $15 \pm 1$  mm thickness with a stainless steel knife and weighted. The fresh samples had a moisture content of  $11.66 \pm 1.42$  g H<sub>2</sub>O/g db (dry basis).

#### 2.1.1 Drying of the fresh strawberry

$30.5 \pm 0.5$  g strawberry slices were spread out evenly and subjected to three different drying methods based either on single continuous drying, namely (i) microwave drying "(CMWD)" at 20 °C; (ii) airflow drying "(AFD) at 50°C" and (iii) freeze drying [5]. In this cases the pulse ratio (PR) =  $(t_{on} + t_{off}) / t_{on} = 1$ .

- Airflow drying (AFD)

Strawberry slices were dried in a airflow dryer (Mettert: Universal Oven UNB Model 800) at 50 °C with an air flux of  $1.2 \text{ m s}^{-1}$ . They were dried until attaining  $0.10 \text{ g H}_2\text{O/g db}$  (dry basis). These samples were recorded as AFD 50°C.

- Microwave drying (MWD)

A domestic combined microwave oven with convection (Samsung, Model CE107F-S. Korea) with maximum output 900 W at 2450 MHz. In each experiment, strawberry slices of  $30 \pm 0.5$  g were placed in petri dish putting at the center of a glass turntable disc in the microwave chamber. Drying

experiments were carried out with 100 W microwave power level at 20 °C. The average value of effective MW power is about 62 W.

- Freeze Drying (FD)

A freeze-drying equipment (RP2V model, Serail, France) was used for drying the strawberry halves. Three steps were used : external freezing (2 h at -20°C), sublimation (-20 °C, 0.66 Pa/12 h) and desorption (25 °C, 0.66 Pa/12 h) [5].

## 2.2 Pulsed Microwave drying (PMWD) of the rehydrated Swell dried SD strawberries

The batch of 1-cm sliced strawberries was partially airflow dried (Memmert: Universal Oven UNB Model 800) at 50 °C and an air flux of 1.2 m/s until 0.25 g H<sub>2</sub>O/g db. Afterwards, the partially airflow dried strawberries were textured by an optimized DIC treatment (0.35 MPa as saturated steam pressure for 10 s) [5]. Finally, after DIC treatment, a traditional airflow drying at 50 °C was performed to get 0.08 g H<sub>2</sub>O/g db as final water content. These samples were analyzed and recorded as control or SD.

50 g of swell-dried slices of strawberries (*Fragaria ananassa*) placed in zipped airtight bags were rehydrated from 0.08 to 0.25 g H<sub>2</sub>O/g db and stored in a cold chamber at 5 °C by 24 h to homogenize their water content. Approximately, 3.25±0.05 g of rehydrated SD expanded strawberry slices were spread out evenly and subjected to three different drying methods achieved from W= 0.25 to 0.1 g H<sub>2</sub>O/g db based either on hybrid three stage drying process, namely (vi) airflow drying at 50 °C; (v) Pulsed microwave drying “(PMWD)” at 20 °C ambient temperature with active time  $t_{on}$  maintained at 2 s at constant 100 W, and three values of tempering time  $t_{off}$  at 2, 5, and 10 s, and (vi) a continuous operation of microwave was also performed (10 s  $t_{on}$  and 20 s  $t_{off}$  is the proper intermittent cycle of continuous use of domestic microwave oven at 100 W).

From literature, initial know-how of LaSIE’s research team, and preliminary experiments, two independent processing factors of PMWD process and their own respective ranges were selected; they were  $t_{on}$  (2 s), and  $t_{off}$  (2-10 s). The petri dish was removed from the oven and weighted at regular intervals at the end of power-off times during the drying period. By recording the successive times of  $t_{on}$  and  $t_{off}$ , we determined the moisture loss and drying rate during the pulsed microwave drying.

The measurements of moisture loss were performed by a gravimetric method at 60°C until weight stabilization, according to AOAC 930.04 [10], and expressed in g H<sub>2</sub>O/g db. After drying, each sample was photographed for assessing the sample visual quality. Drying Rate (DR) (g H<sub>2</sub>O/(g db min)) was calculated from the water contents dry basis values (g H<sub>2</sub>O/g db)  $W_t$  and  $W_{t+dt}$  at time values of  $t$  and  $t+dt$ , respectively.  $t$  was the apparent drying time ( $t_{on}+t_{off}$ ) (s) :

$$DR = \frac{W_{t+dt} - W_t}{dt} \quad (1)$$

## 2.3 Estimation of pressure within the superficial zone of the product during the first cycles

By assuming that the holes of initial sample were full of water without any presence of air, the pressure inside the material matrix, expressed in Pa, can be estimated versus the mass of generated vapor/pulsed cycle (g/cycle) and the initial volume of water in the product (m<sup>3</sup>), as follow:

$$Internal\ vapor\ pressure = \frac{m_v RT}{M_{H_2O} V_w} = \frac{\rho_v RT}{M_{H_2O}} \quad (2)$$

Where,  $M_{H_2O}$  is the molar mass of water (18 g/mol),  $T$  is the product temperature (K),  $R$  is the universal gas constant, and  $V_w$  is the water volume ( $m^3$ ). The amount of water transformed into vapor per cycle should be correlated with the evaporation enthalpy  $\Delta h_{vap}$ :

$$m_v = \frac{0.62 * t_{on} * P}{\Delta h_{vap}} \quad (3)$$

### 3. Results and Discussion

#### 3.1 Effect of PR on drying kinetics

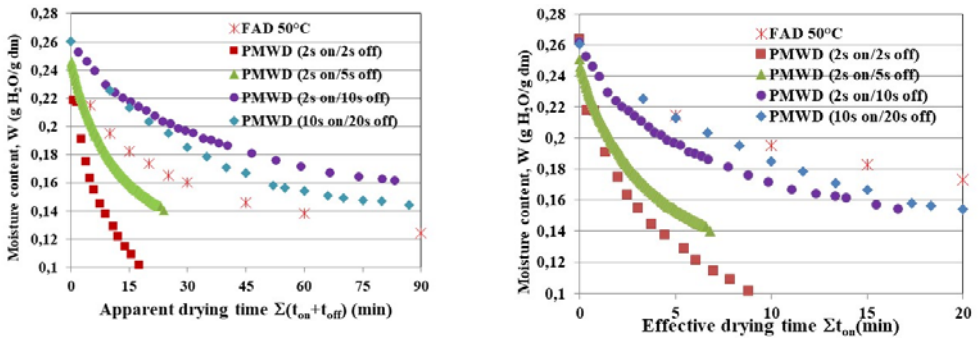

Fig. 1 The moisture content versus time curves for the AFD 50°C, PMWD (100 W) of rehydrated SD strawberries (load of 3.25 g) for apparent drying time  $\Sigma(t_{on}+t_{off})$  and effective drying time  $\Sigma t_{on}$ .

As shown in Figure 1, moisture content ( $W$ ) continuously decreased vs drying time. To reach  $W=0.1$  g  $H_2O/g$  db, PMWD (2 s  $t_{on}$ / 2-5 s  $t_{off}$ ) had a crucial acceleration of the drying process compared with AFD 50 °C. At PMWD (2s  $t_{on}$ /2s  $t_{off}$ ),  $W$  of about 0.1 g  $H_2O/g$  db was reached in 19.6 min, which means only 9.8 min effective drying time. PMWD (10 s  $t_{on}$ /20 s  $t_{off}$ ) was lesser effective and resulted in poor product quality. This trend can be explained by a too high value of  $t_{on}= 10$  s, which would result in increasing the internal heat with a generation of a dispersed deep case-hardening in different place within the volum. Higher tempering period results in an easier water balance within the sample, although without any modification of such a dispersed deep case hardening. By coupling an adequate low values of the active time  $t_{on}$ , and high tempering period  $t_{off}$ , greater availability of Darcy’s transfer of vapor can occur. Nevertheless, an excess of  $t_{off}$  normally results in negative impact in terms of kinetic.

#### 3.2 Effect of PR on drying rate versus apparent drying times

For PMWD, a zigzag pattern of successive cycles of high peak/falling rate period was observed. This could be attributed to the redistribution of moisture and temperature during the tempering time provided by the thermal diffusion resulting in better water homogeneity and, thus, rapid moisture removal during the subsequent active microwave [11]. Thus, PMWD increase the pore pressure and a total pressure gradient between the internal and external media is established due to phase transitions and the thermodiffusion effect, thus leading to a highly effective Darcy-type vapor transfer.

Fig. 2 Drying rate of PMWD operating parameters (effective drying time  $\Sigma t_{on}$  or apparent drying time  $\Sigma(t_{on}+t_{off})$ ) versus moisture content of rehydrated SD strawberries.

The drying rate of different pulsed microwave drying conditions was affected by tempering time  $t_{off}$  (Fig 2). Generally, total drying rate has been as faster as  $t_{off}$  decreased (shorter tempering time). This resulted in higher temperature and, thus, higher vapor pressure with, normally higher Darcy’s vapor mass-transfer. The drying rate value calculated versus the effective drying time, was much higher. This result is crucial for industrial application and can be revealed through an adequate time and/or space intermittent repartition. Moreover, these phenomena did not strictly depend on PR. Thus, for approximately the same PR=3, PMWD (2 s  $t_{on}$ /5 s  $t_{off}$ ) were 5 times more accelerated than (10 s  $t_{on}$ /20 s  $t_{off}$ ).

### 3.3 Quality attributes

#### 3.3.1 Surface pressure during the first cycles

Table 1 shows for  $t_{on}=2s$  aninput heating energy substantially increasing with tempering time  $t_{off}$ . Moreover, PMWD conducted at lower  $t_{off}$  resulted in lower total effective drying time ( $t_{on}$ ) and specific energy consumption compared to other intermittent combinations. This is because the higher the tempering time  $t_{off}$ , the colder the surface because of superficial convection.

Table 1. Values of the total drying time, total ON drying time, specific consumed energy and estimated surface pressure for PMWD rehydrated swell-dried strawberries at different PR.

$t_{on}$ (s)	$t_{off}$ (s)	$PR=(t_{on}+t_{off})/t_{on}$	T (°C)	$\Sigma(t_{on}+t_{off})$ (s)	$\Sigma t_{on}$ (s)	P (bar)
2	2	2	20	1176	588	1.915
2	5	3.5	20	3185	910	1.919
2	10	6	20	5988	998	1.888
10	20	3	20	10800	3600	5.203
-	-	1 (AFD)	50	16200	16200	-

#### 3.3.2 Visual Attributes

The first step of airflow drying AFD at 50 °C gave good visual attributes of the strawberry slices. Just after DIC-texturing, SD strawberry slices maintained the good natural visual color. On the other hand,

it is well-known that the freeze-dried strawberries lose their natural redness initial color. With SD slices as control samples, only PMWD (2 s  $t_{on}$ /5 s  $t_{off}$ ) gave no black/brown spots within the slice.

**Fig. 2** Appearance of exemplary strawberries slices after continuous and PMWD modes.

Nevertheless, as soon as the PMWD active time is above a certain level ( $t_{on} > 10$  s), many black spots emerged with less efficient drying kinetics. This can be attributed to deep “case hardening” delimiting areas with high internal tissue damage.

#### 4. Conclusions

Based on both final product quality and operation performance, a multi-criteria optimization of Pulsed Microwave Drying PMWD was achieved. Microwave active time  $t_{on}$  and tempering time  $t_{off}$  were defined and optimized at 2 s and 2 to 5 s, respectively. Although the microwave power was kept at 100 W for 3.25 g of strawberry slices, this MW distribution has prevented heat accumulation and put in equilibrium the internal water distribution, thus well generating vapor and its effective transfer towards the surrounding medium. These well-defined strawberries dried by AFD/DIC swell-drying and those of PMWD at  $t_{on}=2$  s and  $t_{off}=2$  s exhibited the highest antioxidant activity and total phenol content.

Hence, the present three stage-intensified drying of AFD/DIC swell-drying/PMWD allowed the strawberry to effectively get the advantage of low internal temperature, thus acting against the paradoxical situation and remove the residual water from the porous matrix (after DIC) following Darcy’s permeability as transfer way of residual vapor. With low energy consumption of DIC-expansion and intermittent microwave, and since the drying kinetics was greatly increased, the total cost should become significantly lower than the simple Continuous MicroWave Drying.

#### 5. Nomenclature

MWD	Conventional Micro-Wave Drying	-
CMWD	Continuous Microwave Drying	-
PMWD	Pulsed Micro-Wave Drying	-
AFD	Airflow Drying	-
DIC		-

SD	Instant Controlled Pressure-Drop, which is a second stage well-controlled texturing process
(PR)	Swell-Drying, which combines a conventional (airflow) drying with DIC-texturing. pulse ratio= $(t_{on}+t_{off})/t_{on}=1$
Subscripts	
$t_{on}$	Active time, where both input MW heating energy and vapor mass-transfer occur together
$t_{off}$	Tempering time, where there is no input MW heating energy, and vapor mass-transfer mainly following Darcy's law, is assumed to be negligible.
$T_i$ and $T_s$	Temperature values at the core and the superficial zones, respectively °C
$p_{vi}$ and $p_{vs}$	Absolute vapor pressures at the core and the superficial zones, Pa respectively

### **Abstract**

*This paper is aiming to study experimentally the bubbling and drying characteristic of fructooligosaccharides syrup in the belt drying process. A series of bubble images were acquired by a high-speed image acquisition system during the drying process. By analyzing the characteristics of bubble and drying, the drying process of fructooligosaccharides was divided into three periods: boiling transfer, natural convection and conduction and diffusion period. The drying rate in different transfer stage was: boiling transfer > natural convection > heat conduction and diffusion. The results of the study are of reference value to belt drying.*

**Keywords:** *fructooligosaccharides; belt drying; digital image processing; heat and mass transfer*

---

## **1. Introduction**

Fructooligosaccharides (FOS), also known as fructo oligosaccharides or oligosaccharides, is a kind of functional food additive which is widely used in food, health care products, dairy products, daily chemicals and feed. FOS is not digested and absorbed into the human body, but goes directly into the large intestine. It achieves the purpose of health care by selectively stimulating the proliferation of Bifidobacterium. Japan, Europe, Australia, New Zealand, the United States, China and other countries have approved the FOS as a functional food additive to add in food, health care products, even infant, diabetic food<sup>[1,2]</sup>.

FOS syrup is made from sucrose and inulin by enzymatic method. Dehydrated FOS powder is easier to store and further utilized. There are three main drying technologies in industry to drying FOS syrup: spray drying, freeze drying and belt drying. In spray drying process: the viscosity of FOS syrup is too high to be atomized; the product's powder collecting rate is only about 45%, most of the dried products stick in the pipeline because its lower melting point<sup>[3]</sup>. Although vacuum freeze-drying can guarantee product quality, higher equipment investment and operating costs and longer drying cycle make this drying method difficult to industrialize<sup>[4]</sup>. In belt drying, the heat efficiency and product's powder collecting rate is far higher than spray drying. Many researchers thought that the heat transfer way in belt drying is only thermal conduction<sup>[5]</sup>. It was observed that the liquid material would boiling if the temperature of the conveyor belt was higher than the boiling point of the liquid material, so the heat transfer mode of the belt drying is not only thermal conduction but also boiling transfer and natural convection. The purpose of this study is to determine boiling heat transfer period, natural convection and thermal conduction period.

## **2. Materials and Methods**

### **2.1. Materials and equipments**

FOS powder: its purity was 95%; Distilled water; conveyor belt with a specification 80mm x 80mm; High speed image acquisition system; Digital display temperature controlled electric heating plate; Electronic balance.

### **2.2. Experimental method**

Figure 1 showed the schematic diagram of the experimental system. The FOS syrup was dropped on the conveyor belt with a 1.5ml dropper, and then put it on the heating plate at a set temperature. The mass of the material was weighed in a certain time interval. Then the drying curve under different drying conditions was obtained. In this experiment, the temperatures were set at 120°C, 130°C, and 140°C, respectively.

During the drying process, the camera was placed above the material and the bubble image was taken and recorded at regular intervals. Placed the CCD high-speed camera horizontally, recorded the image of material's thickness at regular intervals.

*Fig. 1 Schematic diagram of an experimental device. 1. Computer, 2. acquisition card, 3. conveyor belt, 4. FOS syrup, 5. digital display temperature control heating plate, 6. transparent plexiglass cover, 7. LED lamps, 8. CCD high-speed camera.*

### 2.3. Image processing

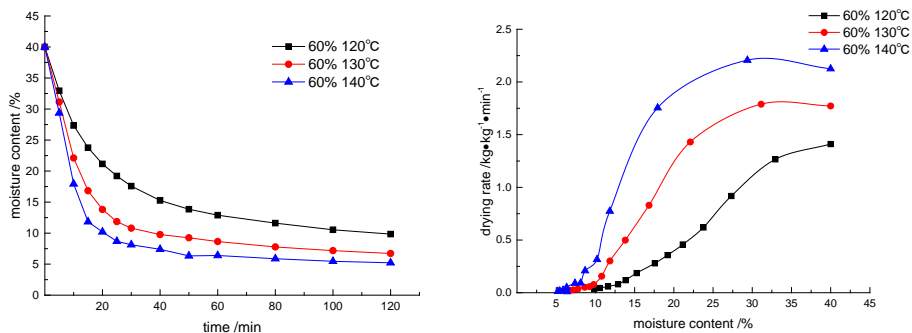

The captured bubble images were imported to in the imageJ software to mark the bubble boundary, gray scale transformation, edge extraction, binaryzation, hole filling and watershed segmentation, and then the binary image of the bubble was obtained. By photographing the steel ruler and marking the pixel size of 1cm length, the conversion relation between the actual length and pixel could be obtained. In addition, The pixel area of bubbles was obtained by using the particle analysis tool in imageJ software, and then convert it to the actual area. In the same way, the total area of the material could be measured by marking the material boundary.

## 3. Results and discussion

### 3.1. Drying characteristic

Figure.2 showed the drying curves and drying rate curves of FOS syrup with a concentration of 60% at different heating temperature conditions. Overall, the higher the heating temperature, the greater the drying rate, and the lower the final moisture content of the dried product. The drying rate had a distinct rising stage at 130°C, 140°C; while decreased from the beginning of drying at 120°C. The boiling point of the 60% FOS syrup was determined to be 105°C. When the heating temperature was 120°C, the degree of superheat, the difference between the heat plate temperature and the material saturation temperature, was too low to keep the material boiling. The boiling period lasted too short to

show on the drying rate curve, and the transfer mode in liquid material turned from boiling transfer to natural convection mode along with the evaporating of the moisture. As the drying process proceeds further, the material concentration was greater and greater, the corresponding viscosity and boiling point increased, which made the material more and more difficult to flow, the transfer process was mainly heat conduction and diffusion, so the drying rate in the whole drying process was getting lower and lower.

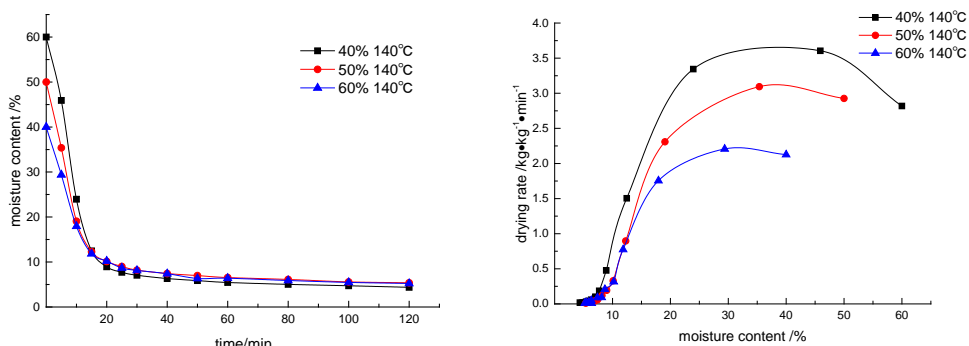

(a) Drying curves (60%)

(b) Drying rate curves (60%)

Fig. 2 Drying characteristic curves at different drying temperature

At 130°C, 140°C heating temperature, the degree of superheat was great enough to keep the material boiling for a while. At the beginning of drying process (the preheating section was too short to be ignored), the transfer mode inside the FOS syrup was mainly boiling transfer mode, so there was a distinct raising stage in the drying rate curves at 130°C, 140°C. With the further development of the drying process, the transfer mode in the material changed into natural convection, heat conduction and diffusion in turn, this was the same like at 120°C.

(a) Drying curves (140 °C)

(b) Drying rate curves (140 °C)

Fig. 3 Drying characteristic curves (initial concentration comparison)

Figure 3 showed the drying curves and drying rate curves of FOS syrup with different concentrations at the same drying temperature 140°C. There was a distinct rising stage in drying rate curves under these three concentrations which indicated that there must be boiling transfer period during the drying processes. The lower the concentration, the greater the drying rate. As everyone knows: the boiling point of the solution decreased with the decreased of concentration. At the same heating temperature 140°C, the temperature difference between the heating plate and the lower concentration material was greater than that of the higher concentration material, so the boiling process was more intense which induced a greater drying rate.

### 3.2. Bubble behavior and transfer mode

*Fig. 4 Bubble images of different time (60% 120 °C)*

Figure4 showed the bubble behaviors inside FOS syrup with the concentration of 60% under 120°C temperature. When the drying process was carried out for 1 minute, there were small bubbles formed on the heating plate. This indicated that the material had entered the boiling transfer period. The bubbles grew rapidly in 1-3 minutes because the material temperature was higher than that of the saturated vapor in bubbles. As the drying process proceeded, the degree of superheat decreased along with the increased of the liquid concentration, the bubbles grew up a little within 3-25 minutes. This indicated that the material temperature was a little higher than the saturated vapor temperature in the bubbles, the material concentration increased a little in this period, which meant that the drying rate was slower than the boiling transfer period. The transfer mode would be natural convection because the material fluidity was better in this period. After 25 minutes, the size of the bubble shrunk more and more slowly until the end of the drying. It was observed that the material had no fluidity in this period, so the transfer mode was heat conduction and diffusion.

Figure5 showed the bubble behaviors during drying process of 60% FOS syrup at 140°C. When the drying process was carried out for 5 minute, there were small bubbles formed on the heating plate. This indicated that the material had entered the boiling transfer period.

The bubbles grew rapidly in 5-7 minutes and joint together. In 7-10 minutes the bubbles interacted with each other, some formed larger bubbles, some ruptured. All of these bubble behaviors were because the material temperature was higher than that of the saturated vapor in bubbles. As the drying process proceeded, the degree of superheat decreased along with the increased of the liquid concentration, and the bubbles' behavior had a little change within 10-23 minutes. This indicated that the material temperature was a little higher than the saturated vapor temperature in the bubbles. The material concentration increased a little in this period, which meant that the drying rate was slower than the boiling transfer period. The transfer mode would be natural convection because the material fluidity was better in this period. After 23 minutes, the size of the bubble shrunk more and more slowly until the end of the drying. It was observed that the material had no fluidity in this period, so the transfer mode was heat conduction and diffusion. Table 1 showed the transfer modes during drying process under different drying conditions.

Fig. 5 Bubble images of different time (60% 140°C)

Table 1. The time of different stages (140°C)

FOS syrup concentration	boiling transfer	natural convection	heat conduction and diffusion
40%	0-13min	13-25min	>25 min
50%	0-12min	12-24min	>24 min
60%	0-10min	10-23min	>23 min

### 3.3. Drying rate

From the above analysis, it could be concluded: most of the moisture in the FOS syrup was removed in boiling and natural convection transfer period. Table 2 showed the average drying rate in different drying period at 140°C.

The calculation formula was as follows:

$$U = -\frac{mdX}{A dt} \tag{1}$$

Where: U: the drying rate, kg/m<sup>2</sup>h;

m: the weight of the dry material, kg;

X: moisture content (d.b.);

A: transfer area, m<sup>2</sup>.

For boiling and natural convection transfer period, A was the area of the material projected on the heating plate, A<sub>j</sub>.

For heat conduction and diffusion period,  $A = A_j - A_b$ ,

A<sub>b</sub> :the bubbles projected area on the heating plate;

t: the drying time, min.

*Table 2. The drying rate of different stages (140°C)*

concentration	The drying rate of different stages/kg*m <sup>-2</sup> *h <sup>-1</sup>		
	boiling	natural convection	conduction and diffusion
40%	5.221	0.404	0.020
50%	4.408	0.381	0.030
60%	3.343	0.687	0.034

From Table 2 it could be concluded: the drying rate in boiling transfer period was 1 order of magnitude of that in natural convection period, and 2 orders of that in heat conduction and diffusion period.

#### 4. Conclusion

(1) According to the bubble behaviors, the transfer mode in fructooligosaccharides syrup was divided into boiling transfer, natural convection and heat conduction and diffusion stage at higher heating temperature (130°C, 140°C, 150°C for 60% syrup); at lower heating temperature (120°C), the boiling transfer was too short to be ignored and the transfer mode in material was mainly natural convection and heat conduction and diffusion.

(2)The drying rate in different transfer stage was: boiling transfer > natural convection > heat conduction and diffusion. At the same temperature, the lower the material concentration, the greater the drying rate; for the same material concentration, the higher the heating temperature, the greater the drying rate.

(3) In the boiling transfer period, there was distinct rising stage in drying rate curves, while decreased from the beginning without boiling transfer period.

### ***Abstract***

*The aim of the present study was to develop an alternative method to the traditional curing process using water vapour permeable bags to obtain a dry-cured pork loin product. The dry-cured pork loins obtained by this new process showed an adequate hygienic quality and good sensory acceptance. The salting-curing process using water permeable bags requires less manipulation, reduces waste generation and allows greater control during processing. This technique could be an interesting alternative to the traditional processes, improving the hygienic quality of the products and minimizing the environmental impact.*

**Keywords:** *Dry-cured loin; Salting; Water vapour permeable bags; Physicochemical properties; Sensory.*

---

## **1. Introduction**

The meat industry innovations are focus on improving the traditional curing processes. Producers seek new methods to reduce processing times, minimise salt waste, reduce overall weight loss and/or improve the hygienic quality. In this line, a new salting process in which the exact amount of salt to be absorbed by the product is directly dosed was proposed by Fuentes et al.<sup>[1]</sup>. This controlled procedure has been applied to different fish products reducing waste and product variability. The combination of this controlled salting process and vacuum packaging was able to accelerate NaCl absorption and dehydration, and can therefore cut the total processing time without affecting physicochemical parameters and sensory traits as compared with traditional fish products. Recently, materials with high water vapour transmission rates have been investigated. The use of highly water vapour-permeable bags (WP) facilitates the control of product dehydration by managing the temperature and humidity conditions, as with the traditional methods (unpacked) and minimising the risk of microbial contamination<sup>[2]</sup>. The combination of controlled salting process with WP bags has been studied to obtain smoke-flavoured fish with similar sensory traits to smoke products obtained by traditional methods and would optimise yields, reduce waste, speed up processes, maintain the hygienic quality during processes, and facilitate transportation and distribution at the same time<sup>[3,4]</sup>. For this reason, we considered that this promising technique could be implemented in the meat sector; making necessary adjustments.

The aim of the present study was to develop an alternative method to the traditional curing process using water vapour permeable bags to obtain a dry-cured pork loin product with physicochemical, microbiological and sensory characteristics similar to traditional products.

## **2. Materials and Methods**

### **2.1. Experimental design**

Pork loin processing was carried out using a controlled salting process where the exact amount of salt, necessary for the product to reach a targeted salt concentration, was dosed. The amount of salt added to each sample was individually calculated from the initial pork loin weight and the initial meat moisture. Pork loins were covered with a thin and homogeneous layer of salt, and then, vacuum-packed in the water vapour permeable bags. Initially, the salting-drying process was carried out at 85% relative humidity (RH) and 4 °C, and these conditions were modified during the process until reaching 65% RH and 10 °C. The loins were kept in the drying chamber until a weight loss of 40% was reached. At the end of the process, the loins were analysed to determine their physicochemical parameters (moisture, salt, aw, pH, total nitrogen and non-protein nitrogen), texture, colour, microbial

counts (mesophilic bacteria, lactic acid bacteria and *Enterobacteriaceae*), and sensory profile.

## 2.2. Analytical determinations

### 2.2.1. Physicochemical analyses

During processing, weight changes in pork loin ( $\Delta M_t$ ) were calculated considering the sample weight at each time and the initial sample weight.

Moisture and lipid content were determined according to the AOAC methods<sup>[5]</sup>. The pH measurements were taken by a micropH 2001 digital pH-meter (Crison Instruments, S.A., Barcelona, Spain) with a puncture electrode (Crison 5231) at five different locations on pork loin sample. Chloride content was determined after sample homogenisation in distilled water using an automatic Sherwood Chloride Analyser Model 926 (Sherwood Scientific Ltd., Cambridge, UK). Water activity ( $a_w$ ) was measured with an Aqualab dew point hygrometer model 4TE (Decagon Devices, Inc., Washington, USA). Total nitrogen (TN) and non-protein nitrogen (NPN) was measured following the method described by Standnik and Dolatowski<sup>[6]</sup>.

Colour determination was directly performed on the pork loin slices. A Minolta CM-700-d photocolourimeter (Minolta, Osaka, Japan) was used, with a 10° observer and illuminant D65. Using the CIE L\*a\*b\* coordinates (where L\* is lightness, a\* deviation towards red or green, and b\* deviation towards yellow or blue), the psychophysical magnitudes of hue ( $h_{ab}^*$ ) and chroma ( $C_{ab}^*$ ) were calculated.

A texture profile analysis (TPA) was performed on the prok loin samples with a Texture Analyser TA.XT2® 174 (Stable Micro Systems, Surrey, UK) equipped with a load cell of 250 N. For this measurement, a flat-ended cylindrical plunger (7.5mm diameter) was employed. This plunger was pressed into the sample at a constant speed of 1 mm/s until it reached 50% of sample height. Samples for this analysis were obtained from middle part of each loin, which were sliced and cut to obtain parallelepiped pieces (1x1x3 cm). Force-distance curves were processed to obtain hardness, chewiness, adhesiveness, springiness, cohesiveness and resilience parameters.

### 2.2.2. Microbiological analyses

Mesophilic bacteria, *Enterobacteriaceae* and lactic acid bacteria were determined according to the methods given by the following ISO standards <sup>[7,8,9]</sup>. The results were expressed as log cfu/g.

### 2.2.3. Sensory analysis

A trained panel undertook the sensory evaluation using quantitative descriptive analysis (QDA). Tests were done with the semi-structured scales (from 0 (very low) to 10 (very

high) by which attributes such red colour intensity, color homogeneity, brightness, hardness, adhesiveness, odour and cured flavor were evaluated.

### 2.3. Estatistical analysis

One-way analysis of variance (ANOVA) was conducted to establish significant differences between samples. The least significant difference (LSD) procedure was used to test for differences between averages at the 5% significance level. Statistical treatment was performed using Statgraphics Centurion XVI (Manugistics Inc., Rockville, MD, USA).

## 3. Results and discussion

### 3.1. Changes in phisicochemical parameters

During the elaboration of the dry-cured pork loin, the loins were weighed periodically with the aim of determining the product weight loss at each sampling time and estimating the end of the drying period (Fig. 1). The salting-curing process lasted for 75 days. In this sense, considering that cured loins have usually a curing period of about 3 months, it could be established that this new process would allow to slightly reduce processing time.

Fig. 1 Total weight changes during the salting process in pork loins obtained by using water permeable bags (average value  $\pm$  standard deviation of each batch).

After processing, moisture of the dry-cured pork loin samples was determined. Moisture was separately measured in the central and in the outer part of the slices in order to detect crust formation during the process. Significant differences were observed between the moisture values of the central and outer parts of the loins ( $p < 0.001$ ), being these differences lower than 2% which evidences the absence of crusting in the pieces obtained by the

procedure developed in this work. Average moisture values were within the range established for commercial products.

Fig. 2. Moisture values of dry-cured pork loins (mean values  $\pm$  standard deviation,  $n=3$ ). The dashed lines represent reference values.

Values of pH, salt content, and  $a_w$  in the different batches processed by the new procedure are shown in table 1.

Table 1. Physicochemical parameters in pork loins (average value  $\pm$  standard deviation,  $n=3$ ).

Parameter	A	B	C	D
pH	5.66 $\pm$ 0.02	5.78 $\pm$ 0.02	5.79 $\pm$ 0.05	5.87 $\pm$ 0.06
NaCl	4.43 $\pm$ 0.12	4.7 $\pm$ 0.2	4.59 $\pm$ 0.16	4.69 $\pm$ 0.14
$a_w$	0.9263 $\pm$ 0.0004	0.9196 $\pm$ 0.0001	0.9171 $\pm$ 0.0053	0.9198 $\pm$ 0.0015
TN	5.3 $\pm$ 0.6	5.3 $\pm$ 0.32	5.1 $\pm$ 0.5	4.7 $\pm$ 0.8
NPN	153 $\pm$ 15	199 $\pm$ 1.9	158 $\pm$ 30	196 $\pm$ 33

NaCl: salt content (g NaCl/100 g); TN: total nitrogen (mg/100 g dry matter), NPN: non-protein nitrogen (mg/100 g dry matter)

Salt content in the dry-cured products obtained in this study was similar than those reported by other authors<sup>[10,11]</sup>. The water content reduction and NaCl incorporation in the meat product as a consequence of the salting-curing process led to a  $a_w$  values reduction. No significant differences were observed regarding to total nitrogen and non-protein nitrogen among samples. During curing period, the proteolytic breakdown of meat proteins increases nonprotein nitrogen concentration in the product. These changes in proteins are an important source of flavour compounds through the involvement of amino acids and small peptides<sup>[12]</sup>. The lower NNP content could be attributed to the shorter ageing period in the present study compared with the traditional processes

Mecanical and colour parameters were similar than those reported in other studies for this type of product (data not shown). These results indicate that the new procedure do not modify texture and appearance of the dry-cured loin compared to the traditional products.

### 3.2. Microbial analyses

The counts for mesophilic, lactic acid bacteria and *Enterobacteriaceae* are shown in Table 2. Dry-cured pork loin samples, showed low levels of mesophilic bacteria and *Enterobacteriaceae* counts were below the detection limit ( $<10^2$  CFU/g).

**Table 2. Counts of mesophilic, lactic acid bacteria and *Enterobacteriaceae* (average values  $\pm$  standard deviation, n=3)**

Parameter	A	B	C	D
Mesophilic bacteria	3.9 $\pm$ 0.2	3.7 $\pm$ 0.3	4.1 $\pm$ 0.5	3.16 $\pm$ 0.12
Lactic acid bacteria	3.1 $\pm$ 0.2	3.2 $\pm$ 0.3	3.6 $\pm$ 0.5	3.05 $\pm$ 0.13
<i>Enterobacteriaceae</i>	nd	nd	nd	nd

These results indicate that the hygienic conditions employed during processing were correct, wich allow to obtained a dry-cured product with a high hygenic quality. As it can be observed, the new procedure does not affect the growth of lactic acid, whose development is considered necessary to control the proliferation of certain altering microorganisms such as coliform bacteria<sup>[13]</sup>.

A sensory analysis was carried out to check the acceptability of the new dry-cured pork loin. The tested samples were those obtained by the new technology (WP) and the commercial ones. The overall scores marked by the assessors for the sensory attributes of the samples are depicted in Fig. 3. No significant differences were recorded between samples for colour homogeneity, brightness and adhesiveness ( $p>0.05$ ). However, commercial samples had a higher intnesity regarding the colour, hardness, and cured flavour. The lower intensity of those attributes in the new products could be correlated with dry-curing time. The increase on taste active components during processins of dry-cured meat products has been reported<sup>[14]</sup>, therefore length of curing exhibit a strong correlation with the typical flavour of these type of products.

Fig. 3. Score average for the different attributes evaluated in samples of commercial dry-cured prok loin and the new product (WP).

#### 4. Conclusions

The processing conditions used and the exact dosage of the salt have been adequate to obtain a dry-cured pork loin with moisture, salt and  $a_w$  values similar to the commercial products. These conditions have allowed to obtain a product with an adequate hygienic quality and a sensory profile similar to the traditional product. This new salting-curing process using water vapor permeable bags present several advantages compared to the traditional processes such as the lower handling of the product, waste reduction and higher control of the process.

### **Abstract**

*The objective of the present study was to test the feasibility of a new salting-curing process using water vapour permeable bags to obtain a reduced sodium dry-cured loin. The process was applied with and without partial substitution of sodium chloride by potassium chloride. The developed methodology allows to obtain a dry-cured pork loin with partial sodium substitution similar to the product without reduced sodium content, regarding to their physicochemical parameters, texture and colour. The results indicated that the new process allowed to obtain a cured meat product with 50% less sodium and similar characteristics than the traditional products.*

**Keywords:** sodium replacement; water vapour permeable bags; dry-cured loin; salt content; physicochemical parameters .

---

## **1. Introduction**

Numerous studies have demonstrated that the dietary intake of sodium significantly influences blood pressure levels and contributes to an increased risk of coronary heart disease and strokes<sup>[1,2]</sup>. In industrialized countries, the sodium intake exceeds the nutritional recommendations; for these reasons, health national and international authorities have set targets for a reduction in the sodium consumed in the diet<sup>[3]</sup>. Studies reveal that the principle sources of sodium in the diet are processed foods. A common EU framework for salt reduction has been developed to reduce the salt intake at population level. In this sense, the EU framework will focus on a limited number of food categories, but which contribute largely to salt intake in the diet in many Member States. Certain food categories such as bread, meat products, cheeses and ready meals have been identified as being among the major contributors across the EU, and are therefore targets for salt reduction at EU level<sup>[4]</sup>. Manufacturers of dry-cured meat products are facing the challenge to lower the sodium content in their products<sup>[5,6]</sup>. In dry-cured meat products, sodium chloride is an essential ingredient which contributes to the water holding capacity, protein binding, colour, flavour and texture. Moreover, salt decreases water activity ( $a_w$ ), and this significantly affects the shelf-life of foodstuffs<sup>[7]</sup>. In addition to an overall bacteriostatic effect of salt, it can also cause a slight shift in the microbial flora toward slower growing, gram positive bacteria species that are less detrimental to product quality and require more time to reach spoilage levels. The partial replacement of sodium chloride by potassium chloride has been proposed as a possible strategy to reduce the sodium content of this type of products<sup>[8-11]</sup>. KCl is less expensive than other salt replacers, has similar properties as NaCl, and also exhibits possible health benefits<sup>[12,13]</sup>. However, the addition of KCl is limited by its bitter and astringent taste demanding a careful choice of the level of substitution<sup>[12]</sup>. Gou et al.<sup>[14]</sup> found that NaCl can be replaced by KCl up to 40 % with only slightly affecting sensory properties in fermented sausages and dry-cured loin. In this sense, Armenteros et al.<sup>[12]</sup> further reported that substitutions of up to 50 % by KCl are possible affecting neither sensory properties nor proteolysis and lipolysis phenomena in dry-cured loin. However, during processing the water transport is influenced if KCl is present leading to a decreased weight loss during salting.

The objective of the present study was to test the feasibility of a new salting-curing process using water vapour permeable bags to obtain a reduced sodium dry-cured loin. A novel salting-curing process using water vapour permeable bags was applied with and without partial substitution of sodium chloride by potassium chloride.

## 2. Materials and Methods

### 2.1. Experimental design

The salting process was carried out with a thermodynamic control by placing a known amount of salt on the product surface and allowing it to dissolve and penetrate<sup>[16]</sup>. The amount of salt to be added to the loin was calculated considering a moisture and salt content in the final product similar to the commercial dry-cured loin ( $X_{NaCl}^{Cl} = 0.06$  g Cl/g dry material and  $x_w^w = 0.47$  g/g (w/w)). Chloride amount,  $M_{Cl}$  (g of chloride), added to each loin was individually calculated according to Eq. (1) considering the initial weight of the loins,  $M_0$  (g):

$$M_{Cl} = X_{NaCl}^{Cl} \cdot M_{Cl} \cdot (1 - x_w^w) \quad (1)$$

Finally, salt amount,  $M_{salt}$  (g), was calculated according to the salt composition (100% NaCl and 50% NaCl:50% KCl). Pork loins were covered with a layer of salt, and then, samples were vacuum-packed in the water vapour permeable bags. Initially, the salting-drying process was carried out at 90% relative humidity (RH) and 3 °C, and these conditions were modified during the process until reaching 65% RH and 20 °C. Pork loins were kept in the drying chamber and periodically weighted until reaching a weight loss of 50%.

### 2.2. Analytical determinations

#### 2.2.1. Physico-chemical analyses

Moisture content was determined in accordance with AOAC methods 950.46<sup>[16]</sup>. Chloride content was determined after sample homogenisation in distilled water using an automatic chloride analyser (Sherwood Scientific Ltd., Cambridge, UK). The same extract was used to determine sodium and potassium contents by absorption spectrophotometry. The pH measurements were taken by a digital pH-meter (Crison Instruments, S.A., Barcelona, Spain) with a puncture electrode at five different locations on pork loin sample. Water activity ( $a_w$ ) was measured with a dew point hygrometer (Decagon Devices, Inc., Washington, USA). Texture profile analysis (TPA) was performed by use of a Texture Analyser TA.XT2<sup>®</sup> (Stable Micro Systems, Surrey, UK) equipped with a load cell of 250 N. Samples were obtained by cutting out parallelepiped pieces of 1 x 1 x 2,5 cm from the central part of each loin silce. For TPA analysis a flat-ended cylindrical plunger (7.5cm diameter) was pressed into the sample at a constant speed of 1mm/s until it reached 50% of the sample height. Force-distance curves were processed in order to obtain the texture parameters: hardness, cohesiveness, elasticity, chewiness and resilience. Colour determination was performed using a photocolormeter (Minolta, Osaka, Japan) with a 10° observer and illuminant D65. The colour system employed was CIE L\*a\*b\*.

### 2.2.2. Sensory analysis

Nine selected and trained assessors evaluated the dry-cured products using quantitative descriptive analysis (QDA). Sensory attributes were grouped in visual appearance of the slice (color intensity and colour homogeneity), texture (hardness, adhesiveness and chewiness) and flavor (saltiness and cured flavour). Attributes were scored using an unstructured scale from 0 (very low) to 10 (very high).

### 2.3. Statistical analysis

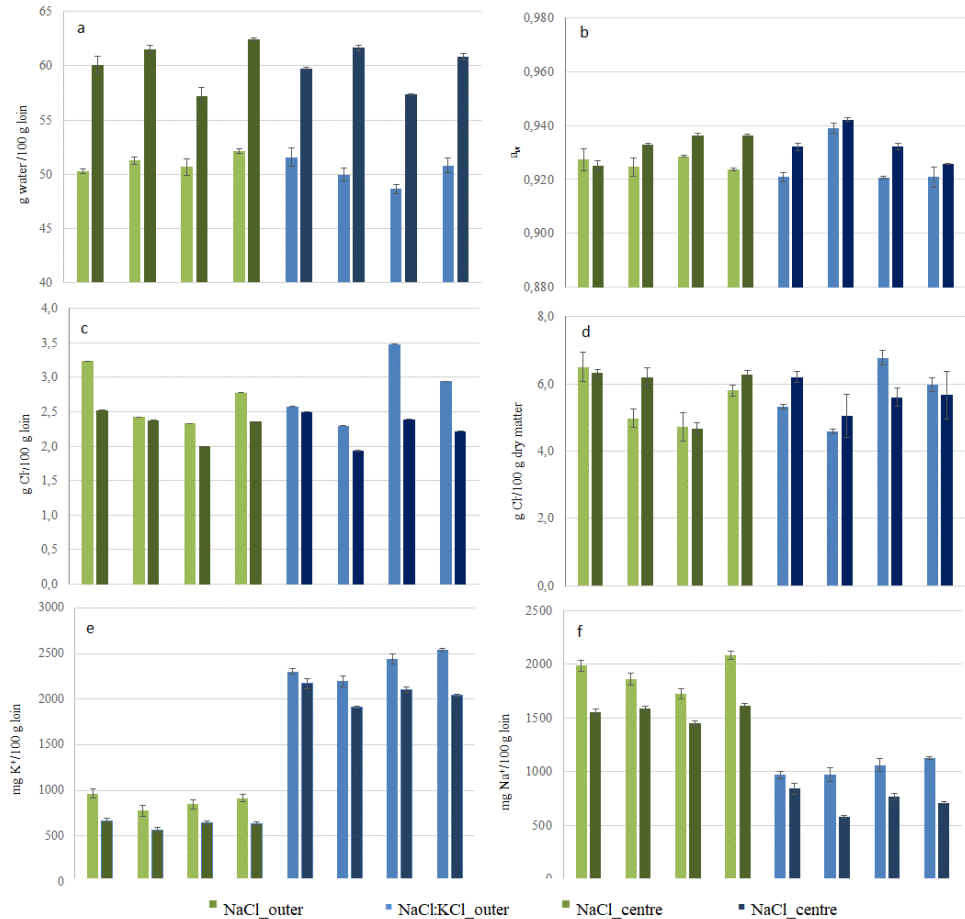

One-way analysis of variance (ANOVA) was conducted for each physicochemical parameter and sensory attribute to establish significant differences between the typer of salt employed. The least significant difference (LSD) procedure was used to test for differences between averages at the 5% significance level. Statistical treatment was performed using Statgraphics Centurion XVI (Manugistics Inc., Rockville, MD, USA).

## 3. Results and discussion

The average values of moisture, aw, and chloride, sodium and potassium content in pork loin samples salted with both type of salt are shown in Figure 1. As expected, the salting-drying process significantly lowered the moisture and aw values, and chloride concentration increased compared with fresh meat. The procedure combining a controlled salting with the permeable bags was applied to reduce the impact of the different cations diffusivities duiring the salt uptake. In this procedure, the exact amount of salt to be absorbed by the loin is directly dosed and then packing forces the salt uptake, minimizing the differences in the Na and K transport. In order to determine mass transfer differences between salts, after processing pork loins were analyzed differentiating between the outer part and central part and the edges of said sections. This differentiation would also allow to detect crust formation. The crust formation poses serious problems for the certification of Serrano ham as a Guaranteed Traditional Speciality (ETG). According to ETG Serrano specifications, the moisture gradient between the outer part and the centre of the ham should not be higher than 12%<sup>[17]</sup>.

Average moisture values of outer and central parts of the slices were 50.2% and 59.9% (w/w) for loins salted with 100% NaCl and 60.3% and 51.1% (w/w) for loins salted with 50% KCl-50% NaCl. No significant differences were observed depending on the type of salt used. It should be noted that the moisture values in the center of the loins were higher than what would be desirable for this type of product. According to the quality standard of meat products, dry-cured loin ("embuchado lomo") should have a maximum moisture content of 55.0%<sup>[18]</sup>. Taking into account the physico-chemical characteristics defined in this standard, it would be interesting to optimize the curing conditions with the aim of reducing the moisture content in the final product.

**Figure 1.** Moisture (a),  $a_w$  (b), chloride content expressed in wet basis (c), chloride content expressed in dry basis (d), sodium content (e), potassium content (f) of the dry-cured loin samples obtained by using 100% NaCl and 50%NaCl-50%KCl. Mean values  $\pm$  standard deviation ( $n = 3$ ).

Similar differences between slice areas were observed in chloride, potassium, and sodium content (Fig. 1). Solute concentration in the central part of the slice was significantly lower than in the outer part of the slice ( $p < 0.001$ ). The application of the new salting-curing process has made it possible to achieve a 50% reduction in sodium in the final product, as it had been established as a target. These results are especially interesting when compared with the alternatives salts in traditional processes, where it is not guaranteed that the final product will maintain this Na: K ratio, due to the differences in diffusivity of both salts. This ratio in the product with low sodium content was close to 1 (Na: K), being a nutritional advantage.

Different studies have shown that sodium substitution by potassium could affect the mass transfer phenomena that occurs during the salting process. In this sense, different authors have reported that partial sodium replacement by potassium decreased water loss during processing<sup>[13,19]</sup>. This could be explained by the larger size of the K<sup>+</sup> ion, which would have more difficulty in penetrating inside the muscle. The salt uptake and water outflow occurs simultaneously, for this reason when replacement strategies are applied using traditional techniques final products had higher moisture values, longer curing processes are required or higher amounts of salt should be dosed to achieve an adequate a<sub>w</sub> value.

Dry-cured pork loin exhibited pH values ranged from 5.8 to 6.2 (data not shown) During processing, the pH values show a tendency to increase slightly, both in the surface and in the interior, throughout the process<sup>[20]</sup>. The type of salt did not affect any of the texture parameters evaluated (data not shown). These results agreed with those obtained in other studies where the effect of the partial sodium replacement by other salts in dry-cured meat products has been evaluated<sup>[5,13,12,15]</sup>. Aliño et al <sup>[15]</sup> concluded that the partial substitution of NaCl by KCl in dry-cured pork loin did not affect texture of the product, except for a slight reduction of the elasticity when sodium substitution by potassium was higher than 50%. Colour of samples was affected by the type of salt employed. In this sense, pork loins salted with 100% NaCl showed values of a and b coordinates higher than samples salted with 50% KCl-50% NaCl. Differences in lightness were not statistically significant (data not shown).

The overall scores marked by the assessors for the sensory attributes of the different evaluated samples are depicted in Fig. 4. No significant differences were recorded between samples for colour and texture attribute ( $p > 0.05$ ), although the scores for taste and odour were slightly higher for pork loins salted with 100% NaCl.

Fig. 2. Sensorial analysis of pork loin salted with 100% NaCl and 50%NaCl:50% KCl

## 4. Conclusions

The developed methodology allows to obtain dry-cured products with partial replacement of sodium by potassium chloride with similar characteristics than products without reduced sodium content. The conditions of relative humidity and temperature used in this study have not been adequate to avoid the crusting of the pieces during the processing of cured loin. The replacement of 50% of NaCl by KCl had significant effect on some of the sensory attributes. The new process of controlled salting-curing using water vapor permeable bags allows to reduce the handling operations of the product and the use of salt, which is an advantage to help improve the hygienic quality of the product and reduce the environmental impact the generation of brine waste that is produced in these industries

### **Abstract**

*Nowadays most studies of drying processes dynamics are established on empirical models without clear physical meanings, which could not predict the drying characteristic on different dryers. In order to describe the change of temperature and water content in the cut tobacco in different dryers, a mathematical model based on heat and mass transfer phenomena was developed, and the model employed the relationship of equilibrium moisture content and air humidity as basis, the difference of moisture between biomass and wet air as mass transfer driver, and the difference of temperature between biomass and wet air as heat transfer driver. The drying experiments under different air temperature and humidity are carried out on the batch rotary dryer, and the variance of temperature and moisture content in the biomass is obtained by using infrared thermometer and oven. The model is validated by two parameters with experiment data under each condition of air temperature and humidity. The results show that the drying dynamic model is well on accuracy and universality, and it could be applied on different drying device to predict the characteristic of kinds of drying processes.*

**Keywords:** *cut tobacco; drying dynamics; equilibrium moisture content; heat transfer; mass transfer.*

## **1. Introduction**

Drying is an important operation to manufacture many products that benefit mankind being drying technology more widely used in biomass, such as drying of grains, seeds, fruits, vegetables, fodder, woody particles, tobacco, and so on.

Measuring the drying process of each individual particle or fiber is almost impossible, but many researchers prefer to gain understanding of the processes in the most comprehensive way as possible. Mohammad et al. (2016) applied the eXtended Discrete Element Method (XDEM) to simulate the temperature, moisture content and drying rate of woody particles during drying in a circulating cylinder. Koji et al. (2014) investigated a simplified quantitative model that simulates changes in the water content and the temperature of the tobacco midrib, and the validity of the model is examined. Zhu et al. (2015) introduced a two-stage convective drying strategy for cut tobacco drying, and the temperature and moisture evolution of cut tobacco were simulated by developed heat and mass transfer models. The above results indicate that obtaining the material's temperature and water content changes in detail under different operating conditions and fitting of measured data with an appropriate drying model can help us to set the optimum operation condition, as well as improve the quality of material in drying process.

Drying process of biomass using the rotary dryer is the one of important process in cigarette factory. Rotary dryers are designed so as to force the drying material to circulate along the unit while in contact with the air, in such way the best mass and heat exchange is attained. Good control scheme may further help improve the intrinsic quality and external quality of tobacco production. Thus a comprehensive understanding of the process characteristics of tobacco water content and surface temperature in the rotary dryer are useful information for setting up suitable control schemes. So the present work has been undertaken to study the drying characteristics of cut tobacco by using a specially designed rotary dryer. A dynamic model has been implemented and found to be satisfactory. The temperature and water content evolution of the cut tobacco as biomass at different drying temperatures were calculated and compared with the results of the experimental investigation.

## **2. Materials and methods**

Cut tobacco was used in this study, which was produced in the Fujian Province of China. Before each experiment, water contents of the cut tobacco samples were adjusted to  $22.5 \pm 0.1$  % by adding calculated amounts of water to the cut tobacco samples respectively.

In order to obtain real time drying characteristics of the material in the dryer, a laboratory rotary dryer was purposely designed in the principle shown in Fig 1.

**Fig. 1. Schematic diagram of the laboratory scale rotary dryer: (1)air filter, (2)blower, (3)air flow meter, (4)steam generator, (5)drying chamber, (6)chamber temperature controller, (7)electrical valve, (8)vapor flow meter, (9)mixing chamber with electrical heater, (10) air temperature controller, (11)inlet air temperature and humidity recorder, (12)inlet air flow meter, (13)outlet air temperature recorder, (14)outlet air humid recorder, (15)drain**

The length of the laboratory dryer is just 1.0 meter, and its diameter has maintained the same diameter as industrial rotary dryer about 1.9 meters. During the experiments, the, inlet humidity and temperature can be controlled to any practical value as the industrial dryer by mixing air with the superheated steam, while the average velocity of the flow was also set at a prescribed value. By detecting the water contents and temperatures of the cut tobacco sample at different drying moments, we can simulate the whole drying process with this laboratory rotary dryer.

The drying experiments were carried out in the laboratory drying chamber. The inlet temperature was respectively set to 338, 358, 378, 398 and 418 K, while the average velocity of the flow was kept to  $0.067 \text{ ms}^{-1}$ , and only the compressed air from atmospheric environment ( $28 \text{ }^\circ\text{C}$  and RH 0.77) was used without inducing the steam in the current study.

During the drying process, the sampling interval was set to 30 seconds, and the sampling groove was quickly pulled out from the chamber. The temperature of the cut tobacco samples in the groove was quickly measured by an infrared thermal imaging device within 2 seconds, and simultaneously cut tobacco samples were taken to offline to measure the water contents separately by weight loss method. The each sample amount taken away for weight analysis was 10 g approximately, which is 0.5 % of the total 2 kg.

### 3. Mathematical model

In order to simulate the mass transfer process, we assume that on the surface of biomass, there exists a film of wet air, which is equilibrium with water content in the biomass. The relationship of equilibrium can be written as

$$RH_e = 1 - \exp(-ATX^B) \quad (1)$$

where  $RH_e$  represents the relative humidity of the film,  $T$  denotes the temperature of biomass, the parameter  $A$  and  $B$  indicate the drying characteristic of biomass.

According to the Antoine equation, the vapor pressure of the film can be expressed as the product of saturated vapor pressure and relative humidity, which is

$$p_e = 1.1939 \times 10^{10} \exp\left(-\frac{3826.36}{T - 45.47}\right) RH_e \quad (2)$$

where  $p_e$  is the vapor pressure of the film with Pa.

Using the state equation of ideal gas, we can get the concentration of vapor in the film as

$$C_e = \frac{1.1939 \times 10^{10} \exp\left(-\frac{3826.36}{T - 45.47}\right) (1 - \exp(-ATX^B))}{RT} \quad (3)$$

where  $C_e$  represents the concentration of vapor in the film with unit  $\text{mol.m}^{-3}$ .

Meanwhile, the vapor concentration in the bulk surrounding the biomass, which indicates dry air, can be expressed as

$$C_b = \frac{1.1939 \times 10^{10} \exp\left(-\frac{3826.36}{T_b - 45.47}\right) RH}{RT_b} \quad (4)$$

where  $C_b$  represents the vapor concentration in the bulk with unit  $\text{mol.m}^{-3}$ , and  $T_b$  is the temperature in the bulk, which is equal to the temperature of the rotary dryer wall.

In order to obtain the mass transfer equation of drying process, we assume that only the convective mass transfer occurs but the diffusion is ignored, so the rate of mass transfer can be written as the product of the convective mass transfer coefficient and driver of mass transfer, which is expressed as the difference of vapor concentration in common. The above statement can be translated as the following formula

$$N = h_m A_m \Delta C \quad (5)$$

where  $h_m A_m$  is convective mass transfer coefficient including the mass transfer surface area.

So the drying process of biomass per kilogram can be gotten as the following differential equation

$$\frac{1}{M_{H_2O}} \frac{dX}{dt} = N \quad (6)$$

where  $X$  is the dry base moisture content of biomass with unit  $\text{kg.kg}^{-1}$ ,  $M_{H_2O}$  is molecular mass of water, and its unit is  $\text{kg.mol}^{-1}$ .

On the other hand, the heat transfer equation of drying process is not difficult to describe. Since the change of temperature of biomass can be contributed to two facts, the one is convective heat transfer from the hot air, the other is endothermic vaporization during the drying of cut tobacco. So the heat transfer equation can be written as

$$\left( X C_{p,w} + C_{p,t} \right) \frac{dT}{dt} = h A_m (T_b - T) + \Delta H_w \frac{dX}{dt}$$

where  $h A_m$  denotes the convective heat transfer coefficient combined with inseparable heat transfer area,  $\Delta H_w$  is the latent heat of vaporization of water,  $C_{p,w}$  is the specific heat capacity of the water with unit  $\text{J}\cdot\text{m}^{-3}\cdot\text{K}^{-1}$  and  $C_{p,t}$  is the specific heat capacity of cut tobacco with unit  $\text{J}\cdot\text{m}^{-3}\cdot\text{K}^{-1}$ .

For the integrity of the heat transfer equation, the latent heat of vaporization and the specific heat equation of water are functions of bulk temperature, and they can be expressed as

$$\Delta H_w = 2891833 \left( 1 - \frac{T_b}{647.13} \right)^{0.321}$$

$$C_{p,w} = 1.459 \times 10^{-6} T_b^4 - 1.971 \times 10^{-3} T_b^3 + 1.005 \times T_b^2 - 228.7T + 23750$$

But the specific heat capacity of cut tobacco is remained constant for simplification of the mathematical model, which is obtained as the following value as

$$C_{p,t} = 1.4286 \times 10^3$$

In summary, the mass transfer equation and the heat transfer equation are clearly shown, which is the governing equations of the drying process. In the mathematical model, the two parameters A and B is related to the properties of biomass, and the convective mass and heat transfer coefficients are the key factors of the model, which are determined by the operation conditions such as inlet velocity of hot air. The two coefficients can not be accurately obtained before the drying experiments or by other independent experiments, but they could be fitted by the temperature and moisture curves of biomass during drying process.

#### **4. Results and discussion**

The mathematical model was fitted by using the functions ode45 and lsqnonlin on MATLAB® 2017a to get the heat transfer and mass transfer coefficients, where the function ode45 is used for solving the ordinary differential equations by 4 order Runge-Kutta methods, and the function lsqnonlin is used for exploring the optical parameters by nonlinear least squares method. Through the experiment data at different dryer temperature, the heat transfer coefficient is 31.2245 with unit  $W \cdot m^{-3} \cdot K^{-1}$  and the mass transfer coefficient is 0.0651 with unit  $kg \cdot m^{-3} \cdot K^{-1}$ . It is obvious that the two most important parameters keep constant for all the drying conditions at different inlet temperature.

Figure 2 shows the temperature and moisture content of cut tobacco in the rotary dryer at different inlet temperature range from 338K to 418K. It can be seen that the simulated curves of water content and temperature are well consistent with the experiment data at each time. It is mean that the mathematical model with only two coefficients can reveal the main mechanism of the drying processing in the labarotary rotary dryer.

It is easy to see that the moisture content of cut tobacco decreases with time and the temperature of cut tobacco increases with time. Moreover, the variance of both moisture content and temperature can be separated into three stages. At the initial stage, the temperature rises up fastly but the moisture content goes down slowly, then the temperature remains stable and the moisture content falls down with constant drying rate at the medium stage, finally at the last stage the temperature of cut tobacco grows up distinctly but the sample moisture content slightly decreases for a long time. We also can find that when the inlet temperature increases, the first stage almostly keeps unchanged, and the medium stage continues a short time period, but the last stage occupies a long time.

(a) 338K

(c) 378K

(d) 398K

(e) 418K

**Fig. 2. the Comparison of experiment data and simulated data of moisture content and temperature with inlet temperature range from 338K to 418K**

## **5. Conclusions**

A laboratory rotary dryer was designed to simulate the drying process of biomass. The evolutions of the water content and surface temperature of cut tobacco at different drying temperatures were investigated. The determination of heat and mass transfer coefficients by calculating from the experimental data of temperature and water content appears as a more convenient method. The mathematical model with equilibrium relationship of moisture content could represent the drying characteristics of cut tobacco accurately. Moreover, the current work provides the essential basis for the future computational fluid-dynamic (CFD) simulation of tobacco drying in industry production line.

## Evaluation of Izmir Tulum cheese pieces by drying with tray dryer at different air flow rates and temperatures

**Kizilalp, G.; Polat, I.; Uргу, M.; Koca, N.\***

Ege University, Engineering Faculty, Food Engineering Department, Izmir, Turkey

\*E-mail of the corresponding author: [nurcan.koca@ege.edu.tr](mailto:nurcan.koca@ege.edu.tr)

---

### **Abstract**

*Izmir tulum cheese pieces were dried using a tray dryer at different air flow rates (1.0 and 1.8 m/s) and temperatures (45°C, 55°C and 65°C). The increase in temperature and air flow rate increased bulk and tapped bulk density and decreased the water holding capacity. The lowest lightness and highest redness were obtained in samples dried at 65°C. The samples dried at 55°C and 1 m/s had the highest flavor and overall impression scores. As a result, a dried cheese product to benefit from left-over pieces obtained during packaging was developed, having advantages such as easy to transport, store and package.*

**Keywords:** *Izmir Tulum cheese; tray dryer; physical, chemical and sensory properties.*

## **1. Introduction**

Drying is one of the oldest method and has recently been applied to various food products to gain different functions. Cheese is exposed to drying process to increase its shelf life, decrease the transport and storage costs and improve some functional properties. Dehydrated cheese is generally used as a food ingredient to improve the flavor and mouthfeel of cheese [1, 2, 3].

Izmir Tulum cheese is a Turkish traditional cheese produced mostly by small or medium scale dairies. It is one of most consumed cheese type in Turkey, characterized with a white or cream color, high fat content, a crumbly and semi-hard texture. During the production of Izmir Tulum cheese, cheese pieces are left-over in large quantities during packaging of the cheese in the industrial production. The goal of the research is to evaluate these cheese pieces by drying with tray dryer which is the easiest drying method of producing dehydrated cheese in small scale dairies. The final quality of the dried cheese can be significantly affected by drying conditions. Therefore, it is necessary to evaluate the drying conditions to obtain a dehydrated food with a high quality. With this research, a new dehydrated cheese product was developed as an ingredient for different purposes in foods such as using in pasta, salad and pizza, etc. and the new product gives an advantages to consumer to use easily at home.

## **2. Materials and Methods**

### **2.1. Material**

Izmir tulum cheese purchased from the local market in Izmir. Samples were transported under cold conditions to the laboratory. Cheeses were grinded to obtain homogenous sample and dry easily. Samples were processed within a day.

### **2.2. Drying process**

The preliminary tests were carried out to determine the duration of drying. The water activity value was considered to be below 0.8. For drying of cheese, 100 grams of grated cheese samples were put on a tray and dried in a pilot-scale tray drier (TK Lab5, Turkey) at different air flow rates (1 m/s and 1.8 m/s) and temperatures (45°C, 55°C, 65°C) for two hours. Dried cheese samples were grinded by food processor (Tefal Masterbland). Grinded dried cheese pieces were kept in glass jars during the analyses. Production procedure was replicated twice.

### 2.3. Compositional analysis

Moisture and ash contents of cheese and dried cheese samples were determined by gravimetric method [4, 5]. Kjeldahl method was used for protein content of the samples [5]. Fat contents of cheese and dried cheese samples were determined by Van Gulik [6] and Gerber [7] methods, respectively. pH values of cheese and dried cheese samples were measured with a digital pH meter (pH 320, WTW, 82362 Weilheim, Germany), and titratable acidity was expressed as percent lactic acid [5].

### 2.4. Water activity

Water activity of dried cheese samples were measured by using a water activity measurement device (Testo, Freiburg, Germany).

### 2.5. Bulk, tapped densities and Carr Index value

Bulk density of the dried samples was measured by pouring the samples to the 100-ml measuring cylinder and recorded the weight [8]. The measuring cylinder was tapped 200 times and the volume was recorded to calculate the tapped density [8]. Carr Index values of dried cheese samples were also evaluated according to Equation 1 [9].

$$CI = \frac{(\rho_{\text{tapped}} - \rho_{\text{bulk}})}{\rho_{\text{tapped}}} \times 100 \quad (1)$$

### 2.6. Water holding capacity

Water holding capacity (WHC) of dried cheese samples were measured according to Heywood et al. [10] and Traynham et al. [11] with some modifications. 2.5 g of dried samples was weighed to 50 ml centrifuge tube. Then, for each sample 10 mL of distilled water were added and well mixed with the sample. Samples stood at room temperature for 3 hours. The mixture was centrifuged at 2680 rpm for 30 min. Just after centrifugation, the supernatant was carefully decanted and the new mass of the sample was recorded. WHC (%) was calculated as Equation 2 :

$$WHC (\%) = \frac{\text{Total water mass}}{\text{Dry matter mass}} \quad (2)$$

### 2.7. Color evaluation

Color values of cheese and dried cheese samples were measured in terms of L (lightness), a (redness and greenness), and b (yellowness and blueness) using a Hunter ColorFlex colorimeter (HunterLabColorFlex CFLX 45-2 colorimeter). Then, color differences ( $\Delta E$ ) and chroma values (color intensity) of the samples were calculated using Equations 3 and 4,

respectively [12]. Color values of Izmir tulum cheese was taken as reference for the calculation of color differences.

$$\Delta E = \sqrt{(L_0 - L)^2 + (a_0 - a)^2 + (b_0 - b)^2} \quad (3)$$

$$Kroma = \sqrt{a^2 + b^2} \quad (4)$$

## 2.8. Sensory evaluation

Desirability of dried cheese samples scales in terms of color, appearance, texture, taste and overall acceptability using unipolar scales were determined by 40 panelists. . Unipolar scale ratings between 1 and 5 referring from not like at all to like very much.

## 2.9. Statistical analysis

Statistical data analyses was performed by using SPSS version 21.0. Data was analyzed by analysis of variance (ANOVA) and Duncan's multiple range test at 95% confidence interval.

## 3. Results and Discussion

### 3.1. Chemical composition

The moisture, ash, protein fat, titratable acidity values varied from 13.02 to 16.74%, from 8.79 to 9.53%, from 36.55 to 40.10%, from 36.28 to 37.71% and from 1.494 to 1.674%, respectively (Table 1). Different drying conditions did not have any significant effect on moisture and water activity values of samples. The higher fat values were obtained in samples dried at 45°C for both flow rates. Increasing temperature at the same air flow rate resulted in a decrease in acidity values.

**Table 1. Composition of Izmir Tulum cheese and dried cheese samples**

Analysis	Cheese	1 m/s - 45°C	1 m/s - 55°C	1m/s- 65°C	1,8 m/s-45°C	1,8 m/s- 55°C	1,8 m/s-65°C

### 3.2. Bulk and tapped densities, Carr Index value and water holding capacity

Densities and flowability of the dried samples is important for the manufacturer and the end user for packaging, handling, storage, transportation, etc. The bulk densities of samples were found between 0,512 and 0,555 g/cm<sup>3</sup> (Table 2). The increase in drying temperature resulted in an increase in bulk densities of the samples. However, tapped density values of

the samples did not significantly change with different drying conditions. The classification of the flowability based on Carr Index are very good (<15), good (15–20), moderate (20–35), bad (35–45), and very bad (>45). In this study, flowability of the samples was found to be moderate level. WHC of the samples varied from 33,0 to 35,6%. The lowest WHC were obtained in samples dried at 1,8 m/s air flow rate and 65°C. This sample was found as harder in mouth by the panelists. The WHC of the samples dried at 1 m/s were high when compared to the samples dried at 1,8 m/s flow rate.

**Table 2. Bulk and tapped densities, Carr Index and water holding capacity values of dried cheese samples**

Analysis	1 m/s - 45°C	1 m/s -55°C	1m/s- 65°C	1,8 m/s-45°C	1,8 m/s-55°C	1,8 m/s-65°C

### 3.3. Color evaluation

Color of the dried foods is an important quality attribute for customer satisfaction and selection. The color values of dried samples were shown in Table 3. The lowest lightness and highest redness were found in samples dried at 65°C even at different air flow rates. Also, no significant changes were found in yellowness of the samples with the changes in air flow rates or temperature.  $\Delta E$  values of the samples calculated with reference sample-Izmir Tulum cheese. When  $\Delta E$  value is greater than 3, it can be distinguished by eyes easily [13]. All samples have  $\Delta E$  value higher than 3. Therefore, their differences were distinguished by eyes. However, increase in air flow rate at same temperature resulted in a decrease in  $\Delta E$  value.

**Table 3. Color values of dried cheese samples**

	L	A	B	$\Delta E$	Chroma
<b>Drying Conditions</b>	85,29±0,41	2,18±0,00	25,19±0,06	-	-
<b>1 m/s - 45°C</b>	83,58±0,91 <sup>ab</sup>	3,36±0,06 <sup>a</sup>	36,41±0,13 <sup>b</sup>	11,4±0,27 <sup>bc</sup>	36,57±0,14 <sup>b</sup>

<sup>a-c</sup>Means within a row with different superscripts differ for dried cheese samples ( $P < 0.05$ ).

### 3.4. Sensory evaluation

The sensory evaluation results were shown in Table 4. The samples that were dried at 1 m/s - 55°C had the highest score in terms of taste and overall acceptability, whereas lowest scores were found in samples dried at 65°C. However, the samples that exposed to drying at 1.8 m/s - 65°C has the highest score in terms of color and appearance.

**Table 4. Sensory evaluation results for dried cheese samples**

<sup>a-c</sup>Means within a row with different superscripts differ for dried cheese samples ( $P < 0.05$ ).

## 4. Conclusions

Higher water activity of foods tends to support the growth of microorganisms, especially molds which causes quality depletion and economical losses. Molds require a water activity level at least 0.80. In this study, the water activity of the dried Izmir Tulum cheese samples did not change with different drying conditions, and samples had water activity values that were below 0.72. Although the densities and water holding capacity of samples changed by the drying parameters, these differences were not very important from the practical point of view. On the other hand, increasing air flow rate and temperature resulted in harder surface of samples, which was not preferred by panelists. The highest flavor and overall impression scores were found in samples dried at 1 m/s and 55°C. In conclusion, a dried cheese using a tray drier has several advantages such as easy to transport, store and packaging. However, there is a need a further study to evaluate the storage stability of the product.

### **Abstract**

*The LNT microwave-multiphase transport model has been applied to the microwave drying of lignite thin layer. Microwave energy, temperature and moisture distribution were obtained to gain a comprehensive understanding on the heat and mass transfer mechanism of the drying process. The required drying time of experiments decreased by 50, 63, 67, and 83%, respectively, with the power level rising from 119 to 700 W, while that decreased by 60, 72, 76 and 86%, respectively, for simulation results. The temperature values of the corner and edge of the lignite thin layer were higher than that of the center region, which corresponded to the microwave energy distribution. The moisture ratio profiles, temperature profiles and temperature distribution indicated good agreement between the experimental and simulation results, providing confidence in the modeling approach, which made it possible to obtain the moisture distribution successfully via simulation method*

**Keywords:** microwave; lignite; thin layer.

## 1. Introduction

Lignite is considered as the main energy source for electricity generation and industry feedstocks because of its abundant reservation and cheap price. The high moisture content in lignite leads to low calorific value, low energy utilization efficiency and high transportation cost. Drying prior to pyrolysis, gasification and combustion can improve the utilization efficiencies of the downstream devices. Microwave drying is an efficient method for lignite pre-treatment due to its high drying rate, volumetric heating and precise process control. Apart from experimental studies, numerical modelling is another way to further understand the physics of microwave heating of food. In order to take every possible transport phenomenon for each phase into consideration, and describe the coupled transport mechanisms in a numerical manner, some efforts have been devoted to the modeling of the microwave drying process. With the advancement of computational power and efficient numerical methods, some researchers employed commercial software to provide an exact solution for the Maxwell's equations. Based on the conservation equations elaborated by Whitaker, some researchers derived mechanistic models to highlight the heat and mass transfer characteristics during microwave drying [1]. A coupled electromagnetic, heat and mass transfer model without accounting for pressure driven flow was established by Law et al. [3] to examine the temperature and moisture content distribution in oil palm kernels during microwave drying. They noted that the calculated results fitted the experimental ones, and the cracks of oil palm kernels was prone to occur at the core of the kernel. According to the pumping phenomenon noted by some researchers experimentally, Zhu et al. [4] modified the above model by taking the vapor pressure into account, which would cause moisture diffusion both in liquid and vapor phase. In the case of the microwave drying of potato spheres, good agreement was found between the experimental data and predicted values. In spite of the complete and predictable model developed or modified by the above researchers, the available models still need to be amended with newly discovered physical phenomenon and theory. Swiss scientist Charles Soret discovered that the concentration difference can be built under temperature gradient and the thermo-diffusion phenomenon was referred to as Soret effect [5]. Reversely, the temperature gradient also could be generated by concentration difference, and the diffusion-thermal phenomenon was known as Dufour effect [6]. As a matter of fact, samples can be heated with microwave radiation due to the dipoles orientation [7], and the temperature gradient would be built for the non-uniform microwave energy distribution and energy decay. Corresponding to the dipoles orientation caused by the oscillating electric and magnetic field, Stewart et al. and Lehmann found that liquid crystals showed a uniform rotation under temperature gradient. The thermal polarization phenomenon was also confirmed by Muscatello et al. [8] and Bresme et al. [9] in subsequent numerical calculations, and they found that the water molecules rotation in the direction of temperature gradient would lead to electrostatic field, whose magnitude would scale linearly with the increasing temperature gradient. Based on the complex coupling effects involving the heat and mass transfer and the molecular polarization, the non-equilibrium thermodynamic theory was applied to modify the available models, which can provide more accurate prediction for the coupled heat and mass transfer in porous media during microwave drying.

In the present study, the LNT microwave- multiphase transport model was employed to thin-layer lignite, which is the typical loose structure, to validate the experimental results in terms of moisture ratio and temperature profiles and distribution. The proposed model will

also be compared with the mechanistic ones with respect to deviation and calculation time. In addition, light is shed on the diffusion-thermal and electric-thermal effect and the microwave-induced coupling transmission mechanism for loose structures during drying process.

## 2. Materials and Methods

### 2.1. Problem formulation

The heat and mass transfer in the lignite thin-layer under microwave irradiation is simplified in Fig. 1. The lignite thin-layer is exposed to the environment where intense microwave energy is introduced from the right side of the oven. The driving force for the liquid water and water vapor diffusion in the thin-layer is the concentration and temperature gradient. The thermal diffusion is caused by the coupling effects of the temperature gradient, the molecular polarization and the liquid water and water vapor diffusion. The molecular polarization is produced by the alternating electromagnetic field and temperature gradient. The heat and mass transfer between the lignite thin-layer and the surroundings only occurs at the top surface.

### 2.2. Major hypotheses

In order to clarify the heat and mass transfer characteristics within the loose structures, the following hypotheses are taken into consideration for the model simplification: (1) local thermodynamic equilibrium exists; (2) the thermodynamic flows scale linearly with the thermodynamic forces; (3) the coupling ratio between the molecular polarization and heat flow presents linear correlation with the average temperature of the sample; (4) all phases are continuous; (5) initial moisture content and temperature within the material are assumed to be uniform; (6) non shrinkage or deformation during drying process; (7) water vapor pressure is shared by all fluid phases; (8) Both the lateral and bottom sides of the lignite thin-layer are insulated; (9) the moisture migration into the surroundings only occurs at the top side of the lignite thin-layer in vapor phase; (10) gravity effect are neglected.

### 2.3. Governing equations

The heat and mass transfer characteristics within the lignite thin-layer during microwave drying can be modelled by the Maxwell equation and the modified mass and energy conservation equations based on the non-equilibrium thermodynamics.

The Maxwell equation is given by [4]:

$$\nabla \times E = -j\omega\mu_0 H \quad (1)$$

$$\nabla \times H = j\varepsilon_0 \varepsilon E \quad (2)$$

$$\nabla \times \varepsilon E = 0 \quad (3)$$

$$\nabla \times H = 0 \quad (4)$$

where,  $E$  is the electric field intensity,  $V\ m^{-1}$ ;  $H$  the magnetic field intensity, T;  $\mathcal{E}$  the complex relative permittivity of lignite thin-layer, which is determined by dielectric constant  $\mathcal{E}'$  and dielectric loss factor  $\mathcal{E}''$ ,  $\epsilon_0$  permittivity of free space,  $8.85 \times 10^{-12}\ F\ m^{-1}$ .

Based on the non-equilibrium thermodynamics, the established mass and energy conservation equations from the former publication [4] can be derived as below and the details can be found in the previous research [10].

The mass conservation equation can be modified as:

$$\rho_s \frac{\partial M}{\partial t} = \left\{ (\lambda_{gq} + \lambda_{lq}) \nabla T \right\} + \nabla (K_g \nabla p_g) + \nabla (K_l \nabla p_l) \quad (5)$$

where  $\rho_s$  is the density of the lignite thin-layer,  $kg\ m^{-3}$ ;  $M$  the moisture content (water vapor and liquid water) on dry basis;  $\lambda_{gq}$  and  $\lambda_{lq}$  the Soret coefficient for vapor and liquid phase, respectively;  $K_g$  and  $K_l$  the permeability for vapor and liquid phase, respectively;  $p_g$  and  $p_l$  the water vapor and liquid water pressure, respectively, Pa.

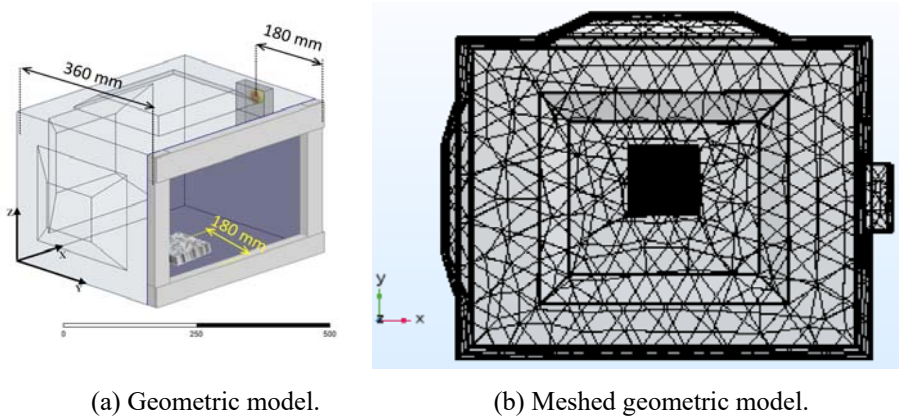

The energy conservation equation can be derived as:

$$\frac{\partial \rho_{eff} C_{eff} T}{\partial t} = \nabla (\lambda \nabla T) + \nabla \left\{ \frac{a}{\tau} (\epsilon_0 \chi E_{eq} - P) \right\} + h_g \nabla (K_g \nabla p_g) + h_l \nabla (K_l \nabla p_l) - \gamma I + Q_{mic} \quad (6)$$

where  $\rho_{eff}$  is the effective value of sample density,  $kg\ m^{-3}$ ;  $C_{p,eff}$  the effective value of sample specific heat capacity,  $J\ kg^{-1}\ K^{-1}$  [11];  $a$  the coupling ratio, V;  $\tau$  the polarization relaxation time, s;  $h_g$  and  $h_l$  the molar enthalpy of water vapor and liquid water, respectively,  $kJ\ mol^{-1}$ ;  $\gamma$  the latent heat of evaporation,  $kJ\ kg^{-1}$ ;  $I$  the evaporation rate,  $kg\ m^{-3}\ s^{-1}$ ;  $Q_{mic}$  the rate of microwave energy absorption,  $W\ m^{-3}$ .  $\lambda$  the thermal conductivity involving the pure heat conduction and substance diffusion,  $W\ m^{-1}\ K^{-1}$ . The details are reported by the previous research.

## 2.4 Geometry model

According to the physical dimensions and shapes of the microwave oven, the geometry model is established with a  $460 \times 360 \times 290$  mm cube and three square frustum metal bumps, which can be applied to improve the uniformity of the microwave energy distribution and obtain accurate simulation results. The dimensional details of the metal bumps can be seen in Fig.2. The microwave energy is generated by a coaxial antenna (10.5 mm in radius and 12 mm in height) and introduced into the oven via a rectangular waveguide.

(a) Geometric model.

(b) Meshed geometric model.

*Fig.1 Geometric model for the microwave dryer setup.*

## 2.6 Physical model and Initial and boundary conditions

The physical model, initial and boundary conditions and parameters in the simulation are listed in ref [10], the mathematic and physical models related to coupling mechanism between the heat and mass transfer, and the molecular polarization in a lignite thin layer were developed as above. The governing equations and boundary conditions would be solved by the finite element commercial software COMSOL Multiphysics.

## 3. Results and discussion

### 3.1 Drying rates profiles

The drying and drying rates profiles of experiments and simulations were shown in Fig. 2. From Fig. 2, the microwave power levels had a significant effect on drying time. Time required for microwave drying was shortened with the increase in power level. As shown in Fig. 2 (a), the simulation data fitted the experimental data well with average deviation of 5% for 119 and 700 W, while 10% for 231-539 W.

### 3.2 Temperature profiles

The temperature profiles of three points (L, C and R) were shown in Fig. 3. Three periods, detected in the temperature profiles for lignite sample with power level of 119 to 700 W, were the rapid heating period (corresponding to the warm-up and constant rate periods in Fig. 2 (a)), the cooling period (corresponding to the falling rate periods in Fig. 2 (a)) and the final isothermal period, respectively, while only rapid heating period (corresponding to the warm-up, constant rate period and the falling rate period in Fig. 2 (a)) and final isothermal period were detected in the simulation results.

(a) Drying profiles of lignite thin layer (b) Drying rates of lignite thin layer.

**Fig.2. Drying and drying rates of lignite thin layer between 119-700 W. Dots and solid line indicates experimental and simulation data, respectively. A<sup>a</sup>-D represents the warm-up period, the constant rate period, the first falling rate period and the second falling rate period, respectively.**

The comparison of temperature between the experimental and simulation data for five power levels was illustrated in Fig. 3. The simulation data fitted the experimental data well with average deviation of 5% for 119 W and about 10% for 231-539 W, 15% for 700 W.

**Fig.3. Temperature profiles of lignite thin layer between 119-700 W. Dots and solid line indicates experimental and simulation data, respectively. I<sup>a</sup>: the heating up period; II: the cooling down period; III: the isothermal period.**

### 3.3 Microwave energy and temperature distribution

The temperature distribution of experiments and simulations at 385 W were shown in Fig. 4. As illustrated in Fig. 4, the non-uniform temperature distribution of sample surface was evidenced by experiments and simulation results with the moisture ratio of 0.8 and 0.2 at 385 W. The temperature distribution obtained by simulation method possessed similar trend with experimental results, which verified the calculation results of temperature distribution based on numerical simulation.

(a) Experimental results. (b) Simulation results.

MR=0.8

(a) Experimental results.

(b) Simulation results.

MR=0.2

*Fig.4. Temperature distribution of experiments and simulation.*

### 3.4 Moisture distribution

Moisture distribution in lignite thin layer at 385 W was illustrated in Fig. 5. As shown in Fig. 5, the moisture content was lower at the right and left regions in the lignite thin layer, which corresponded to the temperature distribution.

*Fig.5. Moisture content distribution in sample at 385 W (MR=0.8).*

## 4. Conclusions

The LNT microwave-multiphase transport model has been applied to simulate the microwave drying behavior of lignite thin layer successfully. Microwave energy, temperature and moisture distribution were obtained to gain a comprehensive understanding on the heat and mass transfer mechanism of the drying process. The simulation data of the moisture ratio fitted the experimental data well with average deviation of 5% for 119 and 700 W, while 10% for 231-539 W. The average deviation of temperature between the simulation and experimental data were 5% for 119 W and about 10% for 231-539 W, while 15% for 700 W. The coupled electromagnetics and multiphase porous media made it possible to obtain the moisture distribution via simulation method. Further investigation on the moisture distribution will be carried out via MRI experiments to verify the simulation result.

---

### **Abstract**

*Thermal properties of brown seaweeds (*Saccharina latissima*) were determined using DSC technique in the temperature range between -150.0 and 50.0 °C. The following phase transitions were detected: glass transitions, incipient point of ice melting and freezing point. The ice content and amount of unfrozen water was detected by analysis of the melting peak. The ice content reduction in the product was predicted for different moisture contents and temperatures for atmospheric freeze-drying process.*

**Keywords:** brown seaweeds, ice fraction, freeze-drying, glass transition

---

## 1. Introduction

Most of the seaweeds, which are used for food purpose in Norway belong to aquaculture products, when hatching, growth and harvesting is controlled continuously. The harvesting season occupies approximately 2 weeks to provide the best quality of the seaweed's blades. The processing technology requires immediate processing of raw seaweeds to ensure production of sustainable and high quality product. Due to high quantities of raw seaweeds during harvesting the immediate freezing is applied to prevent deterioration. However, drying is the common way to preserve food products like seaweed and most of the seaweeds are sold in a dried form [1]. Solar and natural drying of seaweeds is a cost-effective method. At the same time climate conditions can result in a high final moisture content in dried product [2] due to high moisture absorption ability [3], also, the process 5 or 7 days [4]. Due to this, the producers of *Saccharina Latissima* consider the atmospheric freeze-drying process as the most reliable for the given processing condition. Design of equipment and adjustment of the processing parameters is complicated without knowledge of thermal phase transitions at freezing temperatures. The study discusses the thermal properties of seaweeds and seaweed's mucus and their influence on the atmospheric freeze-drying process. The investigation of seaweeds mucus was introduced due to high amount this substance on the blades, which provide stickiness of the particles (blades) during atmospheric freeze-drying.

## 2. Materials and Methods

### 2.1 Characterization of raw material

The brown algae *Saccharina latissima*, which is commonly referred as kelp (Sugar kelp or kombu) was used for the experiments. The seaweeds was cultivated for one year in an aquaculture farm, which is situated in Sør-Trøndelag (Norway). Harvesting season was 15 days in May 2017 to maintain the best quality of the seaweeds and avoid high amount of biofouling. The seaweed was harvested into nets (75-150 kg). The nets were buffered in the seawater at the farm where they were kept in refrigerated seawater (-1.0 °C) for 1 week before freezing. Then the seaweed was weighed out and packed inside vacuum bags with high barrier properties (2.0 kg each). Freezing was at -46 °C until temperature in the center of the bag reached -18.0 °C. After freezing the bags were packed in cardboard boxes, put on pallets and placed in freeze storage at -18 °C. The kelp was delivered in a frozen state by the supplier (June 2017). Chemical composition of the aquaculture seaweeds is given in the Table 1. Protein content of the seaweeds was determined at 11.2 % d.b., which was in a common range for brown seaweeds between 3.0 and 15.0 % [5]. The aquaculture seaweeds form Damariscotta bay (USA) had a protein content of 6.87 % d.b. [6], which was in the range (between 9.9 and 7.6 % d.b.) of the previously obtained results for wild sugar kelp form Scotland, Isle of Seil [7].

**Table 1. Chemical composition of *Saccharina latissima* at harvesting season (analysis performed by accredited analytical laboratory Kystlab preBIO, Frøya, Norway).**

<b>Chemical composition</b>	<b>%, d.b.</b>	<b>Minerals , mg/kg d.b.</b>	
Proteins	11.2	Potassium	84000
Fats	2.9	Sodium	52000
Carbohydrates	55.3	Calcium	10000
Incl. Dietary fiber	46.6	Magnesium	7500
Ash	37.9	Sulfur	7300
Incl. Salt (NaCl)	14.6	Iodine	3670
Water	900.0	Phosphrus	1700

## 2.2 DSC analysis

The DSC analysis was done with a DSC Q 2000 (TA instruments, USA) equipped with a Liquid Nitrogen Cooling System. The heat capacity was calibrated with a sapphire in the range between  $-150.0$  and  $180.0$  °C. Helium was chosen as a purge gas at 25 mL/min, according to TA's instrument recommendations. The reference sample was an empty hermetically sealed aluminum pan.

In this study, the small particles of seaweed blades were used for DSC. The samples with masses between 13.0 mg and 20.0 mg were placed into aluminum pans with hermetic lids. The pans were sealed with a Tzero® DSC Sample Encapsulation Press (TA Instruments, USA). The pans were placed by an autosampler into the DSC cell. Samples were cooled and equilibrated for 5 minutes at  $-150.0$  °C; the cooling rate was 10.0 °C/min. The annealing procedure was applied at  $-50.0$  °C. This was done to avoid cold crystallization during scanning. Then the samples were heated up to 50.0 °C (application of higher temperatures was not effective due to evaporation of moisture) with the heating rate of 10.0 °C/min.

## 2.3 Determination of glass transition

The glass transition was determined with TA Universal Analysis 2000 version 4.5A software (TA instruments, USA). The glass transition is characterized with the following parameters: the onset, end and inflection points. It should be noted, that the glass transition in seaweeds with high moisture content is relatively weak. Thus, the inflection point was determined as a negative peak of the derived heat flow curve [8].

## 2.4 Determination of end of freezing and initial freezing point

The onset of ice melting (or end of freezing point), was determined by analyzing the DSC heating curve. The freezing point was estimated as a minimum value of the ice melting endothermic peak on the DSC heat flow curve.

## **2.5 Determination of ice fraction and unfreezable water**

The amount of unfreezable water and ice fraction was detected by the DSC melting curve analysis. The DSC melting peaks were integrated with the sigmoidal tangent baseline function from the onset of ice melting point. The ice fraction was determined as a ratio of melting energy to latent heat of fusion of pure ice. As soon as melting energy of ice is a function of temperature, the empirical equation suggested by Riedel<sup>[9]</sup> was used for correction of obtained values. The amount of unfreezable water was obtained as the difference between the total water fraction in the product and the ice fraction.

## **2.6 Statistical analysis**

The analysis of variance (ANOVA: single test and two-factor test with replication) was applied to analyze the obtained data. The difference was considered significant at  $p < 0.05$ . All the experimental points were done in six parallels, except of desorption isotherm determination, where each point represents a single experiment.

A regression analysis was done with a software DataFit 8.1 program (Oakdale Engineering). The quality of the regression was evaluated with the following parameters: F-Ratio, Prob(F) and  $R^2$ . F-Ratio is the ratio of the mean regression sum of the squares divided by the mean error sum of the squares. Prob(F) is the probability that the null hypothesis is true.  $R^2$  is the coefficient of multiple determinations. The standard deviation is introduced in the brackets after the values given in the text.

## **3. Results and Discussion**

### **3.1 Glass transition phenomena in raw seaweeds and seaweed mucus**

Two type of material were investigated: seaweed's blades and seaweeds mucus. The DSC investigation revealed two glass transitions at the ultra-low temperature region at -84.77(1.35) and -62.14(0.46) °C for seaweed's blades and at -74.44(2.15) and -55.02(0.48) °C for mucus. It should be noted, that the glass transition phenomena was weak due to high amount of water fraction in the product, however, the negative peak was clearly observed on the derived heat flow curve. In previous study of Sappati et. al., <sup>[6]</sup> only one glass transition event was determined.

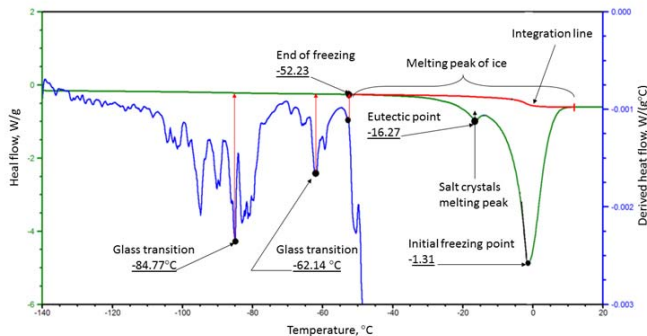

The occurrence of two glass transition refer to different fractions of unfreezable water, which forms independent maximal freeze concentrated solutions. Each of the solution has unique point of glass transition. The presence of more than one glass transition for low-moisture foods, which contain carbohydrates and proteins, was reported before <sup>[10]</sup>. It is explained by transitions of blends and thermal history of the sample. Also, immiscible compounds which forms individual maximal-freeze concentrations can cause the several

glass transitions, however, it is not a strict rule <sup>[11]</sup>. As a conclusion, one can state that the second order phase transition will not influence on the

### 3.2 End of freezing and melting peaks of raw seaweeds and seaweed mucus

The so-called “end of freezing” is an equivalent of the incipient point of ice melting on DSC heat flow curve considering equilibrium freezing process. This point can be found on heat flow curve derived by time. The detailed information of the method available in Tolstorebrov et., al. <sup>[12]</sup>. Seaweeds blades and mucus showed different end of freezing point  $-52.23(1.61)$  and  $-42.1(0.65)$  °C. This information was used for derivation of melting peak for obtaining melting energy.

The melting endotherm consisted of two peaks for both seaweed blades and mucus, (Fig, 1). The low temperature narrow melting peak reflects crystallization of salts (mostly *NaCl*), the peak was integrated in the melting peak of ice, which occupied the temperature diapason between end of freezing and initial freezing point. Initial freezing point was determined as extremum of the ice melting peak  $-1.31(0.06)$  and  $-1.31(0.24)$  °C for seaweed blades and mucus respectively.

**Fig. 1. Thermal transitions in seaweed's blade: heat flow curve and derived by temperature heat flow curve.**

Analysis of the melting peak revealed that significant part of moisture was in a crystalline form at freezing temperatures. The value of melting energy was found at  $271.2(5.0)$  and  $259.35(0.95)$  for seaweeds blades and mucus respectively. It is remarkable, that the highest amount of ice was formed in seaweed's blades while the highest moisture content was determined for mucus  $91.97(0.6)$  vs.  $88.67(0.6)$  % w.b. Relatively high initial freezing point and ice content create good conditions for atmospheric freeze-drying process.

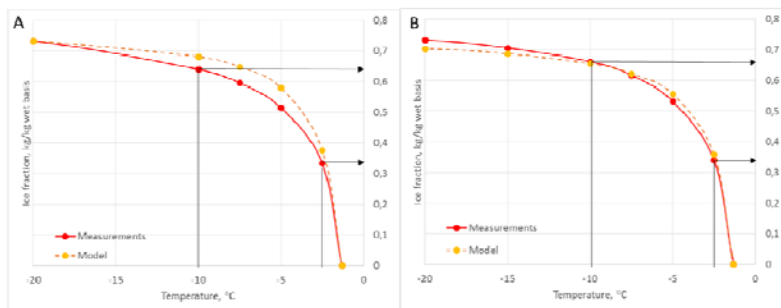

### 3.3 Ice content and unfreezable water in seaweed's blades and mucus

Seaweed blades showed  $10.39(0.59)$ % w.b. of unfreezable water, while the value of  $17.02(1.35)$  % w.b. was determined for mucus. The value of unfreezable water in mucus is

relatively high when compares with other foods. This will result in a low content of solids in the maximal freeze concentration solution, which is formed during transition of water into ice. At the end point of freezing the freeze consternation was at 52.13(0.45) and 31.14(1.05) % w.b. for seaweed's blades and mucus respectively.

Both types of samples showed a significant increasing of ice content in vicinity of initial freezing point, (Fig. 2), which is typical for seafood products of a high moisture content. The concentration of ice reached 63.9 and 66.2% w.b. at -10.0 °C and 33.39 (0.42) and 34.04(0.9) at -5.0 °C for seaweed blades and mucus respectively. These temperature diapason is considered to be the most common for atmospheric freeze-drying process application<sup>[13]</sup>. The model of Schwartzberg <sup>[14]</sup> was used to describe the process of ice formation.

The model accuracy were weak for seaweed blades due to the influence of mucus, while the quality of the model for mucus was relatively good ( $R^2>0.98$ ,  $F(\text{Ration})>500$ ,  $\text{Prob}(F)=0$ ).

**Fig.2. Ice fraction in seaweeds (left) and mucus(right) with respect to temperature. The diagrams introduces experimental data and models.**

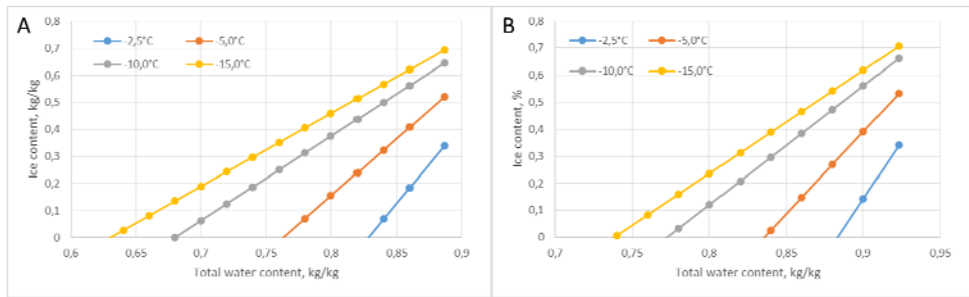

One can notice that the values of ice content are not so different in the seaweed blade and mucus (for the same temperature intervals). At the same time, the concentration of solids (kg/kg w.b.) is low and varies significantly between the samples, which influence on the ice development during the atmospheric freeze-drying process. The data, obtained in this chapter is essential for prediction of ice content during the freeze-drying process.

### 3.4 Development of ice content with respect to total moisture content

The ice content in a product is in equilibrium with freeze concentrated solution and temperature: decreasing of the temperature results in the increasing of ice content, while increasing of solids in a freeze concentrated solution provoke the ice melting. Classical explanation of atmospheric freeze-drying process includes sublimation of ice and formation of dry front in the product. However, this situation will not occur in the case of seaweeds,

as soon as ice crystals will be covered by the layer of unfrozen brine, which include dissolved salt ion, carbohydrates (mannitol) and proteins. Obviously, evaporation of unfrozen brine will be predominant. This will increase the concentration of solids in the concentrated solution and the ice crystals will melt.

Fig. 3 introduces the decreasing of ice content with respect to total moisture content. The ice melting occurs much more rapidly for mucus. Thus, the surface of the product will show the different drying behavior when compared with the whole blades. The application of temperatures below the initial freezing point is suitable only at a high moisture content in the product, when the moisture content (kg/kg w.b.) decreases, for example, to 76.0 % (seaweeds) and 84.0 % mucus at -5.0 °C the application of freezing temperatures is not required, as soon as the process can not be considered as a freeze-drying.

**Fig. 3. Equilibrium ice fraction in seaweeds(left) and mucus(right) for different atmospheric-freeze drying temperatures (with respect to total water content)**

Diagram on the figure 3 can be used for determination the desired freeze-drying temperatures. It should be noted, that the real content of ice will be a function of weight ratio: blade weight to mucus weight.

#### 4. Conclusions

The two glass transition phenomena was detected at the ultra-low temperature region at -84.77(1.35) and -62.14(0.46) °C for seaweed's blades and at -74.44(2.15) and -55.02(0.48) for mucus. Seaweeds blades and mucus showed different end of freezing point -52.23(1.61) and -42.1(0.65) °C. The unfreezable water content in seaweed blades was at 10.39(0.59)% w.b., while the value of 17.02(1.35) % w.b. was determined for mucus. Due to this the maximal freeze concentration was at 52.13(0.45) and 31.14(1.05) % solids w.b. for seaweed's blades and mucus respectively. The application of atmospheric freeze-drying process is limited by these values: full ice melting when the total moisture content is still high (during drying process).

### **Abstract**

*This study discusses the influence of temperature and total moisture content on ice fraction in organic apples during atmospheric freeze-drying process. The ice formation of glass transition events were described by Clausius-Clapeyron and Gordon Taylor equations. The obtained data is essential for design the drying process and for understanding the limiting factors.*

**Keywords:** *ice fraction, organic apples, atmospheric freeze/drying, glass transition*

---

## **1. Introduction**

Atmospheric freeze drying (AFD) of apples results in improved quality of the product which is reflected in better appearance, high porosity and better color, when compared with conventional drying <sup>[1, 2]</sup>. However, the properties of the foods with high moisture content can vary significantly when dehumidifying at the selected freezing temperatures. Extensive research was previously conducted to model and explain physical phenomena of AFD of apples <sup>[3-5]</sup>. The studies revealed high amount of unfrozen moisture when drying at -5.0 and -10.0 °C. However, ice development in apples during AFD process is still unclear. Thus, it is of a great importance to gain a deeper understanding of the thermal properties of apples during drying to further decrease undesired changes of product properties. The aim of current study was the investigation of the development of thermal properties and ice content at different freeze-drying temperatures. Such comparisons will give the essential information to understand factors, which influence the process and limits the AFD process. The same principle can be applied to design the drying regimes of other organic foods, which contain significant amount of sugars (fruits and berries).

## **2. Materials and Methods**

### **2.1 DSC analysis**

Raw and vacuum-frozen dried salmpes were used for experiments. The desired moisture content of vacuum freeze-dried samples was obtained by equilibration in climate camera at defined conditions. The DSC analysis was done wit DSC Q 2000 (TA instruments, USA) equipped with a Liquid Nitrogen Cooling System. Helium was chosen as a purge gas at 25 mL/min, according to TA's instrument recommendations. The reference sample was an empty hermetically sealed aluminum pan. The samples with masses between 13.0 mg and 20.0 mg were placed into aluminum pans with hermetic lids. Samples were cooled and equilibrated for 5 minutes at -150.0 °C; the cooling rate was 10.0 °C/min. The annealing procedure was applied at -50.0 °C. This was done to avoid cold crystallization during scanning. Then the samples were heated up to 150.0 °C with the heating rate of 10.0 °C/min.

### **2.2 Determination of glass transition**

The glass transition was determined with TA Universal Analysis 2000 version 4.5A software (TA instruments, USA). The glass transition is characterized with the following parameters: the onset, end and inflection points. It should be noted, that the glass transition in seaweeds with high moisture content is relatively weak. Thus, the inflection point was determined as a negative peak of the derived heat flow curve <sup>[6]</sup>.

### 2.3 Determination of end of freezing and initial freezing point

The onset of ice melting (or end of freezing point), was determined by analyzing the DSC heating curve. The freezing point was estimated as a minimum value of the ice melting endothermic peak on the DSC heat flow curve.

### 2.4 Determination of ice fraction and unfreezable water

The amount of unfreezable water and ice fraction was detected by the DSC melting curve analysis. The DSC melting peaks were integrated with the sigmoidal tangent baseline function from the onset of ice melting point. The ice fraction was determined as a ratio of melting energy to latent heat of fusion of pure ice. As soon as melting energy of ice is a function of temperature, the empirical equation suggested by Riedel<sup>[7]</sup> was used for correction of obtained values. The amount of unfreezable water was obtained as the difference between the total water fraction in the product and the ice fraction.

### 2.5 State diagram

The thermal transitions can be introduced using the state diagram. A typical state diagram consists of two curves: the freezing curve and the glass transition curve. The freezing curve represents the influence of a solid matter content on the reduction of the freezing point. In this investigation it was obtained from the data of the freezing point of semi-dried apples with different moisture contents. The decrease of the freezing point  $\delta$  (°C) was modeled with the Clausius-Clapeyron equation modified for food by Schwartzberg<sup>[8]</sup>, equation (1):

$$\delta = -\frac{\beta}{M_w} \ln\left(\frac{1-x_s-Bx_s}{1-x_s-Bx_s+Rx_s}\right) \quad (1)$$

where  $\beta$  – molar freezing point constant, 1860 (kg K)/(kg mol);  $M$  – molecular mass, kg/kmol;  $B$  – ratio of unfreezable water to the total solids content, kg/kg;  $R$  – molecular mass ratio of water and solids, kDa/kDa;  $x_s$  – solid fraction kg/kg w.b.

The glass transition curve shows the influence of the solid content on the glass transition temperature ( $T_{g,i}$ ). It was modeled with the Gordon-Taylor equation<sup>[9]</sup>, equation (2):

$$T_{gl} = \frac{x_s T_{gl,s} + k x_w T_{gl,w}}{x_s + k x_w} \quad (2)$$

where,  $x_s$  – solid fraction kg/kg w.b.;  $k$  – system's constant in Gordon-Taylor equation;  $T_{g,i,s}$  – glass transition of pure solids;  $T_{g,i,w}$  – glass transition of pure water.

### 2.6 Statistical analysis

A regression analysis was done with a software DataFit 8.1 program (Oakdale Engineering). The quality of the regression was evaluated with the following parameters: F-Ratio, Prob(F) and  $R^2$ . F-Ratio is the ratio of the mean regression sum of the squares

divided by the mean error sum of the squares. Prob(F) is the probability that the null hypothesis is true.  $R^2$  is the coefficient of multiple determinations. The standard deviation is introduced in the brackets after the values given in the text.

### 3. Results and Discussion

#### 3.1 Thermo-physical properties of apples

The DSC heat flow curve for fresh apples revealed the following endothermic processes: glass transition of unfreezable solution, and melting of freezable water. The unfreezable solution consists of solids and unfreezable water. It is also referred to as maximal freeze concentrated solution [10]. One of the remarkable properties of this solution is its high viscosity. The ice formation is usually not detected when the solids concentration exceeds the value of the maximal freeze concentrated solution. The example of the thermal transitions in apples is introduced on Figure 1a,b.

**Fig. 1** Example of thermal transitions in apples: raw (left) and dried (right): 1- inflection point of glass transition, 2- end of freezing (insipient point of ice melting); 3- eutectic point; 4- ice melting peak.

Glass transition of fresh apples was relatively weak due to a high content of freezable water, but it was easily detected on the derived heat flow curve ( $T_{g,i} = -55.08$  °C, Figure 1a, left, dashed line). At the same time, decreasing of amount of freezable water by drying (semi-dried blanched apples, Figure 1b) made the glass transition shift visible on the heat flow curve,  $T_{g,i} = -53.42$  °C. All the apple samples, which showed an ice melting peak, formed the same maximal freeze concentration of 79.0 % solids w.b. irrespective of the moisture content. Thus, the glass transition shift was detected in the same temperature range ( $T_{g,i}$  between  $-55.5$  and  $-53.0$  °C) as for fresh blanched apples. As soon as the temperature of glass transition is a function of average molecular weight of the system. Such a dependence was determined before for other types of foods [6].

At the same time, the samples, which did not show an ice melting peak (the concentration of solids  $\geq 79.0$  % w.b.), showed a different trend. The glass transition strongly depended on the moisture content: it increased within decreasing of the moisture in the sample. This study determined the inflection point of glass transition of dried apples (0.5 (0.3) % d.b.) in

the range between 38.0 and 46.0 °C. Such a deviation can be explained by accumulation of moisture during sample preparation for DSC. Water molecules work as plasticizers and even a small amount of moisture can decrease glass transition temperature significantly [10]. A recent study revealed the glass transition for dried apples in the range between 33.0 and 84.0 °C [11], when the glass transition was affected by drying temperature from 30.0 to 60.0 °C. However, this study did not show such a dependence for AFD conditions.

The melting peak (solid line, Figure 1a,b) of the freezable water occurred in very narrow temperature range, which indicated the high amount of free water in the product. However, the incipient point of melting (end of equilibrium freezing) was detected at a temperature of -44.2(1.2) °C. The eutectic point was detected on the DSC heat flow curve in the temperature range between -39.2 and 37.4 °C. It was introduced as a weak bend of the melting peak line and as a negative peak on the derived heat flow curve (in the range between -39.11 and -37.40 °C), see Figure 1a,b.

Integration of the melting peak from the incipient point of melting with respect to Riedel's equation [12] allowed to calculate the amount of frozen matter vs. temperature, Figure 2a. The amount of unfreezable water, which was calculated as a difference between total water content and the ice fraction, was found at 3.7 (0.3) % w.b. Thus, apples include solid fraction, freezable and unfreezable water. Most of the freezable water was in crystalline form in the temperature range between -3.0 and -10.0 °C, Figure 2a. Such temperatures is a typical range for the AFD process [3, 13]. At the same time, the moisture content of unfrozen solution at these temperatures was also very high and varies in the range between 60.0 and 43.0% w.b., Figure 2b. This significantly influenced the drying process. The retreating of the ice front from the surface to the inner parts of the product with the formation of a porous zone, which phenomena is widely used for modelling of AFD process, [13] will not occur in such a case. The process of evaporation of the unfrozen moisture and ice melting due to depression of freezing point is much more likely to occur.

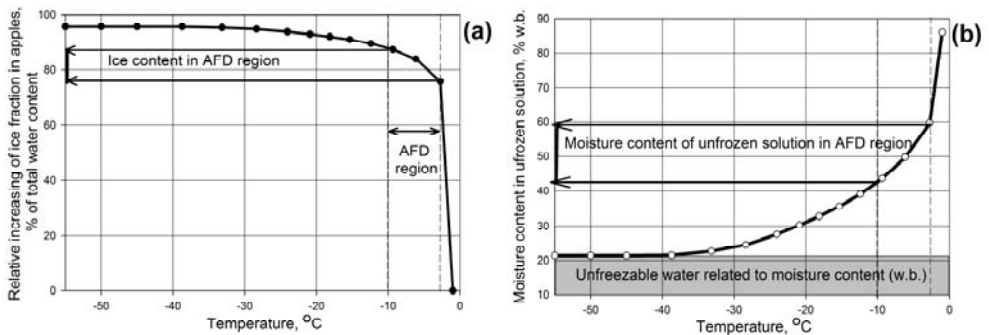

Fig. 2 Ice content increasing in apples (left), Moisture content in unfrozen solution(right)

### 3.2 The state diagram for organic apples

The state diagram, which is constructed on the basis of equations (1) and (2), is introduced in Figure 3. The inflection point of glass transition was used for the modeling. These two lines split the diagram area into four regions with respect to solid content and temperature. The amorphous region appears above the freezing point depression line (Clausius-Clapeyron's equation:  $R=5.48 \cdot 10^{-5}$ ;  $B=12.78 \cdot 10^{-2}$ ); this region is common for atmospheric convection drying of foods. The region of ice and amorphous unfrozen solution is situated between the freezing point depression line and glass transition line. The region of the glassy state can be found below the glass transition line (Gordon-Taylor equation:  $k=4.19$ ;  $T_{gi,s}=42.09 \text{ } ^\circ\text{C}$ ).

Fig. 3 State diagram for apples: experimental results and modelling ( $F(\text{Ratio}) > 600$ ;  $\text{Prob}(F) = 0$ )

The application of the state diagram, Figure 3, allows to predict indirectly the amount of ice during drying at different processing temperatures with respect to the moisture content. Further, the natural limitation of the AFD process can be determined. The minimum AFD temperature is influenced by the formation of maximal freeze concentration, when further decreasing of the temperature does not influence on ice content in the product. The overall amount of ice at any time of the drying process can be easily determined knowing the actual moisture content and the critical solid content, which is a function of the drying temperature, equation (3):

$$x_{ice,T} = x_{w,T} - (1 - x_{s,crit,T}) \quad (3)$$

where,  $x_{ice,\tau}$  – ice content at any time of the AFD process (kg/kg w.b.);  $x_{w,\tau}$  – water content at any time of AFD process (kg/kg w.b.);  $x_{s,crit,T}$  – critical solid content at the AFD drying temperature (kg/kg w.b.).

Critical solid content is the maximum available concentration of solids in unfrozen solution at freezing temperature. It can be determined using equation (1) or Figure 3. Due to this, it is possible to control AFD process using the weight reduction as a reference. For example, Duang et al., [14] suggested to decrease the temperature of the drying air from -5.0 to -10.0 °C to avoid ice melting during atmospheric freeze-drying.

The full melting of ice will occur when the concentration of the solid fraction reaches the critical solids content at a given freezing temperature, Figure 3 (dotted line). At such conditions, the process became the typical low temperature convection drying. Another important issue is glass transition of the samples, when the amorphous solution will solidify. Such a phenomenon depends on the solid fraction and temperature (Gordon-Taylor equation). The subsequent increase of temperature before reaching the glass transition concentration at a given temperature is essential to decrease the drying time. The viscosity of an amorphous solution in the vicinity of the glass transition reaches  $10^{12}$  Pa\*s [15]. This can decrease the drying rate significantly. At the same time, crossing the glass transition line will make the product crispy and brittle, as soon as the viscous-elastic characteristics of the product disappear in the region [6].

#### 4. Conclusions

The temperature of glass transition of fresh and dried apples was determined at -55.08 and -53.42 °C respectively. The inflection point of glass transition of dried apples was detected in the range between 38.0 and 46.0 °C. Both fresh and dried apple samples showed the same maximal freeze concentration of 79.0 % solids w.b. irrespective of the moisture content. The incipient point of melting was found at -44.2(1.2) °C. The eutectic point was detected in the temperature range between -39.2 and 37.4 °C. The amount of unfreezable water was determined at 3.7 (0.3) % w.b. The moisture content of unfrozen solution varied in the range between 60.0 and 43.0% w.b. at -3.0 and -10.0 respectively. The process of AFD should be held in the temperature range below the melting temperature with respect of moisture content, but the temperature should be increased after the ice melting. The region of glass transition should be avoided for rapid and efficient drying.

### **Abstract**

*Mesquite pods contain a high nutritional content, then a protein rich flour can be obtained. Prosopis Laevigata pods were collected from Oaxaca and Durango. Three stages of maturity were identified. The internal structure of the pods was analyzed by scanning electron microscopy (SEM). The pods were dried at 40°C, 50°C and 60°C, 10% relative humidity and air velocity of 2.6 m/s. From experimental data, the characteristic curve was obtained. SEM Images showed a heterogeneous and tortuous structure. The internal structure of the material is a limiting factor for mass transfer. The effective coefficient diffusion for each drying experiment was determined.*

**Keywords:** *Drying; mesquite; pods.*

---

## 1. Introduction

The mesquite is an extremophile tree that grows in arid and semi-arid zones around the world. In Mexico, mesquite is found in northern, central and southern states of the country and in the past was used as a bread, flour, and syrup [1]. The pods having a high content of protein, sugar, calcium, iron and fiber present a wide potential in the development of food products [2]. In order to process the pods a specific drying process is mandatory. Mesquite pods are a highly hygroscopic material due to the high sugar content [3]. The pods have a low moisture content (0.14 g water / g dry mater); however they tend to absorb moisture quickly in humid environments. After drying pods should at least reach a moisture content of 0.06 g water / g dry matter, otherwise they cannot be efficiently milled [4].

## 2. Materials and Methods

*Prosopis laevigata* pods were harvested between April and August 2017 in Oaxaca and Durango (Mexico). The color was measured with a HunterLab Model E-Z spectrophotometer using the CIELab color scale. In the CIELab color scale, the parameter L\* represents the luminosity of the material; the parameter a\* represents changes of coloration from red to green, and the parameter b\* indicates a coloration that goes from yellow to blue. The sugars were quantified following the method NMX-F-312-1978. The mesquite pods were analyzed by electron microscopy, using a JEOL brand electronic scanning microscope (SEM), model JIB-4601F, with a spatial resolution of 1.2 nm. Pods without deterioration were selected for drying. The moisture content of the pods was measured by the oven-dry method (NMX-F-083-1986).

The pods were dried in a tunnel dryer (patent 304462). The temperature, relative humidity, and air velocity were controlled and logged. A National Instrument FP-1000 system was used, in order to log the data. The temperature of the material was measured using J-type thermocouples (Vaisala Veriteq SP 1700). A steam generator model TV / G2F Anghinetti SRL was used for the humidification of the air. Only pods from Oaxaca in stage 3 were dried at three different temperatures (40 °, 50 ° C and 60 ° C) and the Durango pods in stage 3 were dried only at 60 °C. Drying experiments were conducted at constant relative humidity (10%) and air velocity of 2.6 m/s.

### 2.2. The characteristic drying curve.

The experimental kinetics were normalized and the characteristic drying curve was obtained. The reduced moisture content was computed as follows:

$$W_r = \frac{W_t - W_{eq}}{W_i - W_{eq}} \quad (1)$$

A polynomial equation of order 6 was used to depict the experimental drying kinetics, after that the drying rate was computed. The reduced drying rate (dWr) was calculated by using dWref:

$$dWr = \frac{dW}{dW_r} = \left[ -\frac{dW}{dt} \right]_r = f(W_r) \quad (2)$$

According to Equation 2, the reduced drying rate dWr is a function of the reduced moisture content Wr, so an equation is derived to describe the complete kinetics using the following conditions:

$$f(W_r) = 0 \text{ if } W_r = 0 \quad (3)$$

$$0 < f(W_r) < 1 \text{ if } 0 < W_r < 1 \quad (4)$$

$$f(W_r) = 1 \text{ if } W_r = 1 \quad (5)$$

The graphs of reduced moisture content versus reduced drying rate can be described with a straight line for both Oaxaca and Durango pods ranging from reduced moisture content of 1 to 0.01. The initial phase of the of drying rate curves are discarded since it happens very fast and the final period is not taken into account by the model because it represents very low moisture contents [5]. The deduction of the linear model is presented below:

$$W = C + (W_{r0} - W_{eq}) \left[ \left( 1 + \frac{d}{c} \right) e^{\frac{-C \cdot dW_{ref} \cdot t}{W_{r0} - W_{eq}}} - \frac{d}{c} \right] \quad (6)$$

### 3. Results and Discussion

According the Cielab scale, three stages of maturity were defined (Table 1). In Stage 1 pods show a green coloration, in stage 2 the pods are brighter with a reddish coloration. In stage 3 the pods increase in brightness compared to the previous stages, reddish and yellow coloration is still observed, but in a lower intensity compared to stage 2.

**Table 1. CIElab color parameters of mesquite pods at different stages of maturity**

Stage 1	Stage 2	Stage 3
L*70.75 +/- 0.6632	L*71.46 +/- 0.8423	L*73.87(2017) +/- 0.5754
a*-45.84 +/- 0.1567	a*8.68 +/- 0.3214	a*3.66 (2017) +/- 0.1345
b*64.78 +/- 0.4892	b*71.13 +/- 0.5919	b*26.4 (2017) +/- 0.2598

The content of sugars (Table 2) in the three stages of maturity has significant differences; the green pods have a bitter taste, while the mature pods have a sweeter taste. Stage 1 pods have less sugar than other stages of maturity also a bitter taste which isn't good for further processing, stage 2 pods have a higher sugar content however their moisture content (3.08 g.

water/g. dry matter) makes them difficult to dry and a high moisture content after drying makes them unusable for further processing; pods in stage 3 have a sugar content that makes them sweet and a moisture content of 0.22 g. water/g. dry matter. Pods from Durango in stage 3 have a significantly higher sugar content than pods from Oaxaca which prolongs the drying time due the hygroscopic behavior of the sugars on the mesocarp.

*Table 2. Sugar content in the different states mesquite pods*

100 g of Pods.	Stage 1 (Oaxaca)	Stage 2 (Oaxaca)	Stage 3 (Oaxaca)	Stage 3 (Durango)
Sugars.	6.55 g +/- 0.0680	8.15 g +/- 0.3552	7.42 g +/- 0.1305	14.42 g +/- 0.1178

The seeds (Fig. 1) are covered by the endocarp; they have a semi-spherical, brown, smooth and shiny texture. In Fig. 2 a) we observe a cross section of the seed where the tegument constituting the outermost layer of the seed, the endosperm is divided into different sections each with similar structure, finally the embryo is observed in the central and inner part of the seed. The seed measures 2.5 mm thick. In Fig. 2 b) we observe the surface of the tegument presenting a homogeneous conformation with no pores. In Fig. 2 c) the image shows the back part of the tegument as well as the plumule. In Fig. 2 d) we can observe the space between and the endocarp where the seed is contained.

**Fig. 1** Longitudinal image of the seed. **Fig. 2** Transverse images of the seed obtained by SEM.

The mesocarp thickness varies from each pod. This domain is rich in carbohydrates and has a highly hygroscopic nature [6]. It presents a tortuous, rubbery structure and cavernous sections. It is strongly attached to the endocarp and epicarp.

Figure 3 a) shows a section of the mesocarp, which has a heterogeneous, tortuous and rubbery conformation; these characteristics together with the hygroscopic capacity represent a further difficulty in the removal of moisture during drying. Figure 3 b) presents a section of the mesocarp attached to the inner layer of the epicarp, showing an irregular, tortuous, heterogeneous and rubbery structure; strongly adhered to the epicarp. Figures 3 c) and 3 d)

show a cross section of the pod focusing on the mesocarp, again showing an irregular,

*Fig. 3 Transverse images of the mesocarp obtained by SEM.*

heterogeneous and tortuous conformation; presenting cavernous portions that present a further difficulty when predicting how moisture diffuses towards the surface.

In Fig. 4, we show the kinetics for the drying condition at 40°C and 50°C. The pods reached the equilibrium moisture content (W) at different times.. An inconvenience of drying at 40 and 50°C is the high moisture content at the end of drying, since a milling process requires pods with a very low moisture content.

*Fig. 4 Drying kinetics of mesquite pods stage 3 at 40 °C and 50 °C (Oaxaca).*

In Fig. 5 we observe the drying kinetics for drying at 60°C for pods from Oaxaca and Durango. The pods from Oaxaca had an initial moisture content of 0.2234 g water/g dry matter, meanwhile the Durango pods an initial moisture content of 0.1815 g water/g dry matter. In spite of a fast heating period, pods offer an important resistance to moisture

migration due to its microstructure. During the heating period of drying where the evaporation rate increases, the free water diffuses more easily.

*Fig. 5 Drying kinetics of mesquite pods stage 3 at 60 °C (Oaxaca and Durango).*

Table 3 shows the parameters obtained by the characteristic curve model. Figures 6 and 7 show the experimental drying kinetics of Oaxaca and Durango at 60 °C and the characteristic curve.

*Table 3. Calculated parameters of the characteristic drying curve model.*

Temperature °C	dWref	c	d
<b>Oaxaca 60 °C</b>	0.0022	1.0488	0.0014
<b>Durango 60 °C</b>	0.0011	0.9036	0.0067

The characteristic curve (Fig. 6 and 7) shows a good agreement with the experimental data for drying at 60°C (Oaxaca) and 60°C (Durango). This empirical model has the advantage of predicting how pods are dried without the need to know all their properties.

Fig. 6 Comparison of experimental data and the characteristic curve model (Oaxaca 60 °C).

Fig. 7 Comparison of experimental data and the characteristic curve model (Durango 60 °C).

#### 4. Conclusions

The drying process of mesquite pods (*Prosopis laevigata*) was studied. Three stages of maturity were identified and the internal structure of the pod which plays a very important role in drying. The periods of maturity are followed by physical changes such as color and chemical changes such as the sugar and moisture content. The pods in stage 3 of maturity have a sweet flavor and a lower moisture content which is appropriate for drying. Mesquite pods have a heterogeneous and tortuous structure, which is a barrier that hinders the diffusion of moisture. This fact must be considered due to the increase in economic and energy costs when this drying process is carried out on a larger scale. The pods from Oaxaca and Durango must be dried at a minimum temperature of 60°C to obtain a quality dry product. The characteristic drying curve was deduced and it shows a good representation of drying kinetics. The mesquite pods are a multidomain food then the diffusion in a multidomain food must be studied.

### **Abstract**

*This study investigated the influence of the intermittent drying conditions on drying kinetics and on color and carotenoid retention of mangoes. The drying conditions were 95°C (40 min) and 80°C (40 min) in the first stage combined with 70°C and 60°C in the second stage, and continuous drying (70°C and 60°C) as control. Drying time was reduced by thermal intermittence and carotenoid retention was more affected by temperature than drying time. The results also highlighted the carotenoid sensitivity to 70°C temperature, showing the importance of limiting the temperature of the mango to 60°C during the two drying stages.*

**Keywords:** *Intermittent drying; thermal intermittence; carotenoid; color.*

## 1. Introduction

Convective drying process provides many advantages over the shelf life extension of the food products. However, the drying of fruits in its most conventional way, can affect the nutritional quality of the dried products, due to prolonged exposure to oxygen and high temperatures. A possible way to reduce the negative effects of convective drying and still reduce energy consumption is to apply it under conditions of thermal intermittence, in which the conditions of time and temperature are modified during the same operation [1]. The drying of fruits with application of the thermal intermittence is based on their high moisture content at the beginning of the drying, whose surface temperature remains lower than the air because of water evaporation. This allows a higher temperature to be initially used and, consequently, reduces the drying time without causing significant damage to the product [2].

Regarding thermal intermittence, it is noted that this process is widely used in drying of grains and seeds, where tempering periods are used to reduce moisture gradients and avoid cracks [3,4]. However, there is a gap in the literature with regard to drying with thermal intermittence applied to high moisture food products. Among the existing works, most of them focus on the economy that the intermittence provides to the drying process, without evaluating the quality of the product, which can be considered a problem with respect to the nutritional aspects of food. Several authors have shown that intermittent drying conditions can lead to significant reductions in drying time and energy demand. For example, Vázquez et al. (2009) [5] dehydrated mango slices applying intermittence and obtained increased drying rates and reduced overall operating time, indicating a decrease in energy consumption. However, as foods with high water content are susceptible to many changes due to chemical and biochemical reactions, it is important to evaluate quality through parameters such as color and nutrient retention [2,3].

The mango (*Mangifera indica* L.) is one of the most consumed fruits in the world, which is associated with their sensory properties and its high nutritional value, especially because of the antioxidant substances such as carotenoids, related to the prevention of several chronic-degenerative diseases and responsible for the mango color [6,7]. However, it is known that the mango is a seasonal fruit and presents considerable post-harvest losses, therefore, the use of preservation techniques like of convective drying is very important for these fruit, aiming to increase their shelf life.

The objective of this study was to evaluate the influence of the intermittent drying conditions on drying kinetics of mangoes as well as on their color and retention of carotenoids during process, aiming to reduce the time of operation and improve the sensory and nutritional quality of the dry mango.

## 2. Materials and Methods

### 2.1. Sample preparation

The mangoes (*Mangifera indica* L.) cv. Palmer with an average soluble solids content of  $11.0 \pm 1.4$  °Brix and a moisture content between 81.8 and 86.0 % on wet basis (w.b.) were acquired from nearby farms the region of São José do Rio Preto - São Paulo. In order to have a similar degree of maturity in all drying trials, the fruits were selected visually and based on manual contact. In each drying trial, nine mangoes (4.5 kg) randomly selected from a total of approximately 100 fruits were used. The mangoes were sanitized, sliced ( $0.54 \pm 0.03$  cm thick) with an electrical slicer (ECO, Brazil) and then, cut in circles (3.5 cm diameter) with a manual cutter.

### 2.2. Drying trials

The drying trials were performed using two identical fixed bed dryers with forced heated air convection according to Filippin (2018) [2]. A hot wire anemometer (Delta OHM, Italy) was used to determine the average velocity of the air in the drying chamber, which was approximately  $1 \text{ m}\cdot\text{s}^{-1}$ .

Six drying conditions were performed in duplicate, four of which were intermittent (I) in two stages, with the first stage at 95 °C (H=higher temperature) or 80 °C (L=lower temperature), held for 40 minutes, and the second stage at 60 °C (L) or 70 °C (H). The other two conditions corresponded to continuous (C) dryings at 60 °C and 70 °C (controls) (Table 1). The time range of the first stage was determined by monitoring the surface temperature of mango slices at the beginning of drying, considering as stop criterion the period that corresponds, approximately, to the time to reach the second stage temperature. All dryings were stopped when the samples reached moisture of approximately 8.7 % ( $\pm 1.1$ ). To establish the total drying time, the initial moisture of the samples was previously determined and the stopping point was based on the weight of the trays with the samples, which was previously calculated so that the samples reached the desired final moisture. The samples were weighed successively during drying using a semi-analytical balance (Gehaka, BK 4000, Brazil). The equilibrium moisture was determined in samples left in the dryer until reaching constant weight. Temperature and time values of the drying stages, as well as abbreviations used in the following tables of this work are shown in Table 1.

**Table 1. Temperature and time conditions for Intermittent and Continuous dryings**

Trial	Abbreviation	Temperature (°C)		Time (min)	
		1 <sup>th</sup> Stage	2 <sup>nd</sup> Stage	1 <sup>th</sup> Stage	2 <sup>nd</sup> Stage
<b>Intermittent drying</b>					
Intermittent (80 °C / 60 °C)	I-LL	80	60	40	230
Intermittent (95 °C / 60 °C)	I-HL	95	60	40	200
Intermittent (80 °C / 70 °C)	I-LH	80	70	40	200
Intermittent (95 °C / 70 °C)	I-HH	95	70	40	170
<b>Continuous drying</b>					
Continuous (60 °C)	C-L		60		360
Continuous (70 °C)	C-H		70		300

### 2.3. Drying kinetics

The effective diffusion coefficients of water were determined according to the Fick's second law, applied to an infinite flat plate. The analytical solution of the diffusion equation in its modified form, in terms of the mass fractions (dry basis, d.b.) and integrated on distance, is presented by Eq. (1) [8]:

$$X = \frac{\bar{X}_w(t) - X_w^{eq}}{X_w^0 - X_w^{eq}} = \frac{8}{\pi^2} \sum_{n=1}^{\infty} \frac{1}{(2n-1)^2} \exp \left[ -(2n-1)^2 \frac{\pi^2 D_{eff} t}{e^2} \right] \quad (1)$$

where  $X$  is the residual moisture content, dimensionless;  $\bar{X}_w$  represents the mean mass fraction of the water on a dry weight basis ( $\text{kg} \cdot \text{kg}^{-1}$ ) at the drying time  $t$  (s);  $X_w^0$  and  $X_w^{eq}$  represents the water mass fraction on a dry weight basis ( $\text{kg} \cdot \text{kg}^{-1}$ ) at the initial moment ( $t = 0$ ) and at equilibrium (eq);  $D_{eff}$  represents the effective diffusion coefficient ( $\text{m}^2 \cdot \text{s}^{-1}$ );  $e$  is the thickness of the samples (m);  $n$  is the number of terms in the series.

The shrinkage of the sample was considered by applying a simplified procedure that incorporates the volumetric contraction in an approximate way in Eq. (1) through the characteristic dimension ( $e$ ) as a function of the water content. From the fruit volume variation during drying, the final thicknesses of the samples were estimated considering that shrinkage occurred in the same proportion, in each dimension of the solid [9], as follows:

$$\frac{e}{e_0} = \left( \frac{V}{V_0} \right)^{1/3} \quad (2)$$

where  $e$  (m) is the thickness at time  $t$  (s) and  $V$  ( $\text{m}^3$ ) is the volume at time  $t$  (s); sub index 0 represents initial time ( $t = 0$ ).

The volumes were calculated based on the thickness and diameter measurements performed on the mango samples, before and after each drying experiment. The thickness was then described as a linear function of the water content, on a dry basis, and incorporated into the Eq (1), to fit the model to the experimental results.

Water diffusion coefficients were determined according to Eq. (1), for each stage, separately, as described by Filippin (2018) [2]. The fitting method used in the estimation of the nonlinear parameters was based on the Levenberg–Marquardt algorithm [10].

#### 2.4. Analytical methods

Thickness, total solids, total carotenoid, and color parameters were analyzed before and after drying, besides diameter after drying. The thickness was measured using a digital micrometer (MDC-25SB, Mitutoyo, Japan) and the diameter using a pachymeter (Stainless Hardened, 806178, USA), both used to calculate the volumetric variation of the samples during drying. Total solids content was determined gravimetrically, in a vacuum oven (TE-395, Tecnal, Brazil) at 60 °C until constant weight. Total carotenoid content was determined by spectrophotometric reading (Thermo Scientific, GENESYS 10S UV-VIS, EUA) (absorbance at 450 nm) as  $\beta$ -carotene, according to Rodriguez-Amaya and Kimura (2004) [11] and its retention during drying was analyzed as Eq. (3):

$$\text{Ret}(\%) = 100 \frac{(\mu\text{g carotenoid/kg dried mango}) \times \text{kg dried mango after drying}}{(\mu\text{g carotenoid/kg raw mango}) \times \text{kg raw mango before drying}} \quad (3)$$

Color parameters based on the CIELAB system ( $L^*$ ,  $a^*$ ,  $b^*$ ) were obtained using a Colorflex spectrophotometer (HunterLab, Resto, USA). All color parameters ( $P^*$ ) measured after drying ( $t$ ) were evaluated in relation to their corresponding values before drying ( $t=0$ ). The process conditions that presented the ratios  $P^*(t)/P^*(t=0)$  tending to unity were considered effective in reducing the color changes.

#### 2.5. Statistical methods

The fitting efficiency of the diffusion coefficient was evaluated by the correlation coefficient  $R^2$  and the mean relative error ( $P$  %), according to Eq. (4):

$$P (\%) = \frac{100}{n} \sum_{i=1}^n \frac{|y^{\text{exp}} - y^{\text{cal}}|}{y^{\text{exp}}} \quad (4)$$

where  $y^{\text{calc}}$  represents the water content on a dry basis,  $y^{\text{exp}}$  is the experimental value, and  $n$  is the number of observations or residuals.

### 3. Results and discussion

#### 3.1. Drying kinetics

Table 2 shows the values for diffusivity ( $D_{\text{eff}}$ ) and the determination coefficients ( $R^2$ ) and relative errors ( $P(\%)$ ) for the drying trials. In relation to the diffusion coefficients, in general, the higher temperatures lead to higher diffusion coefficients.

Evaluating the fit of the model, high  $P(\%)$  values were observed for the second stage of intermittent drying and for continuous drying (above 10%), as the error measurement makes the relative deviations very high when the water content is very small. However, the coefficients of variation ( $R^2$ ) were all higher than 0.986, indicating satisfactory fit.

From the determination of the diffusivity, the moisture (dry basis) graphs were plotted as a function of time (Fig. 1) of the predicted values, which were compared with the experimental data. From the graphs, it can be observed that the predicted values are close to those observed for both intermittent drying stages and for continuous drying (Fig. 1).

**Table 2. Effective diffusion coefficients ( $D_{\text{eff}} \times 10^{10} \text{ (m}^2\cdot\text{s}^{-1}\text{)})$  for the Intermittent (1<sup>th</sup> and 2<sup>nd</sup> Stage) and Continuous dryings, number of repetitions (Rep), total drying time,  $R^2$  and  $P(\%)$**

### 3.2 Color and carotenoid retention

The carotenoid retention and normalized color parameter values of the dried mango are presented in Table 3. Drying at 95 °C/60 °C (I-HL) was the condition that provided the best preservation of carotenoid, followed by 80 °C/60 °C (I-LL), and also the continuous drying at 60 °C (C-L), which highlighted the carotenoid sensitivity to 70°C.

The color parameters did not show relevant changes in the different operating conditions. However, it was possible to verify that the greatest variations in the normalized a\* parameters were related to the continuous dryings (C-L and C-H), and also with those intermittent dryings in which the second stage temperature was 70 °C (I-LH and I-HH). This suggests therefore, that long drying times and 70°C temperature could affect them more intensively.

Table 3. Carotenoid retention Ret (%) and normalized color parameters P\*(t)/P\*(t=0) for each repetition (Rep) of intermittent (I-) and continuous (C-) trials.

	2	62.03				

## 4. Conclusions

Despite the drying conditions causing only small changes in the color parameters, they seemed to be more affected by the long drying times. More noticeably, the total drying time was reduced by thermal intermittence, by the increase of the first stage temperature of all intermittent dryings, and also when the second stage was 70 °C. Temperature affected carotenoid retention more than drying time, and their sensitivity to 70 °C confirmed the importance of limiting the sample temperature to 60 °C during the two drying stages.

### **Abstract**

*Nowadays, there is high consumer demand in the market for simple to prepare, convenient, healthy and natural foods. Paneer or Indian cottage cheese is an acid and heat coagulated milk product which serves as a rich source of animal proteins for the vegetarians. Due to high moisture content (58-60 %), it is highly perishable in nature. Drying of paneer would undoubtedly extend the shelf life of paneer and also help in value-addition of paneer. Dehydrated paneer would find numerous ways to be use. Drying of paneer by conventional methods poses threats including case-hardening and non-uniform incomplete drying, poor rehydration characteristics, longer drying time, yellow discoloration and oiling off during drying. Freeze drying remains the best in retaining the quality of dried food products. Though it is highly expensive due to high processing and operation costs. The present study focuses on developing cost-effective protocol for freeze-drying of paneer. Efforts have been made by use of pre-treatments prior subjecting to freeze drying. The dehydrated product would be shelf-stable and can be rehydrated to its original state having flavor and texture comparable to the fresh form. Moreover, the final product after rehydration would be more fresh and softer than its frozen counterparts. The developed product would be easily kept well for few years at room temperature without any addition of preservatives.*

**Keywords:** Paneer; freeze-drying; color; rehydration ratio; pre-treatment

---

## **1. Introduction**

Paneer is an important indigenous product which is obtained by heat treating the milk followed by acid coagulation using suitable acid viz. citric acid, lactic acid, tartaric acid, alum, sour whey. Traditionally, India has been a paneer consuming nation with about 5% of milk produced being converted into paneer [1]. As per a conservative estimate, Indian paneer market is expected to grow at Compound annual growth rate of 18% till 2020. Paneer is quite popularly being used in a number of traditional Indian recipes. It is highly perishable with about 58% moisture content (wb). Various attempts have been made to improve the shelf life of paneer by employing different physical and chemical methods. These include low temperature treatment (refrigeration and freezing), chemical treatment, heat treatment, drying, hurdle technology and packaging. However drying remains the best preservation method in achieving a shelf stable product while retaining the quality attributes, it alters the physicochemical characteristics in the dried product. Vishweshwariah (1987) achieved a shelf-life of up to 2 months dehydrated paneer (5-9 % moisture) dried using hot air drying at 75°C for 4 hrs. Rehydration characteristics of were poor and lacked cohesiveness due to irreversible denaturation of proteins and rehydrated paneer was tough and rubbery [2]. Srivastava et al. (2013) reported that time required for drying paneer is 33% higher in VD as compared to low pressure superheated steam drying (LPSSD). Moreover, the effective diffusivity decreased with increase in pressure during vacuum drying of paneer [3]. Singh et al. (2004) conducted hot and cold diffusion of paneer cubes with sodium chloride and potassium sorbate solution and subsequent microwave drying was done. Maximum rehydration ratio was achieved in cold (1.03) and hot (1.09) diffused microwave dried paneer cubes at 30°C for 10 minutes [4]. Undoubtedly, Freeze drying is a standard processing technique for drying of heat sensitive food materials. However, due to its high cost of operation the technology the cost of FD may be as much as 200–500% higher than that of hot air drying, which greatly reduced economic competitiveness of FD products. Hence to widen its application, various approaches have been studied to modify the freeze-drying process. Pre-treatment prior to drying is a good approach to improve the drying kinetics while retaining the product quality. Blanching is known to enhance mass transport in the tissue and affect the drying behavior. Similarly, osmotic pre-treatment with calcium chloride affects the rigidity of the cell membrane and thus assist in removal of water from the tissues during drying. In an effort to reduce drying time, and indirectly the energy consumption, the present research aims to study the effect of pre-treatments viz blanching and calcium choride treatment on the drying characteristics and product qualities of paneer dried with freeze drying. Dried paneer offers numerous culinary applications. It can be used in curry preparation similar to paneer-in-curry, a delicacy in Indian cuisine. It may be added to granola/ trail mix, soup mix, yielding a high energy snack. If grounded to a powder, it may be use as a cheesy spice mix, or used as

popcorn seasoning. Dried paneer powder may be added to pizza dough or added to a white sauce to turn it into a paneer sauce.

## **2. Materials and Methods**

### **2.1 Material**

Paneer was kept at 4°C in a refrigerator until use. The initial moisture content of paneer was about 55% (wb). It was diced in to a cube of two size 1×1×1cm<sup>3</sup> with stainless steel knife.

### **2.2 Pre-treatments**

Paneer cubes were pretreated with two different ways (i) blanching and (ii) dipping in salt solution. Hot Water blanching was carried out by immersing paneer cubes into 100°C for 1 min distilled water in a stainless steel pan heated by an induction cooking plate. The weight ratio of paneer cubes and distilled water was 1:2. After the pretreatment, the samples were cooled using a fan until there was no visible water on the surface of the material. The blanching pretreatment was carried out in triplicate. Salt treatment was done by dipping paneer cubes in solution containing 0.5% calcium chloride for 10 min. Paneer cubes and salt solution was in the ratio of 1:10. After pretreatment cubes were then removed, and drained using stainless steel mesh. Before drying, samples were blotted to remove the surface moisture and put in the drying chamber.

### **2.3 Drying Equipment and Procedure**

Freeze drying (FD) was performed in a laboratory-scale FDL-10N-50-8M freeze-dryer (MRC, Beijing, China) for 12 hrs and 18 hrs to evaluate the difference in moisture content reduction and quality achieved at the two time intervals. The paneer cubes (200 g) were frozen at -20°C in a freezing chamber and freeze-dried to a moisture content of 5–6% (w.b.) at an absolute pressure of 0.100 mbar with a chamber temperature of 20°C and a condenser temperature -50°C. The dehydrated paneer samples were packaged into polyethylene bags with silica gel.

### **2.4 Moisture Content**

Moisture content was determined by the hot air oven method. At regular time intervals during the drying process, samples were taken out and dried for 8 h at 105°C until constant weight. The initial moisture content of the paneer was found to be 54.52 % (w.b.). The tests were performed in triplicate.

### **2.5 Measuring of Energy Consumption**

Industrial freeze drying processes is complicated and quite expensive. For making it feasible for a sumptuous food such as paneer, a lower cost approach to this process needs to

be researched. However, the energy consumption of a drying process is measured by energy cost checker, but for the present study emphasis is given to predict which pre-treatment is the best in maximally reducing the moisture content in given time duration, 12hrs and 18 hrs. This will assist to indirectly reduce the overall energy consumption of the drying.

## 2.6 Color

The color is one of the most important appearance attribute of food materials since it influences consumer acceptability [5]. The color measurements can be used in an indirect way to estimate color change of foods since it is simpler and faster than chemical analysis. Hunter color parameters (L, a, b) have previously proved valuable in describing visual color deterioration. The color of raw and dried samples Colour measurement was done by using Colorimeter (Model: Chroma Meter CR-400, Konica Minolta). The location of any color in the CIELAB color space is determined by its color coordinates, CIEL\* (L\*=0(black) and L\*=100 (white)), CIEa\* (-a\*=greenness and +a\*= redness), and CIEb\*(-b\*=blueness and +b\*=yellowness). The paneer cubes were scanned at three different locations to determine the average L\*, a\*and b\* values as the average of the five measurements. The paneer cubes were cut into small portion with knife and put into adapter for color measuring. The total color differences (TCD) were estimated from the coordinates of the color by applying the following equation (1):

$$TCD = \sqrt{(L_0^* - L)^2 + (a_0^* - a)^2 + (b_0^* - b)^2} \quad (1)$$

where,  $L_0^*$  is the degree of lightness of control sample,  $a_0^*$  is the degree of redness and greenness at control sample and  $b_0^*$  is the degree of yellowness and blueness at control sample.

## 2.7 Rehydration Process

Dried food products are usually rehydrated before consumption. Rehydration can be in general defined as a complex process involving different physical processes such as capillary flow, convection or diffusion [6]. Rehydration capacity indicates degree of damage (cell or structure disruptions) to foodstuff caused during drying. It involves imbibition of water, swelling and finally leaching out of soluble solids from dried food stuffs [7]. Rehydration capacity is studied by reconstituting the dried product in distilled water and amount of equilibrium moisture absorbed within a stipulate time is determined.. Treatments such as drying and rehydration produce changes in the structure and composition of product tissues [8]. The dried paneer cubes were soaked in controlled temperature of 100°C distilled water and were analysed for weight gain after every 1 min by first removing surplus water from the surface using blotting paper. The weight used in each experiment was  $1 \pm 0.1$  g of dehydrated paneer samples. The weighing was performed on a digital balance. A dried paneer cube was added to 150 mL of distilled water. The

sample weighing was performed in triplicate. The rehydration ratio (RR) was evaluated from equation (2) below:

$$RR = \frac{M_r}{M_d} \quad (2)$$

where  $M_r$  is the weight of paneer cubes after rehydration (g) and  $M_d$  is the weight of paneer cubes after drying (g)

## 2.8 Statistical Analysis

Data analyses were determined and analyses of variance (ANOVA) were conducted by ANOVA procedure. Mean values were considered significantly different when  $P < 0.05$ .

## 3. Results and Discussion

In order to assess the advantage of the pre-treatment prior to freeze drying, the reduction in moisture content, color, and rehydration between the pre-treated dried products were compared. The freeze dried (FD) sample with no pre-treatment was used as a control.

### 3.1 Amount of moisture removed

There has been more reduction in the moisture content when the sample was pre-treated. Blanching for 2 minutes significantly increased the amount of water removed up to 57% and 22.6 % as compared to the control sample for both 12hrs and 18hrs drying duration respectively (Table 1). This was because blanching causes disruption of cell membranes and a concomitant faster and more complete drying [7]. This implies that with use of blanching, the time of drying can be reduced, and therefore the overall energy consumption.

**Table 1. Effect of Pre-Treatment and drying time on Moisture Content of Dehydrated Paneer**

Pre-treatment	Drying time (hrs)	Final moisture content (% w.b.)	% Reduction in final moisture content in control sample
Control sample (No pre-treatment)	12	15.207	-
	18	7.522	-
Blanching (1 min)	12	11.345	25.4
	18	6.445	14.3
Blanching (2 min)	12	6.522	57
	18	5.825	22.6

### 3.2 Color of paneer cubes associated with different pre-treatments

The drying causes many changes in color of paneer cubes irrespective of any pre-treatments done. TCD for all drying treatments with respect to the control (FD) is reported in Table 2. It was observed that the color of pre-treated paneer cubes was significantly darker (L value) in comparison with fresh paneer cubes. Out of the pre-treated samples, the lowest value for color change was observed in blanching (2 mins) for 18 hrs dried paneer cubes.

*Table 2. Colour Difference of dried paneer cubes after pre-treatments*

Pre-treatment	Drying time (hrs)	Color parameters			
		L	a	b	TCD
Control sample (No pre-treatment)	12	56.53	2.31	17.28	40.62
	18	61.28	3.61	18.64	36.78
Blanching (1 min)	12	60.24	2.9	16.84	39.56
	18	61.2	3.08	17.18	36.24
Blanching (2 min)	12	62.53	3.04	16.75	35.67
	18	63.86	3.15	17.19	33.80
CaCl <sub>2</sub>	12	59.08	3.28	17.85	38.49
	18	60.23	3.2	15.52	36.61
Fresh paneer	-	80.20	1.65	11.01	16.29

### 3.3 Effect of different pre-treatments on RR and moisture content of dried paneer cubes

The values of the RR for the different drying methods dried paneer sample are detailed in Table 3. In all the rehydration trials, there was an initial reduction in the weight of the sample followed by a constant increase. This loss in weight may be due to the fat oozing out in the water during rehydration. This fat loss process might opens pathway and creates space, surface micro-holes and capillaries for more water imbibitions resulting in an increase in the weight. This consolidated, rigid structure leads to the absence of pathways for water access. The RR was slightly higher, affected by CaCl<sub>2</sub> treatment, showing a 3.6% and 9% increase in 12 hrs and 18 hrs dried sample respectively as compared to the control.

**Table 3. Rehydration ratio of Freeze dried paneer for different pre-treatments**

Pre-treatment	Drying time (hrs)	Maximum Rehydration Ratio (RR)	% Increase in RR
Control sample (No pre-treatment)	12	1.12 (after 8 mins)	-
	18	1.11 (after 9.5 mins)	-
Blanching (1 min)	12	1.06 (after 6.5 mins)	-
	18	1.1 (after 10 mins)	-
Blanching (2 min)	12	1.1 (after 10 mins)	-
	18	1.06 (after 3.5 mins)	-
CaCl <sub>2</sub>	12	1.16 (after 5.5 mins)	3.6
	18	1.21 (after 14.5 mins)	9

\*(-) implies no increase in the RR value, either it remains same or decreases.

**Fig. 1 Moisture content after 12 hrs and 18 hrs freeze drying**

From the figure 1, it can be clearly observed that like CaCl<sub>2</sub> can reduce the drying time by 30% as compared to the control sample. This was followed by blanched (1 min) and then by blanched (2min).

#### 4. Conclusions

By comparing the two pre-treatments i.e. blanching for 1 min. 2 min and CaCl<sub>2</sub> dipping for 10 min, it can be concluded that blanching promises to increase more amount of water removal from the paneer cubes. Also, the color loss was least in the blanched dried sample. But for a good rehydration ratio, CaCl<sub>2</sub> proves to be a good pre-treatment as compared to blanching. Moreover, it is more probable that by combining air drying and freeze drying better quality can be achieved in reduced time and energy consumption.

### Abstract

*The aim of this study was to investigate the effects of wall materials types on the production of double-layered and suppressed-pungent capsaicin microparticles via spray chilling method. For this purpose, palm oil and different proteins (gelatin, sodium caseinate and whey protein) were used as wall materials, while soy lecithin was selected as stabilizer. Sample encapsulated only with palm oil (single-layered) was used as control. Centrifuge stability and kinetic stability were analyzed on the prepared emulsions. Total and surface capsaicin, microencapsulation efficiency, melting point temperature and fusion enthalpy analysis were carried out on the capsaicin microparticles obtained by spray chilling.*

**Keywords:** *Capsaicin; Spray chilling method; Pungency; Double-layered microparticles*

---

## **1. Introduction**

Red hot chili peppers from plants of the *Capsicum* genus in the Solanaceae family are the pungent and carmine fruits generally used as spice to give pungent or hot sensation to many dishes. Capsaicinoids, the group of secondary metabolites, are responsible for the pungency of chili peppers. The main compound of the capsaicinoids is capsaicin (8-methyl-N-vanillyl-6-nonenamide) and it has a high bioavailability with a lot of benefits on human health especially on the cancerous cells. In addition, it can relieve neuropathic pains and is used in symptomatic therapy of arthritis, muscle and joint pains. Conversely to its advantages, capsaicin can cause irritation on the human digestive system based on overconsumption. It can induce burning sensation on the mouth, alimentary canal and stomach of people who are more sensitive to pungency. Therefore, microencapsulation of capsaicin with an appropriate method and suppressing of its pungency via the relevant microencapsulation method is important for taking advantages of capsaicin and reducing its negative effects on the human health [1]. Spray chilling method is an alternative technique for microencapsulation of functional components because it serves rapid, easy-to-use and relatively cheap process [2]. Spray chilling technology, which uses oil-based substances as wall materials, has been used increasingly day by day in different industries such as pharmaceutical and food. The objective of the present study was to produce suppressed-pungent capsaicin microparticles by spray chilling method and to investigate the effects of wall materials type on the emulsion stability, physical properties and microencapsulation efficiency of capsaicin microparticles.

## **2. Materials and Methods**

### **2.1. Materials**

Capsaicin (66.7%) (Xian Sobeco Biotech, China) was used as core material. Ethanol (Sigma-Aldrich, Germany) used for dispersing capsaicin. Hydrogenated palm oil was supplied by Felda Iffco (Izmir, Turkey), while refined sunflower seed oil, whey protein isolate, gelatin, sodium caseinate and soy lecithin were obtained by a local market.

### **2.2. Emulsion preparation**

Capsaicin was dissolved in ethanol (1:1) using ultrasonic bath for 10 min. Then, the capsaicin solution was mixed with palm oil containing soy lecithin as a stabilizer. This oily capsaicin mixture was transferred into aqueous protein solution drop by drop under Ultra Turrax homogenizer, worked at 10000 rpm for 3 min. The final mixture was then added into molten palm oil (in circulation water bath at 65°C) and homogenized again at 10000 rpm for 3 min. For control samples, with or without stabilizer, molten palm oil was mixed with ethanolic capsaicin solution and homogenized at the same conditions. Palm oil, gelatin, Na-Caseinate and whey protein isolate were used as wall materials while soy lecithin was used as stabilizer.

The composition of emulsions was given in Table 1, where the concentrations are given as ratios of components in total 200 g final mixture.

*Table 1. The percent composition of emulsions*

Exp. No	Palm oil	WPI	Na-Cas	Gelatin	Soy Lecithin	Sunflower oil	Ethanol	Water	Capsaicin

9	99.4	-	-	-	-	-	0.30	0	0.30

### 2.3. Emulsion stability

Emulsion stability of capsaicin emulsions was evaluated with kinetic and centrifuge stability analysis. In order to analyze the kinetic stability of obtained emulsions, 10 ml of each emulsion was transferred to a test tube and kept in water bath at 65°C for 4 hours. The volume of lower phase measured after 2 hours. The kinetic stability of the emulsions was calculated as sedimentation index via following equation (1):

$$SI = (H_{l@t}/H_i) \times 100 \quad (1)$$

where SI,  $H_{l@t}$  and  $H_i$  indicate sedimentation index, lower phase height at  $t$  time and initial height of emulsion, respectively [3].

The centrifuge stability of samples was measured as follow; 10 mL of emulsion was immediately poured into graduated centrifuge tube and centrifuged at 10000 rpm for 10 minutes. Then the centrifuge stability of the emulsion was calculated by equation (2):

$$CS = (H_l/H_i) \times 100 \quad (2)$$

where CS,  $H_l$  and  $H_i$  indicate centrifuge stability, height of lower phase and initial height of emulsion, respectively [4].

### 2.4. Spray chilling

Capsaicin emulsions fed into the spray chilling system in order to obtain solid lipid capsaicin microparticles. Spray chilling process was carried out by using Bakon-B15 (Izmir, Turkey).

The inlet temperature of cooling air (10°C), the temperature of nozzle (60°C), the feeding temperature (65°C) and air flow rate (10L/min) were kept constant during spray chilling.

#### **2.4. Melting point temperature ( $T_m$ ) and fusion enthalpy ( $\Delta H$ )**

$T_m$  and  $\Delta H$  of capsaicin microparticles were determined by using DSC (Perkin-Elmer DSC 6000, Turkey). For this purpose, 10 mg of capsaicin microparticles was weighed directly into the DSC aluminum sample pan and sealed with a lid. The purge gas was nitrogen (50mL/min) and the temperature ranged from 25 to 90°C with a heating rate of 15°C/min. The data were then processed using Pyris Manager Software (Perkin-Elmer).

#### **2.5. Powder yield**

The powder yield was defined as the ratio between the total collected powder and theoretical powder quantity from the sprayed solution and calculated as shown in equation (3).

$$\text{Powder yield (\%)} = \frac{\text{Powdered capsaicin microparticles(g)}}{\text{Feeding emulsion (g)}} \times 100 \quad (3)$$

#### **2.6. Total and surface capsaicin content and microencapsulation efficiency (ME)**

The total and surface capsaicin contents of the microparticles were determined using high performance liquid chromatography (Shimadzu Corporation, Kyoto, Japan) according to Consoli et al. [3] with some modifications. The chromatography conditions were: 60°C column temperature, 5  $\mu$ l sample volume, 1.5 ml/min flow rate, acetonitrile:water (50:50) mobile phase and 222 nm with UV-detector. Microencapsulation efficiency was calculated by the following equation (4).

$$ME (\%) = (TC - SC/EC) \times 100 \quad (4)$$

where ME, TC, SC and EC indicate microencapsulation efficiency, total capsaicin amount of microparticles, surface capsaicin amount of microparticles and total capsaicin amount in emulsion, respectively.

#### **2.7. Statistical analysis**

All measurements were performed in triplicate. Results are expressed as mean  $\pm$  standard deviations. All results were analyzed using SPSS version 15.0 Windows program (SPSS Inc., Chicago, IL). To observe significant differences between the samples, paired t-test was used at a 5% significance level.

### **3. Results and Discussions**

#### **3.1. Emulsion stability**

The emulsions are thermodynamically unstable systems. Therefore, protein based emulsifiers are mostly used to improve the stability of emulsions. These emulsifiers vary widely in their ability to form and stabilize emulsions depending on their molecular and physicochemical

characteristics [5]. The emulsion stabilities of capsaicin emulsions (emulsion number 1-7) prepared with different wall materials were evaluated as kinetic and centrifuge stability. The stability analysis for control samples (emulsion number 8 and 9) were not performed due to being a dispersion not an emulsion.

Fig. 1 Kinetic stability and centrifugal stability results of capsaicin loaded emulsions

The emulsion stability study revealed that most of the emulsions were kinetically (87.5-100%) and centrifugally (86.75-100%) stable as shown in Fig 1. Consoli et al. [5] also found similar stability results for gallic acid encapsulation with spray chilling method. The emulsion prepared with gelatin was found to be the most stable kinetically while adding Na-Caseinate and whey protein isolate to emulsions resulted in a decrease in kinetic stability. Gelatin has good water holding capacity because the small pore size of the gel network tightly holds water molecules by capillary forces [5]. Therefore, the separation of aqueous phase was prevented in capsaicin emulsions. The results of centrifugal stability of emulsions showed that emulsions prepared with whey protein and gelatin had the highest stability values. Whey proteins are much more rigid as compared to caseins [6]. Therefore, high concentrations of sodium caseinate resulted in low stabilities of emulsions as reported previously [7].

### 3.2. $T_m$ and $\Delta H$

The melting point temperature ( $T_m$ ) and fusion enthalpy ( $\Delta H$ ) of encapsulated capsaicin microparticles were given in Table 2. Adding whey protein into emulsions as wall material resulted in an increase  $T_m$  of the capsaicin particles, while gelatin-containing microparticles had a lower melting point temperature. On the other hand, Na-caseinate did not have a significant effect on the melting point of the microparticles, but it caused higher melting point than that of gelatin-containing microcapsules. As shown in Table 2, melting points of double-layered samples (except 3<sup>th</sup> sample) were calculated lower than that of the single layered sample. It was probably due to the creation of the less ordered structure of the inner structure of the lipid matrix and/or the small size effect which could be explained by Gibbs-Thomson equations [8] Wang et al. [9] reported that microencapsulation of capsaicin decreased the melting temperature. The capsaicin, nanocapsulated with single coacervation in that study [10], melted at 75°C ( $T_m$ ) and absorbed 160.7 J/g energy. In our study, capsaicin was encapsulated with gelatin (single layered) and melting point temperature and absorbing

energy were calculated as 100°C and 199.9 J/g, respectively. Differences between  $T_m$  and  $\Delta H$  values of the previous and the present study can be resulted from the encapsulation form (single or double layered) and encapsulation technique.

### **3.3. Product yield**

The high product yield is one of the advantages of the spray chilling. The product yield values of the samples obtained from spray chilling were reported as over 75% [11]. Product yield of the capsaicin microparticles obtained from spray chilling method in the present study agreed with the data in the literature. Encapsulation form (single or double layered) did not significantly affect the product yield results and the results were in the range of 77-87%. The samples obtained from the emulsions added by whey protein and gelatin had the higher product yields as compared to that of containing Na-caseinate. The lower product yield value of the samples added by Na-caseinate could be resulted from viscoelastic properties and high gelling power of the Na-caseinate. Therefore, caseinate containing emulsions could stick to drying chamber in spray chilling equipment due to its adhesive structure [12].

### **3.4. Total and surface capsaicin contents and microencapsulation efficiency (ME)**

Total and surface capsaicin contents and microencapsulation efficiency results of the capsaicin microparticles were shown in Table 2. The results showed that capsaicin could be effectively encapsulated with the oil-based wall materials and the amount of surface capsaicin could be reduced. In terms of surface capsaicin content, the microparticles had relatively less amounts of capsaicin on their surfaces. Maximum surface capsaicin content was calculated as 2.08 ppm for single layered (only palm oil) encapsulated sample. On the other hand, double layered (palm oil-soy lecithin-whey protein) encapsulated sample showed the best encapsulation efficiency with the surface capsaicin content of 2.04 ppm. Microencapsulation efficiency of the emulsions increased with an increase in whey protein concentration in the emulsions. In addition, microencapsulation efficiency of the emulsions containing gelatin was higher than that of containing Na-Caseinate. This could be attributed to the viscoelastic properties and gelling power of casein. The maximum microencapsulation efficiency of 99.73% was determined for double-layered (palm oil-whey protein) encapsulated sample, while the minimum result was calculated as 80.48% for the samples produced by single-layered (only palm oil) encapsulation. The results showed that the melting point temperatures significantly affected the microencapsulation efficiency of the samples. The microencapsulation efficiency increased with the increasing melting point. In the previous study with ascorbic acid encapsulation by spray chilling [13], palm and palm seed oil (43°C melting point) were used as wall material while soya lecithin was used as stabilizer. The encapsulation efficiency values of the samples varied from 68.2 to 72.5%. Differences in the encapsulation efficiency results of the previous study and the present study can be resulted from the double-layered microencapsulation used in our study.

#### 4. Conclusions

Capsaicin has a high bioavailability with a lot of benefits on human health. However, it is inconsumable for some people because of irritating effect. Therefore, it can be microencapsulated to suppress its pungency. In the present study, capsaicin is effectively microencapsulated by spray chilling technique by using palm oil and whey protein (as wall materials) and soy lecithin (as stabilizer). The encapsulation efficiencies of the whey protein based emulsions were higher than that of the other emulsions. Furthermore, the sensible pungency of capsaicin can be reduced from 40 ppm to 1.71 ppm (the minimum surface capsaicin content) with double-layered microencapsulation by spray chilling. By this way, capsaicin was converted to a suppressed-pungent component that can be consumed by sensitive people.

### **Abstract**

*The present work studies the microbial load reduction in sapota and beet root by three different drying methods i.e. Open Sun Drying (OSD), Solar Conduction Drying (SCD) and a modified SCD with filters (SCDF). Parameters analyzed were water activity, moisture content, drying kinetics, Total Viable Counts, Total Fungal Counts and ash content. It was found that the samples dried in SCDF showed least microbial counts, faster drying times and lower ash content as comparison to OSD. This study shows that SCD and its modification provide a better alternative for low cost drying of fruits and vegetables for quality retention.*

**Keywords:** *Microbial reduction; SCD Filters; Sapota; Beetroot.*

## 1. Introduction

The global dehydrated food market is being driven by lifestyle changes and dietary choices. An increase in nutritional awareness among the consumers is pushing the industries and researchers to develop novel technologies which will increase the shelf-life of the product without compromising the nutrition and quality. As per APEDA [1], India exported 87,279.99 MT of dried and preserved vegetables worth USD 162.88 Million during 2016-17. Though large in volume, there is plenty of scope of improvement in the value.

Small and medium scale producers require low cost dryers which are easily adaptable to a variety of agri-produce.[2] In rural India, where agricultural losses are predominant and there is lack of cold storage facilities, Open Sun Drying (OSD) is followed extensively. The advantages of OSD are simplicity and zero equipment cost. The disadvantages are longer duration of drying, microbial contamination, insect infestation and overall quality degradation.[3] To overcome these disadvantages, many models of solar dryers have been developed.[4] Solar Conduction Dryer (SCD), an indigenously developed Indian technology, is being used by 1500 farmers at household level and micro food processing centers. SCD uses all three modes of heat transfer i.e. conduction, natural convection and radiation. It is electricity-free and completely dependent on solar energy.

Sapota (*Achrassapota* L.) (Family Sapotaceae) commonly known as chiku in India, is an energy rich fruit with high total soluble solids (20-22%), digestible sugars, protein, fat, fiber and minerals.[5] It is perishable and easily susceptible to microbial contamination due to high moisture content (69.05 - 75.7%), and sugar content (11.14 - 20.43%).[6] The fruits are also easily bruised, which leads to wastage.[7] Beetroot (*Beta vulgaris*) is a root vegetable that belongs to the family of Chenopodiaceae. Beetroot is also characterized by high moisture content, an abundance of nutrients and proximity to soil due to which it forms a favorable habitat for microbial contaminants.

The objective of this study is to analyze effect of different drying methods on the microbial quality of sapota and beet root samples. The three drying methods under study are Open Sun Drying (OSD), Solar Conduction Drying (SCD) and SCD with filters at the air inlet (SCDF). The drying kinetics, moisture content, water activity and ash content of the samples are also analyzed.

## 2. Materials and Methods

### 2.1. Sample collection

3 Kg of both Sapota and Beetroot each were procured from a local market in Mumbai. After washing and air drying, fresh samples were sliced into pieces of 4-5 mm thickness. A part of it was analyzed directly as fresh sample and the rest was dried using OSD, SCD and

SCDF. The fresh and dried samples were analyzed for Moisture Content (MC), water activity ( $a_w$ ), Total Viable Count (TVC), Total Fungal Count (TFC) and ash content.

## 2.2. Open Sun Drying (OSD)

Open sun drying was carried out by placing the slices on sheets made up of 12 micron PET (polyethylene terephthalate) + 50 micron LDPE (low density polyethylene). The arrangement was covered by a steel mesh to prevent loss of samples to animals and birds.

## 2.3. Solar Conduction Dryer (SCD)

*Fig. 1 (a) Solar Conduction Dryer; (b) Solar Conduction Dryer with Filters*

SCD, as shown in Figure 1 (a) (top view) consists of 1mx1m tray on which sapota and beetroot slices were loaded and allowed to dry. The surface of the tray provides a temperature of 50-60°C with air velocity in the range of 0.1-0.2 m/s generated due to natural convection (PCT/IN2012/000843). During the experimental days, the relative humidity of surrounding air was recorded to be 52-60 % at 25-30°C (ambient temperature).

## 2.4. Solar Conduction Dryer with Filters (SCDF)

Filter material (Khosla Profil Pvt.Ltd.), is made up of polypropylene with a thickness of 1.35-1.47 mm (+/-8%) and pore size of 0.1 $\mu$  with maximum temperature resistance of 80°C. Filters were placed at both the air inlets of the SCD, as shown in Figure 1 (b) (white coloured filter cloth visible at both open ends of the dryer).

Moisture Content was measured using Shimadzu MOC-120H electronic moisture balance. Water activity ( $a_w$ ) was measured using a LabSwift Novasina water activity meter. Drying kinetics was studied by measuring the weight of the samples at fixed intervals throughout the drying time to determine the drying rate.

The novel part of SCDF is the use of composite filter attached in such a way so as to provide minimal pressure drop. This is ensured by following ergun type equation.[8]

$$\frac{\Delta P}{\frac{1}{2}\rho V^2} = \frac{A}{NRe} \approx 1 \quad (1)$$

The design of filter is in such a way that there is no kinetic head loss and discharge coefficient (C) derived from the equation 1 takes the following form.

$$V = C \frac{\sqrt{2\Delta P}}{\rho} \quad (2)$$

Where C is close to 1.

### 2.5. Microbiological Analysis

The fresh and dried samples of Sapota and Beetroot were subjected to Total Viable Count (TVC) analysis performed by Conventional Plate Count method as recommended by USFDA BAM.[9] Total Fungal Count (TFC) was performed by Pour Plate method as recommended by FSSAI (2012) [10]. The ash analysis was performed as per the method recommended by FSSAI.[11]

## 3. Result and discussion

### 3.1. Drying Kinetics

Fig. 2 (a) Drying Curve for SCD and SCDF Sapota (b) Drying Curve for SCD and SCDF Beetroot

Fig. 3 Drying Curve for OSD Sapota and Beetroot

From Figure 2 and 3 it can be seen that the drying rate of OSD is higher than SCD and SCDF. The time required for drying by SCD and SCDF of Sapota and Beetroot were found to be comparable. Sapota drying required 510 minutes in OSD whereas SCD and SCDF

required 200 and 240 minutes respectively. For beetroot, the drying times for OSD, SCD and SCDF were 456, 180 and 210 minutes respectively. These values indicate that the drying times in SCD and SCDF are almost half as that of OSD. The drying curves showed a falling-rate period and constant rate period was not observed.[12]

### 3.2. Water activity and Moisture Content

As seen in Table 1, the  $a_w$  of fresh samples of both Sapota and Beetroot was found to be above 0.9. The  $a_w$  of the OSD was found to be marginally higher than 0.6, whereas that of SCD and SCDF was found to be well below 0.6. An ANOVA: Single Factor Test revealed significant difference in the means of  $a_w$  [F(3,8) = 2569.5 , p = 1.59E-09] and MC [F(3,8) = 181.5, p = 4.29E-06] of OSD, SCD and SCDF sapota samples at 5% level of significance. Significant difference was observed in the means of  $a_w$  [F(3,8) = 27289.3 , p = 1.33E-12] and MC [F(3,8) = 10.21, p = 0.012] of OSD, SCD and SCDF beetroot samples. OSD samples showed higher  $a_w$  and MC values as compared to SCD and SCDF. This is due to the temperature difference the food product experiences i.e. 28-30°C for OSD and 50-60°C for SCD and SCDF leading to higher equilibrium moisture content in OSD samples.

Table 1. Mean  $\pm$  SD of Sapota and Beetroot water activity ( $a_w$ ) and % Moisture (on wet basis)

Sample (Sapota)	Water activity ( $a_w$ )	% Moisture (wb)	Sample (Beetroot)	Water activity ( $a_w$ )	% Moisture (wb)
Fresh	0.936 $\pm$ 0.003	69.6 $\pm$ 1.34	Fresh	0.951 $\pm$ 0.001	88.4 $\pm$ 2.61
OSD	0.702 $\pm$ 0.009	5.4 $\pm$ 0.35	OSD	0.625 $\pm$ 0.002	12 $\pm$ 2.89
SCD	0.341 $\pm$ 0.002	1.2 $\pm$ 0.49	SCD	0.407 $\pm$ 0.002	5.4 $\pm$ 0.98
SCDF	0.391 $\pm$ 0.0007	4.8 $\pm$ 0.28	SCDF	0.301 $\pm$ 0.001	6.2 $\pm$ 1.55

### 3.3. Effect of Drying methods on Total Viable Counts (TVC) and Total Fungal Counts (TFC)

Fig. 4 Total Viable Count of Sapota and Beetroot fresh and dried samples

The results for TVC and TFC of Sapota and Beetroot are shown in Figure 4 and 5. The comparison of the log reduction in TVC and TFC is given in Table 2. The highest log reduction is found in TVC for SCD and SCDF in beetroot followed by sapota. SCDF performs better in terms of higher log reduction in both sapota and beetroot samples as compared to SCD. Both SCD and SCDF show close to 1 log reduction for TVC counts in beetroot. Previous studies have reported reduction in food microbial counts due to use of thermal drying techniques. Rahman et al. (2000) reported decimal reduction time (time required for 1 log reduction) of 12.66 hrs for drying of Tuna mince at 60°C which decreased up to 2.63 hrs as the drying temperature was increased to 100°C. [13]

Fig. 5 Total Fungal Count of Sapota and Beetroot fresh and dried samples

Table 2. Comparison of log reduction in the TVC and TFC values of OSD, SCD and SCDF

Sample	Drying Method	TVC Log reduction	TFC Log reduction
Sapota	OSD	0.378	0.072
	SCD	0.514	0.146
	SCDF	0.705	ND
Beetroot	OSD	0.685	0.180
	SCD	1.041	0.308
	SCDF	1.092	0.407

### 3.4. Ash Content

Fig. 6 Ash content (g/100g) (dry basis) in Fresh, OSD, SCD and SCDF samples

Ash content of a food sample represents the inorganic residue which remains after complete oxidation of the organic matter.[14] All the three drying processes are solar-based, hence ash content helps to measure the inorganic content added in the sample during drying either due to settling of dust, sand or extraneous matter from the environment. As seen in Figure. 6, ash content is highest in OSD samples (completely exposed), followed by SCD (partially covered) and the least in SCDF (filter protected) samples.

### 3. Conclusions

SCD and SCDF showed better product quality with respect to drying time, microbial load reduction and lower ash content as compared to OSD. SCD and SCDF could attain 1 log reduction with a decimal reduction time of 180 mins and 200 mins respectively. The addition of filters to the current design of SCD showed lowered microbial counts as compared to SCD. OSD is currently extensively used by low-income farmers and producer groups. SCD and its modification with filter has the potential to replace open sun drying as a cheap and efficient process without compromising the product safety and quality.

### 4. Nomenclature

OSC	open sun drying	
SCD	solar conduction drying	
SCDF	solar conduction drying with filter	
TVC	total viable count	
TFC	total fungal count	
$a_w$	water activity	
MC	moisture content	Pascals
P	pressure drop	m/s
V	velocity of air	
$NR_e$	air flow Reynolds number	
A	constant in laminal flow	

Greek letters

$\rho$	Density	$Kg/m^3$
--------	---------	----------

### **Abstract**

*In this paper, a fluidized bed with a adjustable slotted gas distributor was used to study fluidization in a 230 mm×200 mm rectangular fluidized bed by adjusting the spacing between the two slotted gas distributors. The pressure drop of the distributor at different inlet gas velocities was obtained and the change law between pressure drop and distance between distributors was summarized. This study provides a theoretical basis for the application of adjustable slotted gas distributor fluidized bed.*

**Keywords:** Geldart D; Adjustable slotted gas distributor; Pressure drop

---

## 1. Introduction

Fluidized bed was used in various chemical units, which was common in the production processes of agricultural products, food, pharmacy, biochemistry and so on. It can strengthen the contact and transfer between the fluid and the particles <sup>[1-3]</sup>, which was characterized by good gas-solid mixing, high mass transfer and heat transfer rate, uniform bed layer and strong controllability.

Among them, the most widely used gas-solid fluidized bed was mainly composed of bed, gas distribution device and gas-solid separation device (mostly a cyclone separator). In these parts, the most important part of the whole fluidization operation was the gas distribution device, that is, the gas distributor. The study found that there were many differences between the area near the distributor and the main body of the bed, and more and more attentions had been paid to the distributor <sup>[4]</sup>. The distributor should have a certain pressure drop so that the gas can be evenly distributed. Usually, the pressure drop of the distributor is greater than 1/10 to 3/10 of the total bed pressure drop. But in practical operation, the pressure drop of the distributor is as small as possible to reduce the energy consumption, and sometimes it is designed around 5% of the total bed pressure drop of <sup>[5]</sup>. A gas distributor that can perform well fluidization operation should be able to achieve uniform distribution of gas, low energy consumption, no leakage and clogging, convenient operation and long service life.

The distributor used in various applications were various. The original gas distributor was porous distributor, that is, the holes with the same diameter were distributed on the distributor. With the development of fluidization technology, more and more distributors were applied in the actual operation. Zhao et al. <sup>[6]</sup> used a tubular gas distributor to study the fluid dynamic behavior in an internal circulating fluidized bed. Chen et al. <sup>[7]</sup> used tilted gas distributor to investigate the depth of the distributor jets in a gas-solid fluidized bed. Hassan et al. <sup>[8]</sup> used porous gas distributor and tubular gas distributor to numerically study the solids circulation flux in an internal circulating fluidized bed.

At present, the distributor design was mainly composed of a single-layer distributor, and was often applied only to one type of material in the operation processes or the applicable materials had a narrow range of particle size distribution, it cannot be automatically adjusted according to operation requirements, without adequate consideration of the pressure drop of the distributor, the energy consumption was large.

The purpose of this study was to use a self-developed adjustable slotted gas distributor<sup>[9]</sup> for empty bed fluidization experiments. The pressure drop of the distributor at different inlet gas velocities were obtained, and the change law between pressure drop and distance

between distributors was summarized. It provided a theoretical basis for the application of adjustable slotted gas distributor fluidized bed.

## 2. Experimental

### 2.1. Experimental process and equipment

The experimental process is shown in Fig. 1. The gas generated by the blower was regulated by the bypass valve. The flow rate was shown by the gas flowmeter (VA300 type, flow rate 2~600 m<sup>3</sup>/h, German CS Instruments). After that, it entered a rectangular fluidized bed (homemade, 230 mm×200 mm) equipped with an adjustable slotted gas distributor (opening rate 6%). There were two pressure measuring points on the bed, all along the axial direction of the fluidized bed, respectively 30 mm below the distributor and 30 mm above the distributor. Differential pressure transmitter (TRD-150205A, measuring range 0~1500 Pa, Tianjin Run Da Zhong Ke Instrument Co., Ltd.) was connected to two pressure measuring points through the trachea to measure the pressure drop of the distributor. The data recorded by the paperless recorder (TRD-21R, Tianjin Run Da Zhong Ke Instrument Co., Ltd.).

*Fig. 1 Experimental flow chart.*

A self-designed fluidized bed with a adjustable slotted gas distributor was used in the experiment. The distributor was made up of two slotted gas distributors. As shown in Fig. 2, the upper distributor size was 340 mm×220 mm, the slit area size was 220 mm×190 mm, the distributor opening rate was 6%, the number of the angle steel was 6, the side length of the angle steel was 23 mm, the distance between the angle steel was 2 mm and the height of the angle steel was 16 mm. As shown in Fig. 3, the lower distributor size was 220 mm×190 mm, the distributor opening rate was 6%, the number of the angle steel was 6, the side length of the angle steel was 23 mm, the distance between the angle steel was 2 mm and the height of the angle steel was 16 mm. Two distributors were connected by two guide components. The upper distributor was bolted to the bed. The lower distributor can move up and down under the guidance of the guide rail, so as to achieve the effect of adjusting the distance between distributors.

Fig. 2 Upper distributor.

Fig. 3 Lower distributor.

## 2.2. Experimental method

The adjustable double-layer slotted gas distributor was connected to the fluidized bed with different distance between distributors ( $d$ ) (0 mm, 10 mm, 20 mm, 30 mm and 40 mm). The pressure transmitter was connected to the bed through the trachea and the pressure transmitter was connected to the paperless recorder. Open the blower, open to maximum and gradually reduce the opening, control the gas flow from the maximum  $310 \text{ m}^3 / \text{h}$  to become smaller and keep the open interval of  $10 \text{ m}^3/\text{h}$ . The recording interval of the paperless recorder was 1s, each interval recorded for 60 s. The average value was the pressure drop ( $\Delta P$ ) of the empty bed under the corresponding gas velocities ( $v$ ). Each group of experiments was repeated 3 times and the average value of the data was taken.

## 3. Result and discussion

### 3.1. Influence of distance between distributors on pressure drop

The pressure drop of the distributor was the pressure loss caused by the gas passing through the distributor. Fig. 5 showed the relationship between pressure drop and gas velocity of an adjustable slotted gas distributor under different distance between distributors. It can be seen from the figure that the pressure drop of the distributor increased with the increase of gas velocity, while the pressure drop of the distributor was different at different distance between distributors. When the spacing between the distributors was 0 mm, that was, when the two distributors were almost close, the pressure drop produced by gas passing through the distributor was large and the pressure drop value was close to the 20 mm spacing. It was considered that when the distance between distributors was too small, the flow area between the plates was too small, so the pressure drop was larger. When the distance between the distributors gradually increased from 10 mm to 40 mm, the pressure drop of the distributor increased with the increase of the distance between the distributors at different gas velocities. This was because when there was a certain space between two distributors. The gas needed to consume more energy when it flowed through the space area, so it produced a certain pressure drop.

Fig. 4 Variations in pressure drop at different distance between distributors

### 3.2. Influence of gas velocity on pressure drop.

Fig. 5 showed the relationship between pressure drop and distance between distributors when the gas velocity was 1.59~2.06 m/s, that was, when the gas velocity was large. It can be seen from the figure that when the distance between distributors was the same, the difference between the pressure drops of the distributors corresponding to the adjacent gas velocity were not differ much as the gas velocity decreased, and the difference was approximately 50 Pa. Fig. 6 showed the relationship between pressure drop and distance between distributors when the gas velocity was 0.07 to 0.53 m/s, that was, when the gas velocity was small. It was clearly showed in the figure that when the distance between the distributors was the same, the difference between the pressure drop of the distributor corresponding to the adjacent gas velocity was also decreasing with the decrease of the gas velocity and the difference reduced from 20 Pa to 5 Pa. This was because when the gas velocity was small, the gas flow was relatively stable, so when the gas velocity changed, the pressure drop had a smaller change.

Fig. 5 Influence of pressure drop on distributor when gas velocity was 1.59~2.06 m/s

Fig. 6 Influence of pressure drop on distributor when gas velocity was 0.07~0.53 m/s

### 3.3 Experimental design analysis

It can be seen from Fig. 5 and Fig. 6 that except for the distance between distributors was 0 mm, at the same gas velocity, when the distance between the distributors increased from 10 mm to 40 mm, the change of the pressure drop of distributor showed a trend of linear function. Furthermore, under different gas velocities, the gradient of the pressure drop was approximately the same. This showed that the influence of the spacing between the distributors on the pressure drop was regular. In this paper, the results of orthogonal test were analyzed by Minitab software.

#### 3.3.1. Intuitionistic analysis

Fig. 7 showed the mean main effects plot. It can be seen from the figure that the gas velocity had a significant effect on the pressure drop of distributor and the shape of the image was roughly a parabola. This showed that when the gas velocity was small, the gas velocity had little effect on the pressure drop, but as the gas velocity increased, the impact became greater. This further proved the previous conclusion.

Fig. 7 Main effects plot.

## 3.3.2. Regression analysis

Table.1 Regression analysis

Term	Coef	SE Coef	T-Value	P-Value	VIF
Constant	42.85	5.75	7.46	0.000	
v	-5.79	8.08	-0.72	0.475	20.16
d	-0.559	0.193	-2.90	0.004	3.82
v*v	206.25	3.29	62.71	0.000	15.16
d*v	2.230	0.161	13.85	0.000	8.82

Use Minitab statistical software to perform linear regression analysis on this orthogonal test. The results of the analysis were shown in Table. 1. By analyzing the above data, it can be seen that the self-interaction item of gas velocity had the most significant effect on the pressure drop, followed by the interaction term of the gas velocity and distance between distributors. In the regression analysis, the P value corresponding to the gas velocity was 0.475, which was significantly greater than 0.05. Therefore, the impact of gas velocity on the distributor was not significant. Through the regression analysis, the regression equation of the distributor pressure drop was also obtained:

$$\Delta p = 42.85 - 0.559d - 5.79v + 206.25v^2 + 2.230d \cdot v \quad (1)$$

## 4. Conclusions

A self-designed adjustable slotted gas distributor was used to carry out fluidization experiment. The results showed that when the distance between distributors was 0 mm, pressure drop generated by the gas through the distributor was large. When gas velocity was 2.09 m/s, pressure drop can reach 1040 Pa and pressure drop value was similar to when the spacing was 20 mm. When distance between distributors gradually increased from 10 mm to 40 mm, pressure drop of the distributor increased with increase of spacing at different gas velocities. However, when gas velocity was low, the difference between pressure drop corresponding to the adjacent gas velocity decreased with the decrease of the gas velocity. Through the experimental design analysis, it was concluded that the self-interaction of gas velocity had the most significant effect on the pressure drop, and the fitting relationship between pressure drop, gas velocity and distance between distributors was obtained:  $\Delta P = 42.85 - 0.559 d - 5.79 v + 206.25 v^2 + 2.230 d \cdot v$ .

### Abstract

*In this paper, the effect of spray droplets on the coating of cold spherical particles was studied. The microcapsule granulator produces micron-sized droplets to coat the spherical particles in cold storage, and the high-definition camera and precision balance are used to photograph and weigh the particles before and after the spraying. The droplets are obtained by using the image and data processing technology coating area and coating quality, the droplet coating effect was evaluated by a number of dimensionless parameters such as coating ratio and mass ratio. By orthogonal design experiment and uncertainty analysis, the effects of droplet size and flow rate, spherical particle temperature and diameter on coating effect were studied, and the effect of droplet group coating on low temperature spherical particles was obtained.*

## 1. Introduction

Since 1948, when Benson et al. first used the technique of spray freezing to study the surface area of protein particles <sup>[1]</sup>, this technology has been developing for more than 60 years and has obtained some representative research results. For example, in 1964 Werly used spray-frozen technology to obtain submicron powder products, marking that the spray freezing technology has been developed to the stage of producing products <sup>[3]</sup>; in 1989, Chen Zuyao and others first prepared Ba-Y by means of SFD method. Cu-O system composite oxide ultrafine powder <sup>[2]</sup>; 1994, the technology applied for a European patent; in 1998, Maa et al. proposed the preparation of protein microspheres using SFD technology for the first time <sup>[5]</sup>; in 2006, it achieved regular freezing. Dry alternative to vacuum freeze-drying reduces the energy consumption of SFD technology <sup>[6]</sup>. After more than half a century of development, SFD technology is gradually maturing, and it has been applied in the fields of medicine, food, chemical products, and biological products <sup>[7]</sup>.

In order to solve the phenomena of agglomeration of powders, non-uniform powder particle size and other phenomena, to further improve the application of spray freeze-drying technology in engineering practice and achieve mass production, Li Zhanyong et al <sup>[4]</sup>proposed an inert particle fluidized bed spray freeze-drying Equipment. In order to deeply study the freezing mechanism of atomized droplets impacting the carrier particles, this paper studied the coating area of cryogenic spherical particles by droplets in experiments.

## 2. Materials and Methods

### 2.1. Experimental Materials

Since the coated particles were image-collected after the coating experiment, in order to facilitate the image processing, the material used in this experiment was ink. The inert carrier particles use different diameters of organic glass spheres. The effects of different experimental conditions on the droplet coating process were experimentally studied. By setting different flow rates of 6 and 8 mL/min, atomized droplets of diameter 0.2 mm were obtained. The diameters of the glass spheres were taken as 3, 4 and 5 mm, respectively. Each set of experiments was performed 3 times.

### 2.2. Experimental device

The droplets are generated by a Droplets generator, which uses laminar liquid jets and vibrates at high frequencies to produce extremely uniform round microcapsule particles as shown in Figure.1. Applied to the protection and storage of drugs, microorganisms,

enzymes or cells, the purpose of microencapsulation is to use a polymer mechanism to protect or stabilize the active ingredient, and it can also be used to produce uniform atomized droplets. The device can generate highly reproducible uniform drop particles whose particle size can be pre-set to 0.2 mm depending on the choice of nozzle, with a narrow particle size distribution (<5% standard deviation).

*Fig.1 Droplets generator*

For this study, the collision process of atomized droplets impinging on a solid surface at a temperature of  $-25\text{ }^{\circ}\text{C}$  was studied. Such a low degree of subcooling metal particles at room temperature, the water vapor in the air quickly frozen on the metal surface to form ice, change the structure of the particle surface structure impact on the droplet collision process. In this experiment, a freezer (Haier Company) was used as a cooling space. Its cooling range was as low as  $-50\text{ }^{\circ}\text{C}$ . The internal dimensions of the refrigerator were 100 cm in length, 70 cm in width, and 60 cm in height. The top has a 12 cm diameter feed hole.

### **2.3 Experimental parameters**

The experimental data image was processed by Image J software, and the projected area of the coating liquid film was calculated by converting the image into a grayscale image and pixel scanning to obtain the ink coating area. As shown in Figure. 2.

(a) Total area of coated projection  $S_1$       (b) After coating area removed  $S_2$

**Fig.2 Coated image after processing**

Coating area:

$$S = S_1 - S_2 \quad (1)$$

The  $S_1$  refers to the total area of the projection of the projection, and the  $S_2$  refers to the projection area after the removal of the particles.

Coating ratio:

$$c = \frac{S}{n \times \pi r^2} \times 100\% \quad (2)$$

The  $n$  refers to the number of particles, and  $R$  refers to the radius of the particles.

Coating amount:

$$M = (M_1 - M_2) - (m_1 - m_2) \quad (3)$$

In the formula,  $M_1$  refers to the total mass after coating,  $M_2$  refers to the total mass before coating,  $m_1$  refers to the mass of the empty disk after coating, and  $m_2$  refers to the mass of the empty disk before coating.

### 3. Results and Discussion

#### 3.1 Effect of Particle Diameter Change on Coating

The background of the experimental study in this paper is the collision and coating of atomized droplets with fluidized, undercooled carrier particles. For this reason, it is of great significance to investigate the influence of particle diameter on the coating area of droplets.

In this experiment, 0.5, 1, 2, and 3 g of ink were coated on glass balls with diameters of 3, 4, and 5 mm at a flow rate of 6 mL/min and 8 mL/min, respectively, of droplets with an average diameter of 0.2 mm. Study the change in coated area with ball diameter.

(a) flow rate of 6mL / min

(b) flow rate of 8mL / min

Fig. 3 Variation of coating area and coating ratio with spray amount for different particle sizes under two flow rates

As shown in Fig. 3(a), at a spray flow rate of 6 mL/min, from the start of spraying to when the spray amount reaches 1g, the coating rate hardly varies with the diameter of the particles, the coated area of the particles is basically the same, and the coating ratio is about 40 %, when the spray amount is 1-2 g, the particle diameter increases, the coating rate decreases, from 2-3 g, the particle diameter increases, the coating rate increases, but when the spray amount is 3 g, three kinds The coated area of the particles is substantially the same, and the coating ratio reaches 70 %. As shown in Fig. 3(b), at a flow rate of 8 mL/min, from the start of spraying to when the spray amount reaches 1 g, the particle diameter increases, the coating rate gradually increases, and the particle diameter increases from 1-3 g. Increasing, the coating rate decreases. However, when the spray amount was 1.5 g, the

coating area of the three particle sizes was substantially the same, and the coating ratio was about 55 %.

Fig. 4 Change of coating amount with spray amount under different flow rate and different particle size

As shown in Fig. 4(a), at a spray flow rate of 6 mL/min, the coating amount increases as the amount of spray increases, coating of 3, 4 mm particles is almost the same, but the coating amount of 5 mm particles is apparently seen. It is much smaller than other diameter particles. As shown in Fig. 4(b), at the spray flow rate of 8 mL/min, the spraying amount of the three kinds of particle granules was basically the same from the beginning of the spraying to 2 g, and after 2 g, the particle diameter increased, and the coating was applied. The amount increases.

### 3.2 Influence of Change in Atomization Flow Rate on Coating

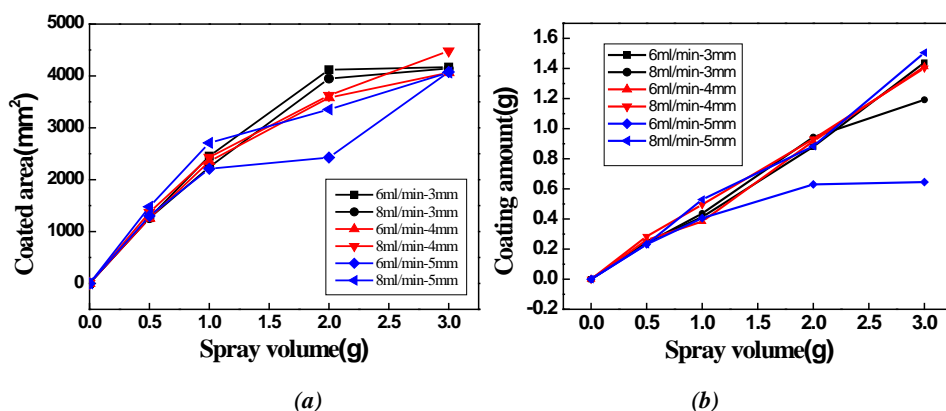

Fig. 5 Change in Coating Area with Spray Volume

As shown in Fig. 5(a), when the particle diameter is 3 mm, the coated area under the two flow rates shows almost the same change trend; when the particle diameter is 4mm, the coated area at 8 mL/min is slightly larger than 6 mL/min when the same spray amount is applied; When the particle diameter is 5mm, the coating area under 8 mL/min conditions is much higher than 6 mL/min under the same spray amount condition, but when the spray amount reaches 3 g, the coated area is the same. It can be seen that when the particle diameter is small, the flow has little influence on the coating. As the particle diameter increases, the influence of the flow on the coating increases, and the larger the flow, the larger the coated area. As shown in Fig. 5(b), when the particle diameter is 3 or 4 mm, the coating amount is basically the same with the variation of the spray amount at different flow rates; with a particle diameter of 5 mm, the coating flow rate of 6 mL/min is much lower than the flow rate of 8 mL/min.

From the above two figures, it can be seen that the particle diameter has a significant effect on the coating. When the particle diameter increases, the curvature of the particle surface decreases, so that the droplets are likely to accumulate on the surface of the particles, so that the coating area is reduced; when the flow rate increases At that time, the influence of the curvature of the particles on the coating is reduced, because the kinetic energy of the spray droplets increases, so that the droplets spread more, so that the influence of the curvature of the particles is reduced.

#### 4. Conclusions

When the spray flow rate is 6 mL/min, the particle diameter has little effect on the coating when the spraying starts to 1 g. With the progress of the coating, the larger the particle diameter, the smaller the coating rate; when the spray flow rate is 8 mL /min, the larger the particle diameter before the coating ratio is 55%, the larger the coated area, and the larger the particle diameter and the smaller the coated area after the 55% coating ratio.

With the same amount of spray, as the particle diameter increases, the flow rate increases and the coating area increases, but when the spray amount reaches 3 g, the coated area is almost the same; when the particle size becomes larger, the spray flow increases. The coating amount increases.

### **Abstract**

*A combination of high power airborne ultrasound and microwaves in hot air drying was developed to investigate the effect of intermittent mode on process effectiveness and quality of carrot. The drying experiments were carried out in an innovative hybrid dryer. The course of moisture ratio, drying rate, specific energy and water consumption, colour, water activity and shrinkage were discussed. The results showed that intermittent ultrasound and microwaves in convective drying accelerate the heat and mass transfer, leading to shorter drying time and faster drying rate. It was found that hybrid-intermittent drying can improve the energy efficiency and product quality.*

**Keywords:** *intermittent drying; ultrasound; microwaves; energy; shrinkage.*

---

## 1. Introduction

Current trends in industrial equipment design or engineering in general place emphasis on the ecological aspect of production. Drying as a food processing method is particularly a good field for engineers and scientists to implement new or improve existing designs. Its most widely used method, hot air drying, is notorious for its bad energy efficiency (a result of constant drying agent replacement, necessary to finish the process) and long drying time.<sup>[1]</sup> What is more, consumers' dietary knowledge is on the rise, which means that product quality should be taken into consideration as well. In that matter, convective drying also has its drawbacks, as it has a substantial impact on the dried foodstuffs' appearance, flavor and nutrients content.<sup>[2]</sup> In latest years some ideas how to improve drying and driers have been reported. Among others, they include hybrid techniques and drying at non-stationary (intermittent) conditions. Former's principle of operation is a simultaneous use of two or more drying methods (heat sources), such as hot air and microwaves. In such a way, different mechanisms of energy transfer are employed, what makes the drying process faster and more energy-efficient. Latter, is based on providing a variable amount of heat during the process, so there are periods of intensive evaporation and so called *relaxation*, when moisture and temperature gradients inside the dried material are reduced. That results in reduction of thermal energy and better product quality, however it may also increase the drying time.<sup>[3, 4]</sup>

In this research, carrot was selected to be an example of a foodstuff. Its distinctive orange color and shape, good nutritious value (content of dietary fiber, vitamins A, K, B6, carotenoids, lutein, zeaxantin) allowed it to take a place in various cuisines.<sup>[5, 6]</sup> Carrots are consumed in various forms, for example raw, boiled, soups, juices or even a cake. Furthermore, when dried, it can be used as an ingredient for dried vegetable mixes. In this paper, a novel drying technique involving hybrid methods in intermittent conditions is investigated. Both of those concepts examined alone proved to improve all three of crucial properties of drying: kinetics, energy consumption and product quality.

## 2. Materials and Methods

Carrot roots (*Daucus carota*, var. Nantes) used for the drying experiments were purchased from a local market and stored for at least 24 h at 4°C. Before drying, the carrots were rinsed, peeled and cut into cubes (1.5 cm side). Next, 50 g carrot samples were dried in a hybrid dryer<sup>[7]</sup>, using eight different drying programs (Fig. 1).

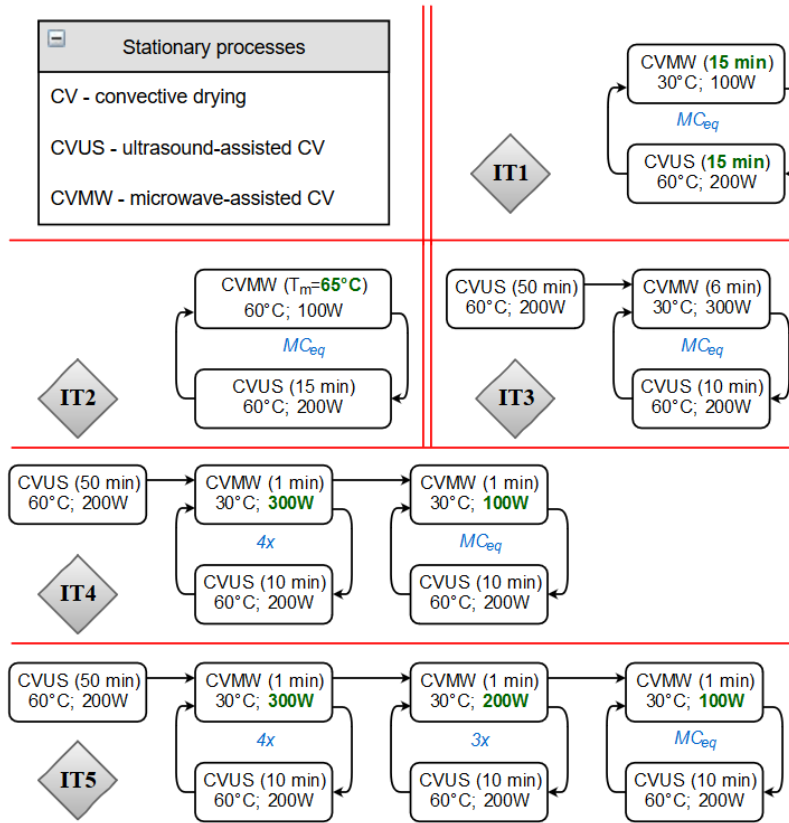

Fig. 1. Schematic illustration of the course drying programs used in the studies:

$T_m$  – material temperature,  $MC_{eq}$  – equilibrium moisture content,  $4x$  – number of loop repetitions.

The drying processes were realized in stationary and non-stationary conditions. The stationary ones (CV, CVMW, CVUS) were conducted at the same air temperature ( $T_a=60^\circ\text{C}$ ) with a constant air velocity ( $v_a=2\text{ m/s}$ ), and with a changeless microwave or ultrasound power ( $P_{mw}=100\text{ W}$  – CVMW;  $P_{us}=200\text{ W}$  – CVUS). The intermittent processes (IT1-5) were carried out in variable drying conditions (Fig. 1).

## 2.1. Process kinetics and energy consumption

The drying kinetics was assessed on the basis of the moisture ratio (MR), drying rate (DR), drying time (DT) and the specific energy consumption (SEC). The moisture ratio (MR) was determined from the following equation:

$$MR = \frac{MC_t - MC_{eq}}{MC_i - MC_{eq}} \quad (1)$$

where:  $MC_i$ ,  $MC_t$  and  $MC_{eq}$  are the initial, instantaneous (for a given time of the process) and equilibrium moisture content.

The initial moisture content ( $MC_i$ ) of the carrot was determined with the moisture analyzer (XM120; Precisa, Switzerland; precision 0.01%). The equilibrium moisture content ( $MC_{eq}$ ) was constant during the research and equaled 0.05 kg·kg<sup>-1</sup> db. The moisture content at a given time of the process ( $MC_t$ ) was expressed as the ratio of moisture mass to the initial mass of wet sample. The energy consumption was measured with a standard electricity meter (precision 0.01 kWh) and recalculated to MJ per kg of evaporated moisture (SEC). Because some devices in the drying system require tap water as a coolant, the specific water consumption (SWC), that is dm<sup>3</sup> of water per kg of evaporated moisture, was also measured.

## 2.2. Quality assessment

The product quality was assessed on the basis of water activity, color, volumetric shrinkage and apparent density. The color of the fresh/dry carrot was measured with the use of colorimeter (CR400; Konica Minolta, Japan; precision 0.01). For this purpose, several randomly chosen (fresh/dried) samples were ground in a laboratory mill (A11; IKA; Germany). On the basis of the obtained CIE Lab tristimulus color coordinates ( $L^*$ ,  $a^*$ , and  $b^*$ ), the relative color change (dE) was determined:

$$dE = \left( dL^{*2} + da^{*2} + db^{*2} \right)^{0.5} \quad (2)$$

where:  $dL^*$ ,  $da^*$  and  $db^*$  are the differences between particular color coordinates ( $L^*$ ,  $a^*$ ,  $b^*$ ), obtained for the raw and dry material, respectively.

The water activity ( $a_w$ ) was measured for fresh/dried samples with the use of laboratory aw meter (LabMaster-aw; Novasina, Switzerland; precision 0.001) at constant temperature of the chamber (25°C). The volumetric shrinkage of the carrot samples (VS) was determined with the use of modified toluene method developed by Mazza.<sup>[8]</sup> The volumetric shrinkage was calculated with the following equation:

$$VS = \left( 1 - \frac{V_d}{V_0} \right) \cdot 100\% , \quad (3)$$

where:  $V_d$  and  $V_0$  are the volumes of dry and fresh sample, respectively.

### 3. Results and discussion

#### 3.1. Drying kinetics, energy and water consumption

In Figure 1, the evolution of moisture ratio (MR) and the average drying rate (DR) for different drying processes were presented.

Fig. 1. Evolution of moisture ratio MR (a) and the average values of drying rate DR (b).

As follows from figure 1, the convective drying (CV) was the slowest drying procedure and lasted about six hours. The application of microwave radiation during convective drying reduced the overall drying time by 85%, as compared to CV. In turn, the ultrasound assistance in convective drying (CVUS) improved the drying kinetics, shortened the drying time by 32%, and increased the drying rate by about 30% in comparison to CV. The total drying time for the samples dried by IT processes was in the range of 1-4 hours. Therefore, hybrid drying with intermittent MW and US application enabled to achieve the desired effect, i.e. increase in process efficiency.

Figure 2 shows the specific energy (SEC) and water consumption (SWC) for different drying strategies. The highest electric energy consumption was observed for CVUS, and the lowest for CVMW (Fig. 2a). Satisfactory results were obtained for intermittent drying. But the differences between the total energy consumed in the IT1-5 procedures were dependent on both durations of MW and US application. In turn, as follows from figure 2b, the longer MW radiation time the more water consumed in the drying process. The IT2-5 methods are characterized by much smaller and similar values of SWC than CVMW and IT1, which is a very positive effect. It means also, that modification of convective-microwave drying into intermittent mode ensures less water consumption.

Fig. 2. Specific energy consumption SEC (a) and water consumption SWC (b).

### 3.2. Quality characteristics

After drying the carrot samples were assessed in terms of water activity ( $a_w$ ), color change ( $dE$ ), volumetric shrinkage (VS) and apparent density ( $\rho_a$ ). Figure 3a presents the water activity of raw and dry material. As follows from this graph the  $a_w$  value was reduced from about 0.989 (for fresh carrot root) to on average 0.333 for dry products.

Fig. 3. Water activity  $a_w$  (a) and relative color change  $dE$  (b).

According to Labuza et al.<sup>[9]</sup>, when the water activity is below 0.4 the dried products are stable in terms of the growth of bacteria, yeast and molds, and natural decay processes (e.g. non-enzymatic browning).

As follows from the data presented in figure 3b, the highest and the lowest relative color change was obtained for the samples dried by intermittent methods (IT3 and IT5 respectively). However, the other samples did not differ significantly, among specific drying programs, i.e. stationary and non-stationary. The exception is CVMW, for which the color change was close to those of IT.

The next quality factor assessed in the studies was volumetric shrinkage (Fig. 4a). On the basis of the results, it was found that the carrot samples dried by CV and CVUS shrank by 85%, on average. In turn, the rest of the samples dried by CV combined with MW, were characterized by a lower shrinkage. This effect results from the so-called “puffing”. The best shape retention was observed for the IT3 samples, but the value of VS is also fairly high. These results were confirmed by calculation of additional value, i.e. apparent density  $\rho_a$  (Fig. 4b).

**Fig. 4. Volumetric shrinkage VS (a) and apparent density  $\rho_a$  (b).**

The highest value of  $\rho_a$  was observed for the CVUS drying whereas the lowest value of  $\rho_a$  was observed for the IT3 drying. Lower values of  $\rho_a$  means higher total volume of the sample, and thus a lower shrinkage after drying. Furthermore, a lower value of the apparent density means that dry sample is characterized by higher porosity (assuming same mass of samples). Therefore, the results of volumetric shrinkage and apparent density demonstrated, that the final physical and microstructural properties of the carrot samples depend on the drying technique and are better for simultaneous MW and US application in convective drying.

## 4. Conclusions

The results showed that intermittent ultrasound and microwaves in hot air drying improve significantly the process efficiency as compared to the CV drying. Furthermore, it was demonstrated that intermittent drying can reduce both energy and water consumption as well as improves the quality of dry carrots. Adequate choice of process parameters positively affects the product color and its physical properties such as lower shrinkage (shape retention) and higher porosity.

---

### **Abstract**

*The residence time distribution (RTD) in a pilot plant spray dryer was characterised for two kinds of air distributors (centrifugal and parallel flow) and for different atomizing air pressures. To determine the RTD - and the RTD of different particle size fractions - the particle concentration and size at the dryer outlet was measured continuously using a particle counter. Results were modelled using the Bodenstein number and the CSTR in series model. An increasing nozzle pressure leads to a decrease in mean residence time and a more narrow distribution. The influence of nozzle pressure is more pronounced than of air distributor and particle size fraction.*

**Keywords:** *Residence time distribution; Particle size; Bodenstein number modelling; Nozzle influence; Mechanism of air distribution*

---

## 1. Introduction

The drying behaviour in a classical spray dryer is determined by the nozzle zone, where the first contact between the hot gas and the product occurs, as well as by the main drying within the drying chamber. In order to describe the drying process, knowledge of the residence time distribution is needed. In addition to the mechanism of air distribution, this is dependent on the nozzle flow and the geometry of the spray dryer. One hypothesis for describing the flow pattern in the drying chamber is based on relatively large vortices leading to different trajectories and residence times depending on the particle inertia or particle size, respectively [1]. The residence time of the particles should be sufficient to ensure the desired moisture reduction of the feed but not too long in order to avoid thermal damage like degradation or loss of volatiles. Large deviations in the residence time of different particles, as indicated by a broad residence time distribution (RTD), lead to an inhomogeneous product.

In general, the RTD is determined by tracer injection at the dryer inlet and measuring the response at the outlet by taking samples in predefined time steps and analysing them with respect to their tracer concentration. This tracer can for example be an optically visible [2,3] or conductive [4,5] substance. Especially for fast processes like spray drying this discontinuity of the measurement leads to a too low resolution.

The most common approach for modelling the RTD is using a number of continuous stirred tank reactors (CSTR) in series [6], where the distribution of residence times  $E(t)$  [-] over time  $t$  [s] is described by the mean residence time  $\tau$  [s] and the number of CSTR in series  $N$  [-].

$$E(t) = \frac{N}{(N-1)!} \cdot e^{-N\frac{t}{\tau}} \cdot \left(\frac{Nt}{\tau}\right)^{N-1} \quad (1)$$

Various CSTR in series with different tank numbers and residence times can also be set in serial or parallel connection which might account for different flow regimes within the system [4,5].

Another approach for modelling the RTD is the dispersion model, which is based on the Fokker-Planck differential equation, describing the change of concentration  $c$  [1/m<sup>3</sup>] over time  $t$  [s] and space  $z$  [m].

$$\frac{\delta c}{\delta t} = -w \cdot \frac{\delta c}{\delta z} + M_{ax} \cdot \frac{\delta^2 c}{\delta z^2} \quad (2)$$

$w$  [m/s] is the average particle velocity and  $M_{ax}$  [m<sup>2</sup>/s] the axial mixing coefficient describing the derivation from radial flow pattern due to axial dispersion. In dependence of the boundary conditions  $M_{ax}$  can be calculated directly from the dimensionless variance of the measured RTD. A better way is to fit  $M_{ax}$  directly to the measured data [7] instead of using these simplifications, although it requires solving the differential equation multiple times. From  $M_{ax}$  the dimensionless Bodenstein number, which indicates the ratio of convective to dispersive transport, can be calculated.

$$Bo = \frac{w \cdot L}{M_{ax}} \quad (3)$$

Here,  $L$  [m] is the characteristic length. A low Bodenstein number indicates a broad distribution, a high number a narrow distribution.

Residence time distributions can also be modelled by linking CFD with particle tracing and observing the particle number over time at the outlet<sup>[8]</sup>. Thus, measurements of the RTD can be used to prove theoretical models.

In the present study, the particle RTD was determined using a particle counter. A pulse of maltodextrin was injected into a continuous water stream. When water is sprayed, the droplets evaporate and no particles are recognised by the detector at the dryer outlet. When maltodextrin particles pass the detector, it recognises the particle concentration as well as their size. This set-up allows a continuous measurement of the particle residence time.

## 2. Materials and Methods

### 2.1 Experimental set up

For the spray drying trials a pilot plat spray dryer (GEA Niro, Søborg, Denmark) with the dimensions 3.1 m x 1.2 m was used. As an injection signal, a 30 s pulse of 20 % (w/w) maltodextrin DE 21 (Agrana, Vienna, Austria) solution was injected into a continuous water stream by changing the position of a three-way valve.

*Fig. 1: Experimental set up, parallel and centrifugal air distributor (left to right)*

A hollow metal tube with 2 mm inner diameter, connected to a scattered light detector (Aerolossensor *welas* 2300, Palas, Karlsruhe, Germany), was inserted in the tower at the outlet of the drying chamber (see Fig. 1). The scattered light detector allows measuring the particle concentration and size within the air stream. From the particle concentration over time the RTD can be calculated.

In order to investigate the effect of the air distributor and nozzle pressure on the RTD the following settings were chosen:

**Table 1: Drying parameters**

Air rate	Feed rate	Inlet temperature air	Outlet temperature air
230 kg/h	9 kg/h	180 °C	90 °C

**Table 2: Air distributor and nozzle pressure**

Air distributor	Parallel	Centrifugal	
Nozzle	2 fluid nozzle, 2 mm orifice diameter		
Nozzle pressure (rel.) [bar]	1	2	3
Atomizing air rate [kg/h]	12	18	25

Trials with a nozzle pressure of 1 bar were performed 9 times, with 2 and 3 bar 5 times each.

## 2.2 Modelling of the residence time distribution

The output signal  $E_{out}(t)$ , measured by the scattered light detector, results from the convolution of the injection signal  $E_{in}(t)$  with the RTD of the spray dryer.

$$E_{out}(t) = E_{in}(t) * RTD \quad (4)$$

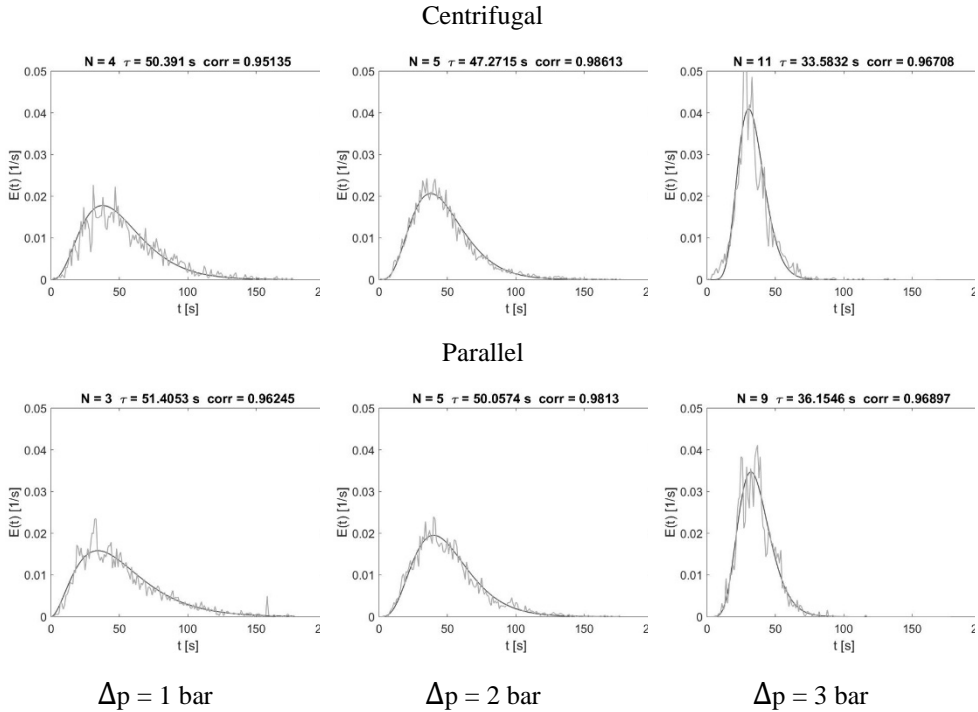

Here, \* indicates the convolution product. Consequently, the RTD can be calculated from deconvolution of the measured output signal with the input signal. Convolution and deconvolution were performed by applying the convolution theorem, whereat numerical Fourier transformation and inverse transformation of discrete data was performed by using the commands implemented in MATLAB®. The obtained RTD were fitted to the CSTR in series model (equation 1) and the dispersion model (equation 2) using the method of least squares. The mean residence time  $\tau$  was determined from the measured RTD. The mean flow velocity  $w$  for the dispersion model was calculated from  $\tau$  and the tower length. Equation 2 was solved numerically using the *pdepe* solver in MATLAB®.

The particle size distribution  $q_0$  [1/m] for each time step was obtained by the Palas measuring device. The characteristic diameters  $d_{10,0}$  and  $d_{90,0}$  were calculated from the total  $q_0$  distribution. For three classes ( $d < d_{10,0}$ ,  $d_{10,0} < d < d_{90,0}$ ,  $d > d_{90,0}$ ) the residence time distribution was calculated from the number of particles within a class at each time step.

## 3. Results and Discussion

### 3.1 Residence time distribution

With increasing nozzle pressure the measured particle RTD becomes more narrow, as shown in the exemplary curves in Fig. 2.

**Fig. 2: Influence of nozzle pressure on RTD for centrifugal and parallel air distributor**

In the CSTR in series model, this can be seen in an increasing  $N$  (For centrifugal:  $N = 4.5 - 4.4 - 10.8$ , for parallel  $3.4 - 7.0 - 8.4$ ). Furthermore there is a decrease in mean residence time  $\tau$  with increasing nozzle pressure (For centrifugal:  $47.67 \text{ s} - 45.84 \text{ s} - 35.58 \text{ s}$ , for parallel  $53.75 \text{ s} - 44.48 \text{ s} - 37.05 \text{ s}$ ). The latter effect can be seen for both air distributors, whereas no significant difference between the centrifugal ( $\bullet$ ) and the parallel air distributor ( $\blacklozenge$ ) can be observed. It was expected that the centrifugal air distributor would lead to an increase in mean residence time.

**Fig. 3: Mean residence time  $\tau$  (left) and number of ideal stirred tank reactors in series  $N$  (right) for centrifugal ( $\bullet$ ) and parallel ( $\blacklozenge$ ) air distributor at different nozzle pressures**

The mean particle residence time is larger than the mean air residence time, which was calculated as 29 s at the given process conditions. The flow within a spray chamber can be described by different flow regimes with a fast main central gas jet and a slower flow close to the wall [9]. Due to an increasing nozzle pressure there is a higher acceleration of the feed by the pressurized gas and a decrease in spray cone angle. Therefore the amount of particles staying in the faster core jet is increased, which leads to the effects seen in Fig. 2 and Fig. 3. Modelling the flow pattern by using an only one- parametric model is possible, which indicates only little formation of different flow regimes at the tested process conditions.

**Fig. 4:** Bodenstein number for centrifugal and parallel air distributor at different nozzle pressures

The Bodenstein number  $Bo$  shows no clear dependency of the nozzle pressure and the air distributor and is approximately constant. The value of the Bodenstein number of 2 - 4 is in accordance with literature data [10].

If the measuring system and injection signal are both constant, variations in the RTD are due to variations in the process, e.g. spontaneous formation of vortices. The RTDs, fitted to the CSTR in series model, are shown in Fig. 5 for all 9 trials at 1 bar nozzle pressure.

**Fig. 5:** Variations in RTD for parallel (left) and centrifugal (right) air distributor at 1 bar nozzle pressure.

The RTDs measured with the parallel air distributor can be modelled by using  $N = 3$  and  $N = 4$ . The mean residence time  $\tau$  is in the range of 51.4 s to 57.4 s. The RTDs measured with the centrifugal air distributor show a larger variance with a  $N$  of 3, 4, 5 and 7 and  $\tau$  from 41.4 s to 57.1 s. The flow within the spray drying chamber caused by the centrifugal air distributor seems to be less stable and more susceptible to fluctuations as indicated by this larger variance.

### 3.2 Particle size dependent residence time distribution

In Fig. 6 the RTDs from Fig. 2 are shown for different size fractions.

**Fig. 6: Influence of nozzle pressure on RTD for different particle size fractions for centrifugal and parallel air distributor**

The mean particle size decreases with increasing nozzle pressure due to the reduction of initial droplet size. No significant difference between the RTDs of the different size fractions can be observed. Thus, the effects of an increasing nozzle pressure on RTD (see Fig. 3) are not caused by the decreased particle size.

It was expected that different particle sizes will lead to different trajectories and therefore to different residence times <sup>[1]</sup>. As indicated by the small difference in between  $d_{10,0}$  and  $d_{90,0}$ , the particle size distribution is narrow which might lead to no size fraction effects in the RTD being visible.

## 4. Conclusions

The residence time distribution in a pilot plant spray dryer was characterised for different kinds of air distributors (centrifugal and parallel flow) as well as for different atomizing air pressures (1, 2 and 3 bar relative pressure). The measurement is based on a quasi-continuous acquisition of the particle concentration and size at the dryer outlet using a scattered light detector. The measured RTDs can be described by models with only one parameter, like the CSTR in series model, which indicates only little formation of different flow regimes at the tested process conditions.

An increasing nozzle pressure leads to a decrease in mean residence time and a more narrow distribution but the mean particle residence time is larger than the mean air residence time. The influence of nozzle pressure is more pronounced than of air distributor and particle size fraction.

In further studies the effect of a broader particle size distribution will be investigated.

### **Abstract**

*The paper demonstrates microwave and convective drying processes in different combinations of kaolin cylindrical samples in laboratory scale. Analysis of the kinetics and sample temperature evolution show that the moment of application and electromagnetic field duration have the biggest influence on characteristics of the drying curve and quality of dried material. Dried samples were subjected to strength tests using the Brazilian method in order to determine the relation between its quality and different drying programs.*

**Keywords:** *ceramic, convective drying, microwave drying, strength test.*

## **1. Introduction**

The use of microwave technology in industrial chemical processing has been developed since the 1970s. This is related to the general tendency to reduce production costs and care for the environment. One of the industrial processes using microwaves as a source of heat is drying. Microwave energy, alone or in combination with conventional energy sources (hybrid methods) enables precise control of the drying process in order to achieve higher efficiency and better product quality in the shortest possible time. In conventional drying, heat is transported to the surface of the material by conduction, convection or radiation and into the material through heat conduction. Moisture is initially evaporated from the surface, and the remaining water diffuses to the surface. This is often a slow process and the diffusion rate is limited. Process time is determined by the heat flow rate in the material from the surface, which depends on its specific heat, thermal conductivity, density and viscosity. Microwaves as a form of thermal energy, manifest themselves through their interaction with materials. The electromagnetic field initially interacts with the outer layers of the material. The inner part of the material is heated when the heat moves from the outer layers to the inside. Most of the moisture evaporates before leaving the material. If the material is very wet and the pressure inside is rapidly increasing, the fluid will be removed from the material due to the pressure difference. This creates a kind of pumping action that ejects the liquid to the surface, often in the form of steam. This results in very fast drying without the need to overheat the atmosphere and emit greenhouse gases from the heat source. The energy is transferred by the material to the electromagnetic way, not as a heat flux. Therefore, the heating rate is not limited, and the uniformity of heat distribution is significantly improved.

In general terms, according to literature data, the group of materials processed using microwave energy includes: food, plants, textiles, wood, soils and other biological materials [n1]. Among the works concerning the use of microwaves in drying, one can find a group of publications regarding the use of dielectric heating in industrial processes [n2, n3, n4]. Another group of publications are purely experimental works concerning both kinetics and material quality [n5, n6]. The next set of works are articles binding theoretical modeling of the drying process with experiments [n7, n8, n9, n10]. In the works that take into account the issue of the quality of the dried material, the emphasis is mainly on the effect of reducing the mechanical properties. The papers [n11, n3, n5] mainly concern the theoretical analysis of volumetric, intermittent drying, which is to reduce the gradients of moisture distribution, and hence the smaller deformations of the dried products. The theoretical part concerns analysis of stresses generated during drying. In turn theoretical work [n12] contains a very detailed and advanced model of the dielectric drying process.

The presented work concerns the investigation of the influence of microwaves on drying kinetics and mechanical strength of kaolin after drying, as the estimation of the quality of microwave dried products only by surface examination may not be sufficient

## 2. Materials and Methods

The material used in the research was ceramic kaolin. A slurry was prepared with a moisture content of 0.4 kg/kg<sub>db</sub>. Then a sample was formed with cylindrical geometry (diameter - 60 mm, height - 60 mm). In the dryer it is possible to control the speed and temperature of the air entering the chamber and the microwave power. Temperature measurements were made using optical fibers in two places: in the axis, half the height of the cylinder ( $T_{in}$ ) and at a distance of 0.5 cm from the upper surface of the cylinder ( $T_{out}$ ). The strategy of combining the above-mentioned drying methods used in this work was partly based on Schiffmann's proposal [n13].

As part of the work, seven different drying programs were carried out. The speed and temperature of the air entering the drying chamber were changed, as well as the stage in which the microwave energy process was supported (Table 1). The criterion of the end of the process was to obtain a sample moisture of 0.06 kg/kg<sub>db</sub>. Regardless of the drying strategy, the critical moisture content corresponding to the theoretical boundary between the constant and decreasing drying rate, was on average 0.23 kg/kg<sub>db</sub>. Additionally, the mechanical strength of the samples was analyzed using the Brazilian method.

*Table 1. Process data*

	$v$ [m/s]	$T$ [°C]	application of MW – 100 W
Exp.1	3	80	-

Exp.4	3	80	falling rate period
Exp.5	3	26	the whole process
Exp.6	3	26	constant rate period
Exp.7	2	26	the whole process

### 1.1. Results and discussion

As a graphical presentation of the process, the drying curves, the drying rate and the temperature of the material were presented, because these parameters show sufficiently the kinetics of the process. The first was to perform convection drying without microwave energy support (Fig. 1).

Fig. 1 Experiment 1.

Fig. 2 Experiment 2.

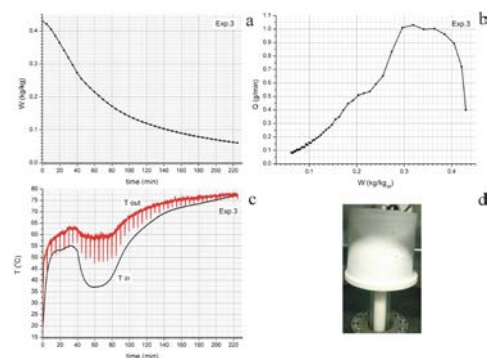

Fig. 3 Experiment 3.

Fig. 4 Experiment 4.

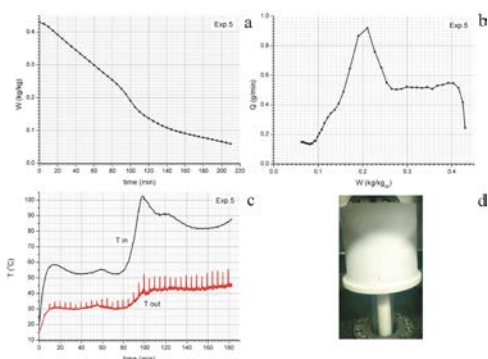

Fig. 5 Experiment 5.

Fig. 6 Experiment 6.

The heating period is clearly visible, a period of constant drying rate at which the material temperature and the drying rate are constant and amount to 0.5 g/min. Then the process enters the second phase, the drying rate decreases and the temperature of the material increases. The final drying criterion is reached after five hours, the material temperature reaches 73°C. In the sample photograph taken after the end of the process (Fig. 1d), a surface crack running circumferentially about 0.5 cm under the edge of the upper surface of the cylinder can be seen. Fig. 2 illustrates the course of the process with continuous exposure of the material to the microwaves. The total drying time is three times shorter and the drying speed in the first phase is twice as high as in Exp. 1. Also, the temperature of the material being subjected to microwave treatment is higher and amounts to 52°C during a constant drying rate. At the end of this phase, the drying rate increases rapidly, and after reaching critical moisture content, it decreases to the end of the process. The material temperature reaches 103°C. Small circumferential cracks can be seen on the side of the sample. A further drying strategy is shown in Fig. 3. Microwave energy enhances convective drying during heating and constant drying rates. After turning off the microwave generator, the drying rate and material temperature decreases accordingly, however, because the average moisture content in the material has not yet reached the critical value, the phase of the constant drying rate is continued, but under conditions with Exp. 1. At the end of the process, the material temperature reaches about 77°C. In the upper part of the cylinder, a distinctive characteristic circumferential crack was again created without a net of smaller cracks.

In Experiment 4, microwaves were used during the decreasing drying rate of the period (Fig.4). Initially, the drying rate was 0.5 g/min (according to data from Exp.1), after turning on the microwave generator the drying rate increased sharply with the increase of the material temperature. Then, with the decrease of the moisture content, the drying rate decreased and the material temperature reached 120 °C at the end of the process. The dried sample according to this strategy has been destroyed. In addition to the crack located circumferentially in the upper part, a deep circumferential fracture in the middle of the heights dividing the sample into two parts appeared.

The next three processes were carried out with the heater turned off. In Exp. 5 (Fig.5), the energy of the electromagnetic field enhances the entire process. The total drying time increased in relation to a similar process, but with the heater turned on (Exp.2). The material temperature during the constant drying rate was 55 °C. As in the case of Experiment 2, the mass flux doubled in the final stage of the constant drying rate and then the temperature of the material reached a maximum value of 102 °C. The dried sample was free of any defects visible to the naked eye.

In Experiment 6 (Fig.6), the microwaves were turned on during the heating period and the

constant drying rate. The drying rate was maintained at 0.5 g/min. After switching off the microwaves, it decreased to 0.15 g/min and was maintained until critical humidity was reached and then decreased. The temperature of the material was maintained at about 50 °C in the first drying period, then it dropped after switching off the microwaves to the temperature of the drying medium, i.e. around 25 °C. The sample, similarly to the previous process, has no scratches or cracks potentially weakening the material.

In the last process the air velocity was reduced from 3 m/s to 2 m/s. Reducing the speed of the drying medium caused the temperature of the wet thermometer to increase by 5 °C compared to a similar process with higher airflow (Exp. 5). However, the remaining process parameters such as the total drying time and the mass flux rate remained unchanged. A few small scratches are visible on the surface of the dried sample.

Analyzing the temperature curves of the dried sample (Fig. 1c-6c), some characteristic steps can be observed. They illustrate how to use the energy delivered to the material by convection, with microwaves or in combination. During the heating period, the temperature of the material and water contained in it increases (sensible heat). At the same time, in the final phase of the heating period volatile substances start to evaporate (latent heat). The start of the evaporation process therefore slows down the temperature increase. Next comes the equilibrium stage - constant temperature of the material. Latent heat of evaporation absorbs most of the energy. The process is in the constant phase of the drying rate. The next stage of the temperature rise occurs due to evaporation of most volatile components. Sensible heat absorbs most of the energy supplied. A phase of decreasing drying rate follows. The drying process from the point of view of mass transport is best illustrated by the drying rate curves (Fig. 1b-6b). In strategies with continuous microwave assist (Exp. 2, 5, 7), a sudden increase in mass flux was noted at the final stage of the constant drying rate period when the evaporation surface moves back into the material. The temperature and pressure in the pores increase, which results in a temporary acceleration of the rate of moisture removal from the deeper layers of the material. This effect is not observed in a conventional process. After a sudden increase, the temperature stabilizes and the process enters the final stage of decreasing speed. Then the water remains are removed from the deeper layers of the material. The moisture diffusion path in the pores lengthens and the capillary processes play a greater role in mass transport.

In the visual assessment of the dried samples, a characteristic circumferential crack is always observed near the upper surface of the cylinder in the case of drying with hot air. This is the result of the greatest drying stresses occurring there. The destructive power determined in the Brazilian test is also lower in these processes: 350 N (Exp.1), 280 N (Exp. 2), 320 N (Exp. 3), than in processes without convection heating: 530 N (Exp 5) and 450 N (Exp 7).

## 2. Conclusions

The use of microwaves during drying results in undoubtedly shortening the drying time, but also an increase in temperature, which is not always beneficial. The application of microwave energy in the phase of decreasing drying rate (one of Schiffmann's proposals) does not work in the case of brittle materials with the geometry used in this work.

The drying strategies used in this work have a significant impact on both the drying time and the final quality of the product. It turns out that the best strategy due to the drying time and the quality of the material is the use of microwave support throughout the process, but without convection heating. The drying time has been shortened and the quality improved compared to conventional drying. These tests do not provide enough information when and how long to turn on microwaves to achieve optimal results. They only indicate that it is possible to shorten the process time and even improve the quality of the material.

### **Abstract**

*Algae drying was carried out using Vacuum Tray Dryer and an Innovative Solar Conduction Dryer. Algae was dried in a Vacuum Tray Dryer at 60°C under varied pressure conditions and makes use of specially designed double condenser system. The open sun drying and solar conduction dryer (SCD) was also used for algae drying. Comparison between open sun drying and solar conduction dryer were done and it was found that the solar conduction dryer gives high performance than the open sun drying. It was also found that, the conductive heat transfer mode plays a crucial role in the solar conduction dryer.*

**Keywords:** *Vacuum Dryer; Solar Conduction Dryer; Algal Drying.*

---

## **1. Introduction**

Algae is a potential source of high-value products such as pigments, nutraceuticals, and protein-rich biomass as food supplements. Microalgae have the following advantages over terrestrial plants:

1. Microalgae has less growth in fresh water than saline or contaminated water.
2. Microalgae has less competition with food for arable lands but can be cultured in seas or in ponds or barrain lands <sup>[1]</sup>.
3. Microalgae can grow faster and also accumulate oil more efficiently than higher plants and oilseed crops <sup>[2,3]</sup>.
4. Microalgae can also produce valuable raw materials which are its coproducts (e.g., proteins, pigments, unsaturated fatty acids, carotenoids, and vitamin) <sup>[4]</sup>, used in the animal feed, food, cosmetics, and pharmaceutical industries.
5. Microalgae can convert CO<sub>2</sub> into biomass with a high efficiency of CO<sub>2</sub> utilization <sup>[5,6]</sup>. In general, 1.83 kg CO<sub>2</sub> consumed gives 1kg of dry biomass of CO<sub>2</sub>.<sup>[3]</sup>

Production of these high-value products from algae requires dry algal biomass with moisture less than 10 % <sup>[7]</sup>. Drying of algae is also essential for storage since harvested algae slurry is perishable and can spoil within a short time. However, microalgae in cultivated medium has low biomass concentration (0.1-1% w/w) and mechanical dewatering of algae in the cultivated medium can produce algae slurry having 20-30% w/w algal biomass <sup>[8,9]</sup>.

In this paper we shall be going through the various drying methods that have been attempted and the drying kinetics comparison study being carried out.

## **2. Materials and Methods**

The harvested and dewatered algal biomass was obtained from Reliance Industries Limited. The centrifuged algae was collected in a can and transported to Institute of Chemical Technology, Mumbai, India and stored in the refrigerator at 4°C until the drying experiments to prevent putrefaction. Before experiments, the slurry was brought back to ambient conditions. Trials were conducted in a Teflon coated plate of dimensions 21 cm x 27 cm x 5 cm. Trials conducted in Vacuum Tray Dryer and Solar Conduction Dryer.

## 2.1. Vacuum Tray Dryer

It is a conventional vacuum tray dryer manufactured by Salvis Lab, which originally had a single condenser for condensing the vapours generated in the dryer. The operating temperature was 60°C, hence the single condenser was inefficient in condensing and therefore a second condenser was added to it. The condensers were attached to a chiller whose temperature was maintained at 4°C. The condenser was attached to a measuring cylinder, where the volume collected is measured. A flask containing silica gel was placed between the vacuum pump and cylinder, which acted a water trap, to prevent the uncondensed water from entering into the vacuum pump. The sample was dried over a pressure range of 30-50 mbar.

The samples were weighed and taken in the Teflon coated plate and kept for drying. The tray dryer and chiller were first allowed to attain the desired temperature of 60°C and 4°C respectively. The sample was then loaded to the dryer and a vacuum pressure applied. The water collected in the measuring cylinder was noted at a regular interval of 10 minutes. However, the rate of drying drastically reduces after 8 hours, and the water collected in the measuring cylinder barely increases by a milliliter even after 30 minutes.

## 2.2. Solar Conduction Dryer

An innovative Solar Conduction Dryer (WO2014097307A1) <sup>[10]</sup> was used for drying the sample. “The dryer comprises a radiation absorbing heat conducting surface, and a convection channel formed by a radiation controlling cover over the conducting surface” <sup>[10]</sup>. The solar drying experiment took place in Mumbai (19.0239° N, 72.8575° E), India. The sample was loaded in a Teflon coated plate, weighed and kept inside the dryer, whose loss in weight was measured at a regular interval of 30 minutes. The other parameters that were measured and noted included the surface temperature of algae, surface temperature of the conduction plate and the atmospheric temperature using an infrared thermometer gun. Experiments were carried out between 09:00 hours and 16:00 hours on sunny days in the month of December 2017. At the end of the day (16:00 hours), the partially dried sample was covered with an aluminum foil and kept inside a drawer, for continuing the drying study the subsequent days. The drying experiment was continued till no change in weight was observed.

## 3. Mathematical Models

### 3.1. Thin-layer Drying Model

The thin-layer model is usually represented by the equation in terms of drying parameters to characterize the changes of the mean moisture content of food product during drying.

The parameters that account for the combined effect of various transport phenomena in the drying process can be determined from the graphical method [11-12]. It can be expressed as:

$$\phi = k_0 \exp(-kt) \quad (1)$$

where  $k_0$  and  $k$  represent the lag factor and drying constant of food product, respectively. The moisture diffusion coefficient,  $D_{eff}$  can be obtained from the following expression:

$$D_{eff} = k \frac{L_d^2}{\mu_1^2} \quad (2)$$

Where  $L_d$  is the moisture diffusion path and  $\mu_1$  is the characteristic parameter which can be obtained from the equation:

$$\mu_1^2 = (\mu_1)_\infty^2 \frac{1}{1 + \frac{A_1}{Bi_m^p}} \quad (3)$$

where  $Bi_m$  represents the Biot number for mass transfer. The  $(\mu_1)_\infty$  is the value of  $\mu_1$  at  $Bi_m = \infty$ . The values of the constants  $(\mu_1)_\infty=1.5708$ ;  $A_1 = 2.24$ ;  $p = 1.02$ , considering the algae to be a slice inside the plate. The Biot number can be obtained in terms of lag factor,  $k_0$  of drying characteristic curve using following relation [13]:

$$Bi_m = \frac{5.132 \ln k_0}{1 - 3.948 \ln k_0} \quad (4)$$

Knowing the value of  $D_{eff}$ , the convective mass transfer coefficient,  $h_m$  can be calculated from the standard relation

$$h_m = Bi_m \frac{D_{eff}}{L_d} \quad (5)$$

The characteristic parameters  $\mu_1$  and Biot number  $Bi_m$  computed from respective Eqs. (3) and (4) are used in  $D_{eff}$  and  $h_m$  estimation.

#### 4. Results and Discussion

Figure 1 shows the dimensionless moisture content against drying time for the repeated experiments under a varied vacuum pressure of 30 millibar and 50 millibar in the vacuum tray dryer having an initial weight of 200 gm at 60 °C.

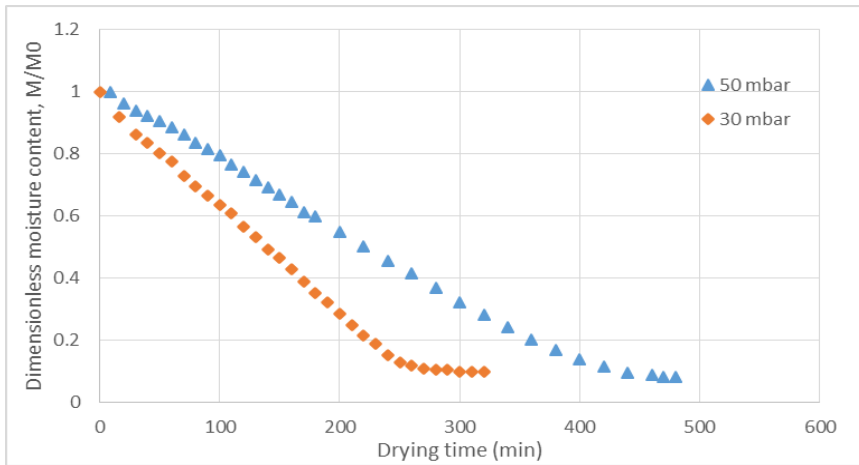

Figure 1. Variation in drying time with the change in vacuum applied

Table 1. Results of mass transfer co-efficients ( $D_{eff}$  and  $h_m$ ) & Biot number ( $Bi_m$ ) for the 30 mbar and 50 mbar pressure.

	30 mbar	50 mbar
Biot Number	$1.435 \times 10^{-4}$	$8.951 \times 10^{-5}$
$D_{eff}$ ( $m^2/s$ )	$9.451 \times 10^{-8}$	$8.043 \times 10^{-8}$
$h_m$ (m/s)	$2.296 \times 10^{-4}$	$1.074 \times 10^{-4}$

As it can be seen that by reducing the vacuum pressure from 50 millibar to 30 millibar, the drying time reduces and hence there is an increase in the drying rate. This fact is quantitatively reflected in the values obtained in Table 1.

Figure 2 shows the dimensionless moisture content against drying time for the open sun and solar conduction dryer for 200 gm algae slurry. As expected, solar conduction dryer gives higher performance than the solar conduction dryer. Solar conduction dryer takes less time than the open sun drying to achieve the required moisture content. Effective diffusivity ( $D_{eff}$ ), mass transfer coefficient ( $h_m$ ) and mass transfer Biot number ( $Bi_m$ ) values are depicted in Table 2. These values suggests that the solar conduction dryer gives higher performance than the open sun drying.

**Figure 2. Comparison between the performance between open sun drying and solar conduction dryer for algae drying**

**Table 2. Results of mass transfer co-efficients ( $D_{eff}$  and  $h_m$ ) & Biot number ( $Bi_m$ ) for open sun drying and Solar Conduction Drying.**

	Solar Conduction Dryer	Open sun drying
Biot Number	$5.517 \times 10^{-5}$	$6.56 \times 10^{-5}$
$D_{eff}$ ( $m^2/s$ )	$1.355 \times 10^{-7}$	$1.24 \times 10^{-7}$
$h_m$ (m/s)	$8.826 \times 10^{-5}$	$8.04 \times 10^{-5}$

## 5. Conclusions

Algae drying was done by using various methods such as vacuum, open sun drying and solar conduction dryer. Vacuum drying suggests that, by reducing the pressure there was reduction in the drying time. At low pressure, the value of effective diffusivity and mass transfer coefficient were higher. Comparison between open sun drying and solar conduction dryer was done. It was found that, the performance for solar conduction dryer was higher than the open sun drying. The performance was checked on the basis of effective diffusivity and mass transfer coefficient. Comparison between the solar conduction dryer and vacuum dryer suggests that the time required for Solar Conduction Drying is longer than Vacuum Tray Drying, however the operation cost for Solar Conduction Drying is negligible.

---

### **Abstract**

*Dekopon or Hallabong (Citrus reticulata “Shiranui”) is a hybrid fruit that belongs to the citrus fruits. The scientific and commercial interests in dekopon is due to its nutritional composition. The objective of the study was to verify the influence of ethanol as a pretreatment in reducing drying time as well as maintaining nutritional quality (vitamin C, total phenolic compounds, and antioxidant activity) of dekopon slices. The drying with ethanol at 70 °C promoted the greatest reduction in drying time, but the processed pretreated samples at 50 °C presented the highest level of nutritional quality parameters.*

**Keywords:** *drying time; vitamin C; phenolic compounds; antioxidant activity.*

---

## 1. Introduction

The vitamin C, consisting of ascorbic and dehydroascorbic acid, is widely found in fruits and foods, being characterized by its instability to technological processes <sup>[1, 2]</sup>. There are also other health-promoting substances, such as phenolic compounds, which are secondary metabolism in plants that have been identified as major antioxidants in fruits <sup>[3]</sup>. Those compounds are present in the fresh form of fruits and vegetables, especially in citrus fruits. Dekopon (*Citrus reticulata* “Shinarui”) is among the citrus fruits. It is a cross between Kiyomi (*Citrus uses Marcov. x Citrus sinensis Osbeck*) and Ponkan (*Citrus reticulata Blanco*). The commercial value of dekopon is due to its sweet taste and pleasant aroma <sup>[4, 5]</sup>.

Generally, fruits and vegetables in their fresh form show high moisture content and water activity, providing high degradation rates which may cause significant postharvest losses. To minimize these effects, various processing techniques can be used, as drying. Convective drying is a simple but time consumer process with consequent high energy demand. High temperatures reduce the drying time, but could carry out to food quality and nutritional composition reduction <sup>[6]</sup>. In order to minimize the negative effects of drying, some pretreatments such as ultrasound <sup>[7]</sup>, osmotic dehydration <sup>[8]</sup> and ethanol application in the environment and on the surface of the samples are commonly used <sup>[9, 10]</sup>.

The aims of this work were to (i) investigate the effects of the immersion of the samples in ethanol on drying time, (ii) examine the influence of ethanol and drying temperature on phenolic compounds content, vitamin C and antioxidant activity.

## 2. Materials and Methods

### 2.1. Sample preparation

Dekopon (*Citrus reticulata* “Shinarui”) were selected based on uniform maturation characteristic with peel color. The fruits were washed and sanitized with sodium hypochlorite solution <sup>[11]</sup> and stored at 7 °C ( $\pm 2$  °C) until the beginning of each experiment. The moisture content of the fresh dekopon (method 934.06, AOAC (2005)) was  $5.92 \pm 0.01$  kg H<sub>2</sub>O kg<sup>-1</sup> d.b.

For the experiments, the samples were peeled manually, eliminating the edges of the fruit. Samples were sliced with the aid of a stainless steel knife and a cutter so as to standardize the size of the slices. After cutting, the dekopon slices presented standardized dimensions  $3.27 \pm 0.32$  mm x  $60.54 \pm 1.12$  mm (thickness x diameter) and were measured using a digital caliper (Western, DC-60 model, Zhejiang, China).

## 2.2. Convective drying

The convective drying was performed in a tunnel dryer (Eco Engenharia Educacional, MD018 model, Brazil) The mass variation of samples during the drying was monitored using a digital balance (Marte Científica, AD33000 model, Brazil) (accuracy $\pm$  0.01 g) coupled to the sample holder allowing to obtain the kinetics of drying. In each experiment, 145.113 $\pm$ 5.862 g of fresh fruits (totaling five slices) were dried. The process was performed until an average final moisture content of 0.235 $\pm$ 0.054 kg H<sub>2</sub>O kg<sup>-1</sup> d.b.

The drying process followed a 2x2 factorial design to study the effects of air temperature variation (50 and 70 °C) <sup>[11]</sup> and the immersion or not of the samples in ethanol, as a pretreatment. Air velocity was keep at 2.00 m s<sup>-1</sup> <sup>[12]</sup>. Pretreatment samples were completely immersed in 95% ethanol in a petri dish for 10 s <sup>[13]</sup> in a ratio sample/ethanol of 1:1 (weight/weight) approximately. The moisture content of the dried dekopon was determined according to the AOAC (2005). The water activity (a<sub>w</sub>) determination was performed in a hygrometer (Aqualab, 3-TE model, Decagon Devices, Inc., Pullman, WA, USA).

## 2.3. Quality analysis

The total phenolic compounds were quantified using an adaptation of the method of Folin-Ciocalteu. Quantification was performed by spectrophotometer reading at 750 nm and the results expressed in mg of gallic acid.100 g<sup>-1</sup> dry matter <sup>[14]</sup>.

The ascorbic acid (vitamin C) determination was performed by the colorimetric method, 2,4 dinitrofenilhidrazina <sup>[15]</sup> and the results expressed as % retention of ascorbic acid in the dry product, according to Eq. 1

$$\% \text{retention} = \left( \frac{\text{g ascorbic acid in the dehydrated sample}}{\text{g ascorbic acid in the fresh sample}} \right) * 100 \quad (1)$$

The total antioxidant activity (AAT) by DPPH (2,2-diphenyl-1-picrylhydrazyl) <sup>[16]</sup>. The results are expressed as % sequestration. The percentage of sequestration expresses the ability of the food to inhibit the action of the reactive species present in the DPPH radical.

## 2.4. Statistical analysis

All analytical determinations were performed in triplicate. Parameter values are expressed as the means $\pm$ standard deviation. The results were analyzed using analysis of variance

(ANOVA) and the Tukey test at 5% significance to compare the mean values using Statistic (Statsoft, Tulsa, USA).

### 3. Materials and Methods

#### 3.1. Convective drying

The Fig. 1 shows the evolution of drying of dekopon slices treated and untreated with ethanol, at 50 and 70 °C. The drying time for the pretreated fruits to reach a final moisture content of  $0.235 \pm 0.051 \text{ kg H}_2\text{O kg}^{-1} \text{ d.b}$  was  $300.33 \pm 0.95$  and  $1193.33 \pm 0.64$  min for 70 and 50 °C respectively. For the untreated samples the total drying time was  $343.33 \pm 0.91$  and  $1540.00 \pm 0.83$  min for 70 and 50 °C respectively.

Fig. 1 Evolution of moisture content of treated ethanol immersion and untreated dekopon at 50 e 70 °C.

The experiments at 70 °C with pretreatment and without pretreatment did not obtain a significant difference between them ( $p > 0.05$ ), presenting times of  $303.33 \pm 2.49^a$  min and

343.33±2.65<sup>a</sup> min, respectively. However, these experiments differed statistically from the others (p<0.05), in addition, the experiments at 50 °C with pretreatment and without pretreatment showed a statistical difference between them (p<0.05), reaching a final processing time of 1193.33±3.46<sup>b</sup> min and 1540.00±1.73<sup>c</sup> min. These data demonstrate the effectiveness of the application of ethanol to the samples of dekopon slices as well as the increase of the drying air temperature with respect to the reduction of the total process time, which can bring benefits mainly in the energy economy. The use of ethanol in direct contact with the sample, as pretreatment to convective drying, was studied by [10] during the drying of banana having the same effect in relation to the increase of the diffusivity allowing the pretreated experiments to present a lower drying time. With the application of the ethanol under the sample, a homogeneous mixture is formed (ethanol has hydroxyl that binds with water by hydrogen bond) and this mixture presents a higher vapor pressure when compared to the solution without ethanol, justifying the reduction of the drying process [10, 11, 17]. As the temperature of the air increases, a higher rate of drying occurs due to the greater mobility that the water reaches inside the pores, reducing the internal resistance to the transport of moisture [7], and similar results are found in the literature [18, 19].

The  $a_w$  is an important parameter in food preservation and the results have proved the efficiency of the drying process in reduced the values. The fresh samples presented  $a_w$  of 0.97±0.02<sup>a</sup>, differing from the others (p<0.05). The experiments at 50 °C with pretreatment, and without pretreatment, as well as those of 70 °C with pretreatment and without pretreatment, presented  $a_w$  of 0.36±0.05<sup>b</sup>, 0.37±0.03<sup>b</sup>, 0.38±0.05<sup>b</sup>, and 0.360±0.021<sup>b</sup> (p>0.05), respectively, according to literature [20].

### 3.2. Quality analysis

The effect of air temperature drying and ethanol immersion on the phenolic content, vitamin C retention and total antioxidant activity of dekopon slices dehydrated are showed in Table 1.

**Table 1. Phenolic content, vitamin C retention and total antioxidant activity in dekopon slices dehydrated**

Conditions	Phenolic [mg 100 g <sup>-1</sup> ]	AAT [%sequestration]	Vitamin C [%retention]
50 °C, pretreated	766.67±10.25 <sup>a</sup>	74.80±0.12 <sup>a</sup>	39.09±0.91 <sup>a</sup>
50 °C, untreated	642.89±6.14 <sup>b</sup>	59.06±1.14 <sup>b</sup>	32.45±0.04 <sup>b</sup>
70 °C, pretreated	622.16±6.06 <sup>bc</sup>	51.71±0.59 <sup>c</sup>	30.71±0.03 <sup>c</sup>
70 °C, untreated	609.75±4.77 <sup>c</sup>	49.54±0.80 <sup>d</sup>	28.85±0.09 <sup>d</sup>

Different letters mean significant difference (p<0.05).

The reduction of bioactive compounds in foods and the degradation of phenolic are usually pointed as drying disadvantages. The lowest phenolic compounds, percentage of retention of vitamin C and total antioxidant activity were found in the experiments at 70 °C. By the drying, the polyphenols could have interactions with other compounds or have their chemical structure changed [3]. Temperature have a negative effect on phenolic [21]. The increase in temperature also brings reductions in the vitamin C, a thermosensitive compound [22]. In addition, the effect of the use of ethanol was clearly evidenced. The higher retention and antioxidant activity were found with the use of ethanol. Moreover, one can see that those indexes were more relevant at lower temperatures. For example, the antioxidant activity was 26.7% higher by the use of ethanol at 50 °C whereas it was 4.4 % higher by the same use at 70 °C. The alcohol causes a more intense evaporation of water, reducing the time of exposure of the sample to the drying process, minimizing the effects of temperature under the quality parameters analyzed [23].

#### **4. Conclusions**

The immersion in ethanol and the use of higher temperatures lead to shorter drying time. In addition, the quality compounds analyzed had greater preservation in the experiment at 50 °C and with application of ethanol, evidencing the importance of the use pretreatment as well as the choice of the range temperature process.

### **Abstract**

*The aim of this work was to evaluate the influence of vacuum application on the phenolic acid content of osmodehydrated eggplant, carrot and beetroot samples. The contents of catechins and chlorogenic acid were determined by HPLC analysis. Changes in the contents of phenolic acids after the osmotic processes were observed. It was found a reduction in catechins and chlorogenic acids, probable due to the migration and degradation losses. In a general way, the vacuum reduced the catechin and chlorogenic acid contents, compared to the osmotic dehydration at atmospheric pressure.*

**Keywords:** Pulsed vacuum osmotic dehydration; chlorogenic acid; catechins.

---

## 1. Introduction

The osmotic dehydration (OD) is a technique that provides partial water removal from a food product, with low energy consumption by been carried out at room or moderate temperatures [1]. It is based on the immersion of pieces of fresh fruits or vegetables in a hypertonic solution. The process involves simultaneous counter-current water diffusion from the food to the solution and solute diffusion into the food, under the influence of osmotic pressure gradient [2,3]. It is considered a pretreatment to many processes and preserves physical, chemical and sensorial characteristics of food with few changes on its integrity [4,5].

A mass transfer rate increase can be achieved with the vacuum application in the beginning of the OD, in a process presented as pulsed vacuum osmotic dehydration (PVOD) [6]. The reduction in the pressure causes liberation of the occluded gases in the pores of the fruit and vegetables making them expelled, due to the action of hydrodynamic mechanisms (HDM) enhanced by pressure difference, increasing the surface area for mass transfer [7–9].

The PVOD process is related to the intensification of water loss and solid uptake, compared with OD. Besides this two mass fluxes, the lixiviation of some nutrients affect qualitatively the nutritional and functional properties of the food subjected to this process [6–8].

As the water is removed, some water soluble constituents, as vitamins and phenolic acids are lixiviated, implying in significative nutritional losses [10]. The vegetables are source of bioactive compounds, among them, the phenolic acids. They confer antioxidant properties and are therefore indicated for the treatment and prevention of cancer, cardiovascular disease and other diseases [11]. This work aimed to evaluate the effect of different vacuum pressures applied in the OD of eggplant, carrot and beetroot slices in the phenolic acid content.

## 2. Materials and Methods

### 2.1 Sample and osmotic solution preparation

Fresh eggplants (*Solanum melongena* L.), carrots (*Daucus carota* L.) and beetroots (*Beta vulgaricus* L.) were purchased in a local market (Lavras, MG, Brazil) and stored in a refrigerator at  $8 \pm 1$  °C before the experiments.

All of the vegetables were washed with tap water, peeled and sliced (2.00 cm length x 2.00 cm width x  $0.40 \pm 0.03$  cm thickness) using a stainless steel mold. The ternary osmotic solution was prepared with distilled water, sucrose (40 kg 100 kg<sup>-1</sup> (w/w)) and sodium chloride (10 kg 100 kg<sup>-1</sup> (w/w)).

## 2.2 Osmotic processes

The osmotic processes were performed in an osmotic dehydrator with temperature and inner pressure control (Fig 1) [8]

**Fig. 1** Vacuum pulse osmotic dehydration device. 1 - inside osmotic dehydrator, 2 – thermal jack; 3 - outlet of thermal jacked section 4 - output to remove osmotic solution, 5 - motor coupled to the blade inside dehydrator to promote agitation; 6 - vacuum pump.

The experiments were conducted in three different conditions and the total time of the osmotic process was 300 min. Part of this time, in the beginning of the process (10 min), could involve vacuum pulse application, followed by atmospheric pressure restoration (755 mmHg). The treatments are presented in the Table 1.

**Table 1. Experimental conditions**

Treatment	Conditions
1	OD (absolute pressure = 755 mmHg)
2	PVOD (absolute pressure = 455 mmHg)
3	PVOD (absolute pressure = 155 mmHg)

The processes temperature was set at  $35 \pm 1$  °C and the ratio of solution to vegetable was 1:10 (w/w). After the osmotic processes, the samples were removed from the solution and immersed in a bath of cold distilled water during 10 s to stop the osmosis and to remove

solution excess. The surface of the samples was gently wiped with absorbent paper, and they were weighed and submitted to moisture content determination [12] and chromatography analyses. All the experiments were performed in four replicates.

### 2.3 Chromatography analyses

The polyphenols for high performance liquid efficiency chromatography (HPLC) were extracted using 2.5 g of pulp and 20 mL solution containing 70% methanol in water (v/v) [13]. Briefly, the samples were homogenized and placed in an ultrasonic bath at 20 °C for 60 min. The extracts were centrifuged at 1400 g for 15 min at 4 °C and filtered through Whatman n° 2 filter paper. The extracts were again filtered with regenerated cellulose filters 0.45 µm (Millipore, Bedford, MA, USA) and stored at -18 °C until the analyses.

The chromatographic analyses were performed using an Ascentis C18 5-µm (250 mm x 4 mm) column. The mobile phase consisted of 2% (v/v) acetic acid in water (mobile phase A) and 70:28:2 methanol/water/acetic acid (mobile phase B), set to a flow rate of 1.0 mL min<sup>-1</sup> and conducted using a gradient elution programme and a 65 min run time. The injection volume was 20 µL. Analyses were performed at 15 °C. The phenolic compounds generated a UV-Vis spectral result in the HPLC chromatogram at 280 nm. Quantitative determination of compounds was conducted by comparison with dose-response curves based on *m/z* data from authentic standards of individual polyphenols [14]. The results of three replicates were expressed as mg 100 g<sup>-1</sup> (d. b.).

### 2.4 Statistical analyses

The results were subjected to analysis of variance (ANOVA) using software STATISTICA 8.0® (Statsoft, Tulsa, USA). Tukey's test was used to compare means at the 5% significance level ( $p < 0.05$ ).

## 3. Results and discussion

For the identified phenolic acids, significant differences after the osmotic processes ( $p \leq 0.05$ ) have been found (Table 2) for all the vegetables.

According to the Table 2, catechin was identified in all the different vegetables, with higher concentration in beetroot samples, followed by carrot and eggplant. The chlorogenic acid (5-O-caffeoyl-quinic acid; CQA) was observed only in the eggplant samples.

A reduction in the catechin content was observed for all osmodehydrated vegetables (Table 2). This occurred probable due to the migration and lixiviation losses, that are related with

the mass transfer during the osmotic dehydration. It is well known that as the water is removed from the products (due to the osmotic pressure gradient between the material and the osmotic solution), some water soluble compounds also migrate from the cell tissue to the liquid media [15–17]. For the beetroot samples, the catechins were lightly preserved in the treatment 2 (PVOD with absolute pressure of 455 mmHg) (Table 2).

**Table 2. Phenolic acid content of fresh and osmodehydrated vegetables [mg 100 g<sup>-1</sup>] (d.b.)**

Treatments	Fresh	1	2	3
Catechin				
Eggplant	21.26±1.66 <sup>a</sup>	12.22±1.24 <sup>b</sup>	13.42±0.61 <sup>b</sup>	2.40±0.15 <sup>c</sup>
Carrot	36.89±2.89 <sup>a</sup>	28.72±1.44 <sup>b</sup>	31.42±2.06 <sup>b</sup>	21.09±0.10 <sup>c</sup>
Beetroot	215.48±4.31 <sup>a</sup>	90.17±3.93 <sup>c</sup>	116.67±4.20 <sup>b</sup>	75.17±2.88 <sup>d</sup>
Chlorogenic acid				
Eggplant	367.71±11.43 <sup>a</sup>	219.07±11.42 <sup>b</sup>	183.17±8.29 <sup>c</sup>	82.92±3.62 <sup>d</sup>

*Average value ± standard deviation. Mean followed by different letters in the row differs significantly (p < 0.05), according to Tukey's test.*

Comparing the catechin content in fresh and osmodehydrated blueberries [18] also observed significant reduction in its retention. They concluded that the vacuum application reduced the catechin content, compared with OD treatment.

Studies indicate that the main phenolic compound in the eggplant is the chlorogenic acid [19]. Its content was reduced in PVOD treatments by 50-75 % (Table 2). This phenolic compound is a hydroxycinnamic acid derivative, and such a reduction occurred probable due to the mass transfer intensification when the vacuum was applied [20-22]. Nevertheless, the losses of this polyphenol acid was also observed in OD treatment. This indicates that besides the losses by lixiviation, some oxidative and hydrolytic modifications were observed.

According to the Table 2, the vacuum application implied in a pronounced phenolic reduction, compared to the OD. The retention in phenolic compounds are desirable, once they present a wide range of biological activities, related to the risk decrease of heart and neurodegenerative diseases, and certain forms of cancers [23].

## 4. Conclusions

The osmotic dehydration of vegetables (eggplant, carrot and beetroot) was achieved in different conditions. It was observed changes in the phenolic acid contents after the osmotic processes. It was found a reduction in catechins and chlorogenic acids, probable due to the migration and degradation losses. In a general way, the vacuum reduced the catechin and chlorogenic acid contents, compared to the OD. It was concluded that the osmotic process (under vacuum or atmospheric pressure) reduces the analyzed phenolic acid content.

## **1. Introduction**

The disposal of waste such as sludge on land is a social problem in response to the prohibition of marine discharges of waste. Most of the wastes such as sludge have a very high water content and it is necessary to dry them in order to treat them on the land. Various studies have been conducted on drying for wastewater sludge treatment.

It is very important to analyze the characteristics of sewage sludge for the treatment of sewage sludge because the characteristics of sewage sludge vary according to the area and temperature. Wang et al.[1] has studied the properties and toxicity of sewage sludge in more than six regions of China. Krzeminski et al.[2] studied the relationship between the properties of the sludge and the seasonal temperature. This study suggests that the sludge varies according to the season.

In recent years, research on sewage sludge has been focused on the treatment of sewage sludge. Especially, the sewage sludge has a high water content, and therefore, a drying process is essential for the treatment. Drying process for sewage sludge treatment has been using hot air or steam. Recently, various pretreatment processes and new heat sources have been studied to improve energy efficiency. Na et al.[3] studied the improvement of dewatering performance by applying ultrasonic treatment to sludge. In this study, it was mentioned that ultrasonic pretreatment had a positive effect on sludge dewatering and also helped to reduce volume and mass of sludge.

Recently, various methods of utilizing various heat sources have been researched to reduce the energy cost for the sewage sludge treatment process. Lye Bennamoun[4] reviewed various studies on sludge drying using solar energy. There are many reasons to utilize ocean heat energy for sludge drying, but most of all to reduce the energy cost of the drying process.

This study was also conducted to reduce the energy input to the sludge drying process. In particular, the efficiency of the drying process is the most energy involves higher costs is necessary in order to take advantage of the waste. This study analyzed the characteristics of the energy efficiency change of the system by introducing outside air into the existing sludge drying process and conducted an experimental study on a method for obtaining higher system efficiency.

## **2. Materials and methods**

In this study, we used a vertical thin film dryer. The vertical thin film dryer is a device for drying various sludge and waste material using. Vertical thin film dryer is using non-continuous indirect heat drying method, drying the sludge and waste products. Figure 1 shows the vertical thin film dryer used for this study.

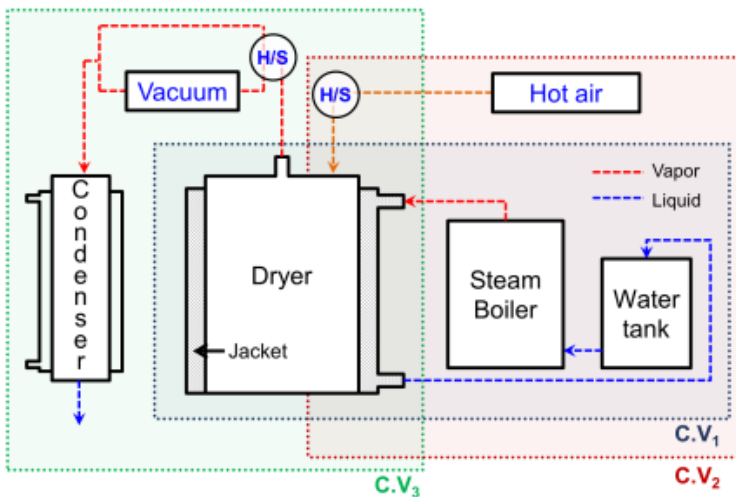

Fig. 1 The image and schematic of experimental facility.

The sludge with an initial moisture content of 80% or more can be dried to a final moisture content of 10 to 20% by using this experimental facility. The experimental facility includes a main body(dryer), a water tank, a steam boiler, an exhaust gas blower, a cooling tower, an exhaust gas condensing heat exchanger, and a platinum catalyst deodorizer. A stirrer blade is installed in the main body(dryer) so that the wastewater sludge is agitated during drying

and the heat transfer between the material and the jacket is performed well. The material used in the experiment is sewage sludge from urban areas.

*Table 1. Experimental test cases*

<b>Cases</b>	<b>Detail</b>
Inflow X	No outside air inflow
Inflow 1	Inflow of air from 10 minutes after operation
Inflow 2	Inflow of air from 20 minutes after operation
Inflow 3	Inflow of air from 30 minutes after operation
Inflow 4	Inflow of air from 40 minutes after operation
Inflow 5	Inflow of air from 50 minutes after operation

The initial moisture content is about 80%. In this study, the drying was carried out until the final moisture content was 10% or less. The pressure of the steam supplied to the system is 2 kg / cm<sup>2</sup>, and the temperature inside the chamber is 155 ° C on average. The supply of steam was on / off controlled based on the pressure. The pressure and temperature were measured at intervals of 5 seconds using a data logger. In order to improve the accuracy of the experiment, only the initial water content and the final water content were measured without extracting the sample during the experiment.

As mentioned above, this study evaluated the drying performance by introducing outside air into the conventional vertical thin film drying apparatus. For the study, the experiment was carried out under the condition that no external air was introduced and the external atmosphere was introduced. The total experiment time was 60 minutes, and the detailed experimental conditions are shown in Table 1.

The purpose of this study is to improve the energy efficiency of the drying system by changing the outside air inflow operating conditions of the vertical thin film drying system. The initial moisture content and moisture content after sludge drying were measured. In order to confirm the energy input during each drying experiment, a strategic meter was installed to add the total power of all systems. The pressure inside the chamber and the relative humidity were measured so that the inside of the chamber can be confirmed. Based on this, the energy efficiency of the system is calculated and the system drying energy efficiency calculation formula is as follows.

$$\text{Drying efficiency} = \frac{\text{Amount of water evaporation}}{\text{Input energy amount}} \times 100\% \quad (1)$$

### 3. Result

Table 2. shows the results of the experiments conducted through this study. The initial sample weight was 10 kg. The initial and final moisture contents were measured as described above. The calculated drying efficiency is shown in Figure 2.

*Table 2. Experimental test cases*

Cases	Material (kg/s)	Initial moisture contents(%)	Final moisture contents(%)
Inflow X	10.08	80.39	8.7
Inflow 1	10.08	83.64	7.36
Inflow 2	10.82	83.64	6.7
Inflow 3	10.17	83.92	5.17
Inflow 4	9.99	78.43	3.31
Inflow 5	10.17	82.83	11.82

As shown in Figure 2., the drying efficiency in the condition with outside air inflow is higher than the drying efficiency in the the condition without outside air inflow. As drying proceeds in conventional drying systems, the humidity inside the dryer is kept close to 100%. This means that the drying resistance is increased. However, by introducing outside air inflow, the humidity inside the chamber can be lowered during the drying process. This means a decrease in drying resistance and is directly related to improvement in drying efficiency.

Experiments were carried out by varying the outside air inflow conditions in order to check the influence of the outside air inflow in detail. In this study, the experiment was conducted for the case where the outside air was introduced after a certain period of time after the device was operated. Figure 2 shows that the drying efficiency increases as the initial operating time is kept longer and the outside air inflows to the latter part.

Generally, in the case of drying system, the drying rate is kept constant after the initial operation, so that the drying efficiency is maintained above a certain level irrespective of the inflow of outside air. However, as the drying progresses, the drying rate is reduced and the drying efficiency is reduced.

That is, if the outside air inflow is carried out at the latter stage of the experimental test, the drying efficiency of the system can be increased because the reduction in the internal drying resistance can be prevented in the drying system entering the reduced drying section.

Fig. 2 Drying efficiency depending on outside air inflow conditions.

The final water content is the lowest in *Inflow 4*. As a result, it can be seen that there is an optimum point in the inflow condition of the outside air. Considering both final water content and drying efficiency, *Inflow 4* is the optimal driving test in this study.

#### 4. Conclusions

In this study, we studied about drying characteristics of wastewater sludge according to outside air inflow conditions. We conducted the experiment using a vertical thin film dryer. And experimental studies were conducted with and without outside air inflow and with various outside air inflow conditions. Materials used for the experiment are sewage sludge.

As a result of the study, higher drying efficiency was obtained in the case of outside air inflow than in the case of no outside air inflow. In addition, optimum condition of outside air inflow was derived. This is because the drying resistance inside the drying device is reduced through the inflow of outside air. Also, it was confirmed that higher drying efficiency can be obtained by progressing the inflow of air outside the rate reducing drying zone.

### **Abstract**

*The drying of beef has gained an increasing interest and the organic market shows an increasing demand for dried beef products. In this study, organic beef meat slices were dried at 50 °C, 60 °C and 70 °C. Moisture content and color was measured throughout the drying process alongside Vis/VNIR hyperspectral images of the slices. The results of the total color difference ( $\Delta E$ ) showed the biggest change for samples dried at 50 °C ( $\Delta E = 25.6$ ). The  $a_w$  value was the lowest for slices dried at 50 °C (0.744). The hyperspectral data gave promising results regarding non-invasive prediction of moisture content and color.*

**Keywords:** *beef drying; drying behavior; color; hyperspectral imaging; quality.*

---

## 1. Introduction

The dehydration of meat has a long tradition as a preservation method and is still an option in areas where no refrigeration is available. Meat is a valuable protein source. However, a high protein and water content is exactly the reason why meat is also very perishable product and meat is often linked to foodborne disease [1–4]. There are various options for dehydration, e.g. whole muscles or parts of the muscles, which are very common as intermediate meat products such as ham or are known as *biltong* in South Africa and need to be sliced into bite-sized pieces after drying. Further examples for dried meat products are *jerky* from the USA and *charqui* from countries of South America which are cut to thin slices even before drying. While charqi is usually an important ingredient for daily meals and is rehydrated by cooking, jerky is a typical ready-to-eat snack food. There are neither restrictions regarding the meat variety (beef, pork, chicken etc.), nor regarding the varieties of spices that are added before drying (salt, pepper, honey, etc.). Further, smoking can present a post-drying processing step, but have been shown to influence the drying behavior, while the final product color is not influenced [5,6].

In organic processing, the food additives are highly restricted and the processing itself is the main factor to gain high quality products. In this paper, beef was dried at 50, 60 and 70 °C to a jerky style product to investigate the influence on the final product quality. Drying behavior and development of color were investigated. The reflectance of the samples was detected by hyperspectral imaging to investigate the option of implementation of non-invasive control systems into beef drying.

## 2. Materials and Methods

### 2.1. Meat type

For the experiment the roast beef (*longissimus dorsi*) of 4 26 months old heifers carcass weight 320 kg) of Uckermarker breed was used which led to four repetitions for each drying temperature. The beef was shock frozen 2 days after slaughter and stored at -18 °C until use. 24 h before each drying experiment, the beef was thawed at 4 °C for 24 h.

### 2.2. Sample preparation

The thawed beef was sliced with an electrical slicer (Graef, Alleschneider Vivo V 20, Arnsberg, Germany) with the fiber to slices of five mm thickness and cut to 50 x 50 mm samples with a knife. The initial weight was determined with a lab balance (lab scales, E2000D, Sartorius, Göttingen, Germany), further the color was determined with a Chroma Meter CR-400 (Minolta, Osaka, Japan) measured on three spots per sample and expressed using the CIELAB color space. Eight slices were used per repetition, four were dried in an oven (SLE 500, Memmert GmbH, Germany) at 105 °C for 24 hours after the drying

process to calculate the initial and final moisture content, the remaining samples were analysed with a water activity meter (LabSwift. Novasina, Lachen, Switzerland) to determine their  $a_w$ -values.

### 2.3. Drying process

The samples were dried at 50, 60 and 70 °C in a hot air tray dryer (HT mini, Innotech Ingenieursgesellschaft mbH, Germany). The samples were weight and the color was determined invasively by taking the samples out of the dryer every 20 minutes for the first hour of drying, in a 30 min interval for the second hour and hourly afterwards. Based on an estimated initial moisture content of 73 %, the drying process was stopped after 420 min for the drying temperature of 70 °C, after 480 min at 60 °C and after 600 min at 50 °C.

### 2.4. Calculations

Based on the weighing during drying and after oven drying for 24 hours, the moisture content (MC) on the dry basis was calculated and the moisture ratio (MR) was determined with the following equation (simplified by Rayaguru and Routray (2012) [7]):

$$MR = \frac{M}{M_i} \quad (1)$$

With  $M_t$  and  $M_{t+\Delta t}$  as moisture content in gH<sub>2</sub>O/gDM at time  $t$  and  $t+\Delta t$  and the time in hours. The color change  $\Delta E$  at every time of measurement compared to the initial color was calculated by:

$$\Delta E = \sqrt{(L_i - L_t)^2 + (a_i^* - a_t^*)^2 + (b_i^* - b_t^*)^2} \quad (2)$$

with  $i$  representing the initial  $L$ -,  $a^*$ - and  $b^*$ -values and  $t$  the values for color at every time.

### 2.5. Hyperspectral imaging

The samples were also imaged with an hyperspectral camera before and during drying in the intervals mentioned above. The visible near-infrared (VNIR) hyperspectral imaging systems consists of an ImSpector V10E PFD camera coupled to a linear translation stage (SPECIM Spectral Imaging Ltd., Finland). 27 cm above the belt conveyor tray (working speed 8mm/s) a 35 mm lnes (Xenoplan 1.9/35, Schneider Optische Werke GmbH, Germany) was positioned, which resulted in a spatial area of 0.03 mm<sup>2</sup> per pixel. This setting allowed to capture spectral data of 400-1010 nm in 1.5 nm increments. More details, including the image processing with Matlab software package (Matlab R2013a) are described by Crichton et al. (2017 a,b) [8,9], Retz et al. (2017) [10] and von Gersdorff et al. (2018) [6].

### 3. Results and Discussion

#### 3.1. Drying behavior and water activity

The drying curves of beef dried at 50, 60 and 70 °C are illustrated in Figure 1 a), further Figure 1 b) represents the drying rate (DR). As compared to Başlar et al. (2014) [6], who investigated the drying of beef with three different drying methods at 55, 65 and 75 °C, the beef dried the fastest at the highest temperature due to a higher heat and mass transfer at higher temperatures [7]. The MR decreases exponentially, with is in accordance with other raw materials e.g. pumpkin [8], diverse vegetables [9] and apples [10], only to mention a few, and can be explained by a high heat and mass transfer coefficient during surface evaporation [7] in the initial stage of drying. During drying, the flux of moisture from the inside to the surface decreases and is smaller than the evaporation on the surface [11]

Figure 1: Drying curves of beef dried at 50, 60 and 70 °C a) and related drying rates (DR) Figure 1b)

However, the distance between the drying curves of 70 and 60 °C is obviously bigger than between 60 and 50 °C. This can be explained by a significantly higher drying rate of beef during drying at 70 °C, which becomes clearer by illustrating the drying rate (DR) as a function of moisture ratio (MR) (Figure 1 b). With 1.85 (g H<sub>2</sub>O/g DM)\*h<sup>-1</sup> beef dried at 70 °C shows the highest DR after 20 min of drying and a MR of 0.73, but decreases rapidly with the decreasing MR during drying. The distance between the three DR curves decreases during drying and at low MRs the DR is nearly the same regardless of the temperature applied. This might be an effect of the decreasing heat and mass transfer mentioned above, but also structural changes (e.g. protein denaturation) might occur during protein and collagen denaturation[12,13] which effects the transfearability of water.

The water activity was 0.753 (± 0.047) for beef dried at 50 °C, 0.762 (± 0.034) for 60 °C and 0.763 (± 0.038) for 70 °C. Therefore, all the samples are safe from growth of the most

bacteria and from mycotoxin production of mold and yeasts ( $a_w \leq 0.85$ ) [4], and although the 50 °C samples showed the lowest water activity, the highest standard deviation indicate not a significant influence between the drying temperatures.

### 3.2 Development of color

The development of L a\* and b\* values and the related change of color during drying is illustrated in Figure 2 a)-d). The graphs show that meat is not a homogenous product which is expressed in different values for CIELAB data before any heat treatment was applied at point 0. The development for L values for beef dried at 60 and 70 °C is very similar, the lightness of beef dried at 50 °C decreases more during the whole drying process compared to the dehydration at 70 °C. The development of the lightness seems to be linked directly to the moisture content, while the redness (Figure 2b) develops unequal for different dehydration temperatures until a certain moisture content is reached. Those investigations are not in line compared to drying of ostrich jerky, where the drying air temperature was found to have an influence and not the moisture content [14] and needs further investigations. An air temperature of 50 °C seem to retain the red color better, expressed in a slight increase in redness

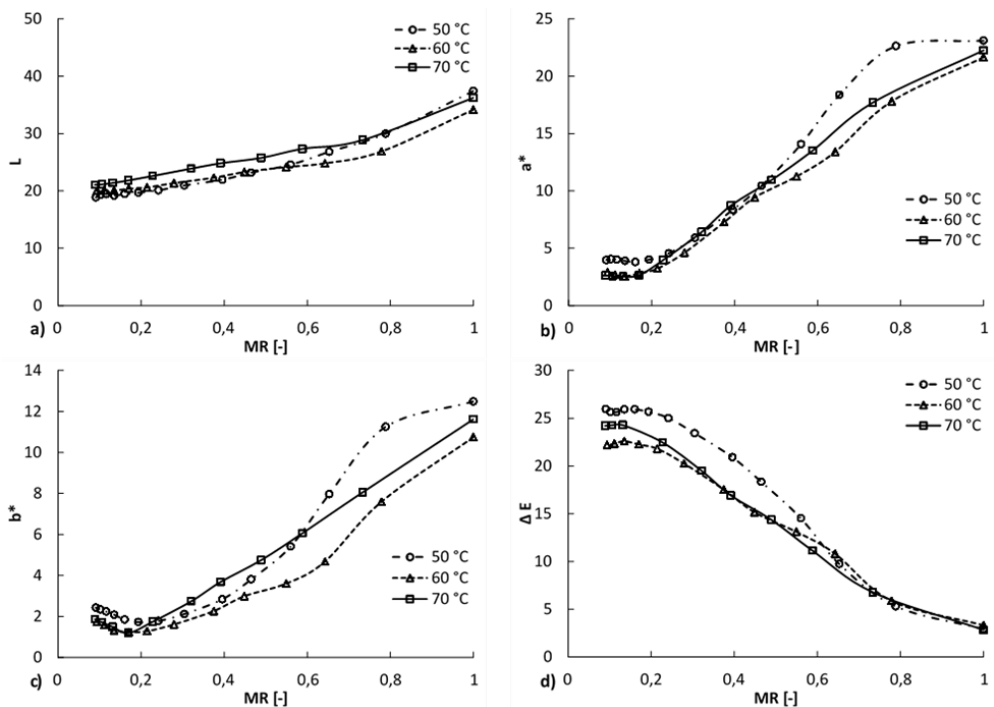

Figure 2: Development of L- a\*- and b\*-values during drying of beef at 50, 60 and 70 °C (a-c) and corresponding color change  $\Delta E$  as functions of MR.

compared to the 60 and 70 °C, however, the initial a-value might be the influencing factor for the final redness. The yellowness is not an indicator of moisture content at higher moisture contents, as it develops very different throughout the three drying temperatures until a low moisture content is reached and the b\*-value develops nearly the same from a certain point on for all three drying temperatures. Regarding the the total color change ( $\Delta E$ ), beef samples dried at 50 °C changes the most in color, while samples dried at 60 °C showed the lowest change related to the initial color. For all samples the color stops changing at a low moisture content. However, usually the drying should be as short as possible, as long drying periods may influence both the energy efficiency and the quality parameters negatively [15], which might explain the higher  $\Delta E$  for the 50°C processing. The second highest  $\Delta E$  for samples dried at 70 °C might be explained by the denaturation of proteins due to heat treatment [12,16]. However, the non-invasive measurements might also have an influence on the color development due to the differences in temperature (cooling during measurements, heating up in the drying intervals).

### 3.3 Hyperspectral imaging

The relative reflectance of raw beef, dried for 120 min at 50, 60 and 70°C and beef dried to the final moisture content is shown in Figure 3. The reflectance of beef is at the highest level in the visible spectral region in the red range due to the red color of the beef, which was documented by Wu et al. (2013) [17] before.

**Figure 3: Relative reflectance of beef dried at 50, 60 and 70 °C air temperature after 0 and 120 minutes of dehydration and at final moisture content.**

The reflectance is decreasing over time which is reasoned by the decreasing moisture content during dehydration. Further, both, the visible and the NIR region of the spectrum affects the relative reflectance. The drying temperature affects the reflectance during drying (120 minutes) in particular in the NIR region, samples dried to the final moisture content show nearly the same reflectance, regardless of the drying air temperature, which might be

due to different moisture contents after the same time after drying at different temperatures. However, differences in reflectance spectra do not necessarily affect the successful implementation of color and moisture content prediction models like shown for apple drying [8].

#### 4. Conclusion

The present investigations show the shortest drying time for the highest drying time, but there are indications, that drying a lower air temperature might save quality attributes better, while too low temperatures again might influence the quality negatively. As quality indicator, final color shows minor changes for beef dried at 60 °C compared to 50 °C and 70 °C. However, the difference in color was not visible with the bare eye and might further be negatively influenced by the invasive measurements which needs further research. The spectral results will be further investigated and used to build prediction models to test the useful implementation of simplified non-invasive sensors.

### **Abstract**

*Scientific and technical studies on the intensification of removal moisture from dispersed materials and their simultaneous dispergation in the hollow heating element of a thermo-vacuum apparatus is researched. Continuous thermo-vacuum dehydration and dispergation process of zirconium hydroxide, brown coal, graphite, sawdust, biological materials is considered. Based on conducted studies was made conclusions about perspective to use this technology. Thermo-vacuum technology is different from the other by low-temperature heating, low time processing, humidity indicators controlling and nano-dispersion grinding.*

**Keywords:** *dehydration, dispergation, energy saving*

---

## **1. Introduction**

Intensification of production processes as well as solution the problems of energy and resource saving at dehydration of dispersed materials has become increasingly important in recent times.

There are drying installations in which the mechanical process of dispersion and dehydration of dispersed material are used in parallel; it leads to intensification of the process and reduction in capital expenditures [1]. In this case, preheated air is used as a drying agent.

In the paper [2] it is shown, that a significant amount of heat is released at fine grinding of materials in impact-reflective mills. This phenomenon is associated with impact and friction of material particles on working surfaces of the mill, emergence of new surfaces during destruction and also due to turbulence of the dust-gas mixture in the working zone of the mill.

Thus, heat occurrence in the process of fine grinding in impact-reflective mills ensures in parallel the processes of dehydration and dispersion of various materials.

However, due to lack of a rational technology for performing dehydration and dispersion in parallel, such processes have not became widely used in practice, especially in chemical technology.

There are various methods and devices designed for dehydration of agricultural dispersed materials [3, 4]. However, they require considerable energy consumption and do not ensure obtaining a product with specified characteristics, in particular, dispersion and humidity which largely affect its quality.

## **2. Materials and methods**

Thermal-vacuum energy-efficient pulse-impact method for continuous dehydration and dispersion of wet materials has been developed on the basis of the performed theoretical and experimental studies. The proposed method is based on the principle of combining the rapid evacuation and thermal heating upon direct contact of a wet material with a heated surface of the spiral heater, which provides instantaneous heating of wet material particles in vacuum to a specified temperature. The contact of the wet material with the heated wall of the heater causes heat transfer from the heater wall to the surface layer of the material, and the reduced pressure inside the heating element allows moisture to be removed from the material at a temperature substantially below the vaporization temperature at atmospheric pressure. The rate of destruction of the surface layer of the wet material depends on the heating temperature and its internal state.

The thermal-vacuum installation for continuous dehydration and dispersion is presented in Fig. 1 [5].

The installation consists of a feed hopper (1), hollow heater (2), vacuum pump (3), pipelines (4, 11), cyclone (5), receiver of dried raw materials (6) and rotary valve (7). It has thermocouples (8, 13), control panel (9), conveyor (10), filter (12), level sensor for dried raw material (14), vacuum gauge (15).

This installation design provides simultaneously both high-performance continuous dehydration and dispersion of material in heat insulated space.

Fig. 1. Diagram of the thermal-vacuum installation

### 3. Results

#### 3.1. Dehydration and dispersion of zirconium hydroxide

Let us consider a continuous process of production of zirconium dioxide fine-dispersed powder from zirconium hydroxide in a thermal-vacuum installation. The initial humidity of zirconium hydroxide is 80%, the diameter is 6mm, the length is within the range of 10 - 15 mm. Zirconium hydroxide together with an air enter the lower cavity of the heating element. The rate of a two-phase flow in the thermal-vacuum installation is determined from the expression:

$$v = \frac{\pi \cdot r^2 \cdot d^2 \cdot P \cdot \rho \cdot v_1}{2 \cdot \beta \cdot l \cdot \eta}, \quad (1)$$

where,  $v$  - rate of a two-phase flow in the heating element, m/s;

$r$  - internal radius of the heating element, m;  $d$  - diameter of the particle to be dried, m,;

$P$  - average pressure in the heating element, Pa;

$\rho$  - medium density kg/m<sup>3</sup>;  $v_1$  - hovering rate, m/s;

$\beta$  - friction coefficient, kg / s;  $l$  - the heater length, m;  $\eta$  - coefficient of air dynamic viscosity, Pa s.

Moving inside the heating element of the thermal-vacuum installation (Fig. 1) the zirconium hydroxide granules (Fig. 2, a) come into contact with heated walls of the heater.

Fig. 2, a. Zirconium hydroxide

Fig. 2, b. Zirconium dioxide

An instantaneous heating of zirconium hydroxide to a temperature  $T_1$ , which is above the evaporation temperature  $T_2$  ( $T_1 > T_2$ ), occurs. Local intensive vapor emission occurs inside the body of zirconium hydroxide granules under reduced ambient pressure. An instantaneous pressure gradient occurs as a result of vapor emission and zirconium hydroxide granule falls into small particles, which increases liquid removal from the material to be dried. Zirconium hydroxide with an initial humidity of 80%, diameter of 6 mm and length of 10 ... 15 mm turns into a fine-dispersed powder of zirconium dioxide with moisture of 1%, fraction of 0.1 - 10  $\mu\text{m}$ . There are no conglomerates in this powder. (Fig.2, b). The process of zirconium dioxide obtaining from zirconium hydroxide in thermal-vacuum installation takes 15 seconds.

The moisture ( $m_{\text{вл}}$ ) removed from the material to be dried in the thermal-vacuum installation is directly proportional to the heater power ( $P_H$ ), the heating temperature of the material to be dried ( $T$ ), the coefficient of heat exchange between the heating element and the material to be dried ( $a$ ), the evaporation area ( $S$ ). It is inversely proportional to the environment pressure ( $P_c$ ), the vapor kinematic viscosity ( $\nu$ ), the impact elasticity of the material to be dried ( $W$ ), the volume of the material to be dried ( $V$ ) [6].

$$m_{\text{вл}} = \frac{2 \cdot (m_{\text{о\u0434\u0430}} - m_c) \cdot P_H \cdot T \cdot a \cdot S}{P_c \cdot \nu \cdot W \cdot V}, \quad (2)$$

where,  $m_{\text{total}}$  – total mass of the wet material, kg;  $m_c$  – mass of the material during dehydration, kg.

### 3.2. Dehydration and dispersion of brown coal

Dehydration and dispersion of brown coal (Fig. 3, a) in thermal-vacuum installation reduces the content of sulfur and nitrogen in coal, which leads to decreasing the amount of harmful emissions into the atmosphere during its combustion. The minimum particle size of the dried coal was 40 nm (Fig. 3, b), the moisture content was less than 2%. The moisture of the initial stock was 40%, the size - 6 mm. Drying the brown coal took 14 s, its color varied from brown to black. The temperature of the dried brown coal at the heating element output did not exceed 76 ° C. At the same time, the quantity of energy expended for dehydration and dispersion of brown coal does not exceed 600 MJ

*Fig. 3. a. Initial brown coal*

*Fig. 3. b. Electron microscopy of dried brown coal*

### 3.3. Dehydration and dispersion of graphite

Nano-dispersed graphite of size 10 - 40 nm was obtained from fine-dispersed graphite in the thermal-vacuum installation (Fig. 4 a, b). The processing time was 15 s. The process was continuous. The quantity of energy expended for dehydration and dispersion of graphite was 320 MJ / t.

*Fig. 4. a. Initial graphite*

*Fig. 4. b. Graphite processed in thermal-vacuum installation*

### 3.4. Dehydration and dispersion of sawdust

An energy-saving, highly effective thermal-vacuum technique of continuous dehydration of wood-working industry wastes was developed. Dehydration of wet sawdust depending on the temperature of the heating element was studied. The quantity of thermal energy expended for dehydration did not exceed 360 MJ / t. Dried pine-tree sawdust and its

moisture content depending on the temperature of the heating element in the thermal-vacuum installation is presented in

Fig. 5 (b, d, g). The sawdust initial humidity is 70%. (Fig. 5, a).

Fig. 5, a. Initial sawdust Humidity 70%

Fig. 5, b. Heater temperature 150<sup>0</sup> C, Humidity 20%

Fig. 5, d. Heater temperature 200<sup>0</sup> C, Humidity 5%

Fig. 5, g. Heater temperature 250<sup>0</sup> C, Humidity 1%

Sawdust dehydration in the thermal-vacuum installation lasts for 20 s, the process is continuous.

### **3.5. Dehydration and dispersion of agricultural products**

Dehydration of sugar production waste was carried out in the thermal-vacuum installation. The initial humidity was 65%. Fig. 6, a. The temperature of the dried beet pulp did not exceed 50°C. Humidity - 5%. Fig. 6, b. Dehydration time was 20 c. The process was continuous. Nutritive substances are kept. The quantity of thermal energy expended for dehydration was equal to 720 MJ / t.

*Fig. 6. a. Initial pulp*

*Fig. 6. a. Dried pulp*

Thermal-vacuum drying of alfalfa with humidity of 48% is presented in Fig. 7, a. After drying the alfalfa moisture was 12%. See Fig. 7, b. Drying time was 20s. Nutritive substances were kept. Heat energy consumption was 580 MJ / t

*Fig. 7. a. Initial alfalfa*

*Fig. 7. b. Dried alfalfa*

The results of study on moisture removal from dispersed materials depending on mode parameters of the thermal-vacuum installation made it possible to create an industrial science and technology base for developing energy-efficient thermal-vacuum installations, to define requirements for optimizing the technological processes of dispersed materials dehydration taking into account their physicochemical and structural compositions, to reduce energy cost per unit of the dried product, to speed up the dehydration process, to develop a highly efficient thermal-vacuum technology of production of fine-dispersed

materials of high purity, to keep quality and ecological purity of the products obtained. This method allows simultaneously to remove moisture from the dispersed material and to disperse it.

The development results are of current interest for updating the existing and creation of new thermal-vacuum drying installations.

#### **4. Conclusions**

1. Scientific and technical studies on the intensification of removal moisture from dispersed materials: zirconium hydroxide, brown coal, graphite, sawdust, biological materials are researched. The regularities of heat exchange processes between heating element and wet dispersed material in the hollow spiral-heating element of the thermo-vacuum apparatus are established. Demonstrated that in thermo-vacuum apparatus by 15 seconds it possible to obtain dried nano-dispersed materials.
2. A low-temperature thermo-vacuum dehydration technology of biological materials was developed. Conducted studies demonstrated that most optimal, from the point of view of preserving biological material quality, is dehydration mode at temperatures up to 50 °C.
3. Conducted scientific and technical studies are relevant to improve existing equipment and creation of new heat-technological equipment.

### **Abstract**

*Hot water extract of sugar and red maple bark was added to maple syrup and dried by freeze (FD) and vacuum drum drying (VD) techniques. Addition of maple bark extracts to syrup helped to develop polyphenols-enriched maple sugar. X-ray diffraction revealed that sugar obtained from FD was amorphous in nature, while crystalline when dried by VD. Furthermore, the observation of maple sugar samples under scanning electron microscopy showed smooth and porous surface for FD sugar, while rough and grainy surface for VD sugar. Hausner ratio indicated that sugar produced by VD showed better flow characteristics than FD sugar.*

**Keywords:** *drying techniques; maple syrup; phenolics; microstructure*

---

## **1. Introduction**

Drying of foods, solid (fruit and vegetables) or liquid (juices and syrups), increase their shelf life along with ease in handling and transportation. However, drying of foods cause the modifications of its physicochemical properties. In general, drying involving high temperatures effect thermo-labile compounds. Freeze drying (FD) is well-known technique for drying foods containing heat-sensitive and oxidative compounds such as polyphenols, because of the use of very low temperature and high vacuum. However, drying time and operation costs are major drawbacks of freeze drying [1]. Vacuum drum drying (VD) is another technique that operates at high temperature under vacuum, making it possible to dry food faster in comparison to freeze drying. Similar to FD, it may also preserve oxidative compounds due to the use of vacuum. Physical properties of powder such as moisture, flowability, morphology, etc depends on the type of drying method used [2, 3]. Therefore, drying techniques ought to be selected carefully, depending on the desired quality of the final product.

Canada accounts for approximately 71% of maple syrup production in the world (Statistics Canada, 2016). Maple syrup is a natural sweetener with high nutritional value based mainly on its sucrose, minerals, proteins and polyphenols [4]. Depending on the percentage of light transmission (at 560nm), maple syrups are classified into four grades: golden, amber, dark and very dark (Canadian Food Inspection Agency). A class of “very dark” maple syrup, which has light transmission less than 25%, is considered as substandard. Therefore, drying of such substandard maple syrup to produce a maple sugar can add value to a natural sweetener containing minerals, polyphenols, etc. However, the polyphenols are present at a very low concentration in maple syrup. When dried, the concentration of polyphenols may further diminish. Therefore, the main objective of this work was to produce polyphenol-enriched maple sugar by adding, red and sugar maple bark extracts to maple syrup, and subsequently drying the mixture.

For this study, freeze drying and vacuum drum drying technologies were explored. Thus obtained maple sugars were examined for total phenol content, moisture content, flow characteristics, crystallinity and morphology in order to study the effect of drying methods on developing the polyphenol-enriched sugars.

## **2. Materials and Methods**

### **2.1. Hot water bark extraction and addition of extracts to maple syrup**

Maple barks (sugar and red maple) were extracted using hot water following the method previously described by Geoffroy et al. [5]. Hot water extracts of maple barks were then added (at 0.01 % w/v) to maple syrup (very dark, 66 °Brix) and subsequently dried. Maple

syrup without any extract was considered as control. Hereafter, dried maple syrup (without extract, control) will be denoted as MS, while maple syrup with sugar and red maple bark extract are identified as MS-SX and MS-RX, respectively.

## 2.2. Drying experiments

Freeze drying (FD) was done by using a laboratory freeze dryer (Freeze Mobile 24, Virtis Company Inc., Gardiner, NY). Sample was frozen at  $-40\text{ }^{\circ}\text{C}$  overnight and freeze-dried for 25h. The heating plate temperature was initially set at  $-36\text{ }^{\circ}\text{C}$ , vacuum level was below 30 mtorr and the condenser at  $-90\text{ }^{\circ}\text{C}$ .

For this study, a laboratory-scale vacuum drum dryer (Buflovak, Buffalo, USA) was used. Sample was fed between the nips of two rotating drums, where drum temperature increased up to  $110\text{ }^{\circ}\text{C}$ . The dried maple sugar powder were scraped off using in-built scrapers.

The obtained FD and VD samples were vacuum packed and stored in  $4\text{ }^{\circ}\text{C}$  for further analyses.

## 2.3. Analyses of maple sugar powder

### 2.3.1. Total phenolic content

Total phenolic content (TPC) in maple sugar powder was determined using the Folin-Ciocalteu method using microplate spectrophotometer (X Mark<sup>TM</sup>, BIO-RAD) following the method used by Zhang et. al [6]. The results were expressed in milligram gallic acid equivalent per gram of oven dry sample (mg GAE/100g sample, db). TPC was measured in triplicates.

### 2.3.2. Moisture content

Moisture content of maple sugar powder was measured by vacuum-oven method at  $70\text{ }^{\circ}\text{C}$  and  $-22\text{ in.Hg}$  vacuum for 24h. Analyses were done in triplicates.

### 2.3.3. Flow properties

Hausner ratio (HR) was used to obtain the indication on flow characteristic of maple sugar powders. HR was calculated using the measured bulk and tapped density of the sample. Bulk density was measured by pouring the known mass of sample ( $m$ ) to a cylindrical glass tube and volume occupied ( $V_b$ ) was noted. For the tapped density, the glass tube was tapped from the vertical distance of  $12\pm 2\text{ cm}$  until no successive differences in volume ( $V_t$ ) was recorded. Bulk and tapped densities were calculated using the following formula;  $m/V_b$  and  $m/V_t$ , respectively. Measurements were done in triplicates.

#### 2.3.4. X-ray powder diffraction

The crystallinities of freeze and vacuum dried maple sugars were analyzed by powder X-ray diffractometer (SIEMENS/Bruker, Germany). Samples were measured at a diffraction angle ( $2\theta$ ) between 0 to 50° under operational conditions of 40 kV and 40 mA using Co ( $K\alpha_{1+2}$ ) radiation.

#### 2.3.5. Microstructural analysis by environmental scanning electron microscopy (ESEM)

Freeze and vacuum dried maple sugar samples were analyzed by environmental scanning electron microscopy (ESEM). The samples were scanned at 500X magnification at 20 kV.

### 3. Results and Discussion

#### 3.1 Effect of drying on total phenolics of maple sugar powder

Regardless of the type of drying techniques used, TPC of sugars containing maple bark extracts showed higher values than the control. Sugar containing red maple bark extract presented higher TPC value than other sugar samples. This can be explained by the higher phenolic content of the red maple bark extract [7]. MS-RX obtained from VD had around 8% higher TPC than the control (MS). In general, FD method is preferred to dry a food containing a thermo-labile compound such as phenolics. On contrary, we observed that VD maple sugars had relatively higher TPC than those of FD sugars. This could be due to high temperature in VD that could have caused the breaking of the phenolic-glycoside bonds. Resulting in more phenolics becoming readily available to form complex with Folin's reagent while determining TPC by Folin-Ciocalteu method. However, it has yet to be validated by identifying the phenolic profile in maple sugar powders using techniques of chromatography and mass spectrophotometry.

#### 3.2 Moisture content

Moisture content of freeze-and vacuum dried maple sugars are presented in Fig. 1. The moisture content in VD maple sugar (0.6-0.7%, on dry basis) was significantly lower than that of FD (4 to 5 %, dry basis). The drying temperature in VD was higher (110 °C) than in FD. Therefore, it was obvious that VD produced sugars had lower moisture content than that of FD. Similar tendency was also observed for the production of mango powder by freeze and drum drying [8].

**Fig. 1** Moisture content of freeze-and vacuum drum dried maple sugars. MS: maple sugar, MS-SX: maple sugar with sugar maple bark extract, MS-RX: maple sugar with red maple bark extract, FD: freeze-drying, VD: vacuum drum drying.

### 3.3 Flow characteristics of maple sugar

The calculated Hausner ratio of FD and VD maple sugars are presented in Table 1. Lower the Hausner ratio, the better is the flow properties [3]. The Hausner ratio was significantly higher ( $P < 0.05$ ) for the FD maple sugars (1.45 to 1.48, poor to very poor) than that for VD sugars (1.14 to 1.20, good to fair flow). Therefore, VD maple sugars showed better flow characteristic than that of FD.

**Table 1.** Flow characteristics of freeze-and vacuum dried maple sugars.

Drying techniques	Sample	Hausner ratio
FD	MS	$1.45 \pm 0.03^a$
	MS-SX	$1.48 \pm 0.07^a$
	MS-RX	$1.47 \pm 0.06^a$
VD	MS	$1.14 \pm 0.02^b$
	MS-SX	$1.20 \pm 0.04^b$
	MS-RX	$1.20 \pm 0.05^b$

Values represent Mean  $\pm$  S.D. <sup>a,b</sup>different superscript letters in the same column are significantly different ( $P < 0.05$ ) by Tukey's test.

### 3.4 Effect of drying on crystallinity of maple sugar

Fig. 2 depicts the profile of X-ray diffractogram of maple sugars produced by FD and VD techniques. Amorphous material shows large and disperse peaks due to disorderly arranged molecules in amorphous state. On the other hand, crystalline material shows sharp and defined peaks since the molecules are present in a highly ordered state. From Fig. 2, it can be observed that freeze dried maple sugar (FD\_MS) is in amorphous state, whereas vacuum dried maple sugar (VD\_MS), in crystalline state. However, the degree of crystallinity has yet to be identified. Crystalline state is important for the stability of food powders. Considering this results, VD sugars seemed to have an advantage of stability.

*Fig. 2 X-ray powder diffractogram of maple sugars produced by different drying methods. FD\_MS, freeze dried maple sugar, VD\_MS: vacuum dried maple sugar.*

### 3.5 Microstructural analysis

Microstructural analysis of maple sugar obtained from FD and VD techniques are shown in Fig. 3. FD maple sugar showed irregular and porous structure (Fig. 3a). Freeze-dried food normally shows porous structure due to the fact that ice removal by sublimation during drying prevents shrinkage and volume reduction [1]. Vacuum-dried maple sugar resulted in rough and grainy surface (Fig. 3b). The difference in microstructure of FD and VD maple sugars can also be related to the the difference in their crystallinity (shown in Fig. 2).

*Fig. 3 Enviromental scanning electron micrograph (ESEM) of freeze-dried (a) and vacuum dried (b) maple sugar.*

#### 4. Conclusions

Considering the overall results, polyphenol-enriched maple sugar obtained either by FD or VD have potential applications in foods, particularly as sweetener for natural food products. For instance, FD maple sugar could be used in instant-drinks owing to its amorphous (powder) nature and VD sugar as functional food ingredient due to its high phenolic content as well as its better flow characteristics.

### **Abstract**

*This research work aimed to evaluate the physicochemical properties of arrowroot starch films plasticized with glycerol and incorporated in film-forming solution directly (D) and by sprinkling (S) with 0%, 20%, 30%, 40% (mass blackberry solids / biopolymer mass) of blackberry pulp (BL) powder and freeze dried microencapsulated blackberry pulp (ML) using mixture of gum arabic and arrowroot starch (1: 1, mass / mass). Thickness, water solubility and water vapour permeability of the films significantly increased with increasing concentration of blackberry powder. Compared to arrowroot starch film (0%), the surface of films with BL and ML powder became irregular and rough.*

**Keywords:** *Lyophilization; microstructure; water solubility; water vapor permeability; packing.*

---

## 1. Introduction

Fruit pulp has great potential to be incorporated in the film-forming solution in order to produce edible films with functional compounds such as preservation agents (antimicrobial or antioxidant compounds), innovative colours and flavours, as well as suitable mechanical and barrier properties of the biopolymer.[1] Thus, blackberry is a fruit that has great potential to supply these requirements and be used in combination with arrowroot starch to form a biopolymer matrix to create edible films. Blackberry (*Rubus fruticosus*) cv. Tupy is a fruit rich in anthocyanins and phenolic compounds, which has high antioxidant activity.[2] However, using its beneficial effects is limited because its bioactive compounds exhibit instability when exposed to high temperature, light, oxygen, among other conditions, changing their functional and antioxidative properties.[3] This situation can be mitigated by applying microencapsulation technologies in order to protect it from unfavourable environments. Freeze drying is a technological process based on dehydration by sublimation of a frozen product resulting in a dry material.[4] These processes can be used as encapsulation method when it incorporates 'active' material within a protective matrix, which is essentially inert to the encapsulated material.[5] Recently, the incorporation of micro and nano particles in film-forming solution to produce starch films with modified structure and properties have shown promise.[6] Therefore, the objective of this work was to incorporate directly and by sprinkling, blackberry pulp powder and microencapsulated blackberry pulp powder in arrowroot starch film-forming solution. The influence of type of incorporation and variation of concentration of blackberry powders on physicochemical properties of edible films were investigated.

## 2. Materials and Methods

### 2.1. Materials

In this work, frozen fruits of blackberry (*Rubus fruticosus*), cv Tupy, were acquired from "Agro Monte Verde Eirelli", Cambuí – MG, Brazil. Blackberry soluble solids content was 9°Brix, determined with digital refractometer with 0–90 °Brix range and 0.2 °Brix resolution (Reichert, Model AR200, USA). Blackberry pulp presented total solids content of 10.3 g/100g of pulp. For microencapsulation of blackberry pulp, arrowroot starch and Instantgum® gum arabic (Colloides Naturels, São Paulo, Brazil) were used as encapsulating agents. In elaboration of edible biodegradable films, arrowroot starch containing  $15.24 \pm 0.19\%$  of water,  $0.40 \pm 0.03\%$  of protein,  $0.12 \pm 0.01\%$  of fat,  $0.33 \pm 0.01\%$  of ash and  $83.91 \pm 0.00\%$  of carbohydrates [7] and amylose content of  $35.20 \pm 1.63\%$ , determined according to the methodology described by Martinez and Cuevas (1989), with adaptations [8], was used as film-forming matrix and glycerol P.A. (Reagen, Quimibrás Indústrias Químicas S.A.- Rio de Janeiro, Brazil) as plasticizing agent.

## 2.2 Microencapsulation of blackberry pulp by freeze drying

Blackberry pulp was obtained by grinding the fruits in a blender, filtered through a sieve to remove the seeds, and homogenized. Blackberry pulp was added to the encapsulating agent, arrowroot starch and gum arabic mixture (1: 1 mass / mass) in a ratio of 1:1.78 (mass / mass, blackberry pulp solids for encapsulating agent). Solution of encapsulating agent and blackberry pulp was performed in a mixer type homogenizer at room temperature for 5 minutes. Portions of frozen blackberry pulp with and without encapsulating agent was lyophilized (Mod. 501, Edwards Pirani, Crawley, West Sussex, UK), with an initial temperature of  $-40\text{ }^{\circ}\text{C}$ , pressure of 0.1 mmHg, and final temperature of  $25\text{ }^{\circ}\text{C}$  per 2 h, with total cycle time of 48 h. The resulting product was ground in a hammer mill (MR Manesco and Ranieri LTDA, model MR020, Piracicaba- Brazil), sieved and stored in polyethylene packages in desiccators, for further analysis.

## 2.3 Incorporation of blackberry into film-forming suspension

### 2.3.1. Preparation of film-forming suspension.

Film-forming suspension was obtained by dispersing arrowroot starch in distilled water (4%, mass / mass, as optimized by Nogueira, Fakhouri & Oliveira, [9]). This suspension was heated to  $85 \pm 2\text{ }^{\circ}\text{C}$  in a thermostatic bath (TECNAL, Brazil), with constant agitation, for about 5 minutes. The freeze dried blackberry pulp (BL) and the freeze dried microencapsulated blackberry pulp (ML) were added to film-forming suspension in different concentrations, 0%, 20%, 30% and 40% (mass/mass of dry starch) in two different ways. The first one consisted of direct incorporation in film-forming suspension and the second one was by sprinkling into film-forming suspension. Glycerol was added to the solution at concentration of 17% (mass/mass of total solids, [9]).

### 2.3.2. Direct incorporation of blackberry powder into film-forming suspension (D).

Freeze dried blackberry pulp (BL) and freeze dried microencapsulated blackberry pulp (ML) were added directly into film-forming suspension and homogenized in previously mentioned proportions. Aliquots of 25 mL of resulting suspensions were distributed on support plates (12 cm diameter). Films were dried at room temperature ( $25 \pm 5\text{ }^{\circ}\text{C}$ ), until they could be easily removed from the plates, approximately for 24 h. Films were conditioned at  $25\text{ }^{\circ}\text{C}$  and  $55 \pm 3\%$  of relative humidity for 48 h, before their characterization.

### 2.3.3. Incorporation of blackberry powder by sprinkling into film-forming suspension (S).

Aliquots of 25 mL of resulting film-forming suspension were distributed on support plates (12 cm diameter). Freeze dried blackberry pulp (BL) and freeze dried microencapsulated blackberry pulp (ML) were dispersed through a stainless steel sieve (53 mesh), homogeneously in all the surface area of film-forming suspension already disposed on the plates. Then, films were dried for 24 h at room temperature ( $25 \pm 5$  °C). After drying, films were removed from the support plates and conditioned at 25 °C and  $55 \pm 3\%$  relative humidity for 48 h, before their characterization.

## 2.4 Films characterization

### 2.4.1 Microstructure

Electronic Scanning Electron Microscope with X-ray Dispersive Energy Detector (SEM) bench (model of MEV: Leo 440i, model of EDS: 6070, Leo 440i - LEO Electron Microscopy/Oxford- Cambridge, England) was used to observe morphological characteristics of surface and cross section developed for sample of the films formulations.

### 2.4.2 Film Thickness and solubility in water

Films thicknesses were measured with accuracy of  $\pm 0.001$  mm, at ten different regions of the film, using a micrometer (Mitutoyo brand, model MDC 25M, MFG / Japan).

Water solubility of films was determined according to the method proposed by Gontard, Guilbert, and Cuq. [10] and expressed according to Equation (1).

$$\text{Solubilized material (\%)} = \frac{m_{si} - m_{sf}}{m_{si}} \times 100 \quad (1)$$

In which 'msi' is the initial dry mass of the films (g), 'msf' is the final dry mass of the non-solubilized films (g).

### 2.4.3 Water vapor permeability

Water vapor permeability rate of the films was determined gravimetrically based on ASTM E96-80 method [11], using an acrylic cell, with a central opening (diameter of 4.3 cm), in which the film was fixed. The bottom of the cell was filled with dried calcium chloride, creating a dry environment inside (0% relative humidity at 25 °C). This cell was placed in desiccator containing saturated sodium chloride ( $75 \pm 3\%$  RH), equalized for 48 h previously to analysis. Water vapor transferred through the film was determined by mass gain of calcium chloride. The cell weight was recorded daily for, at least, 7 days. The film thickness consisted on the average of 5 random measurements made on different parts of

the samples. The water vapor permeation rate (PVA) was performed in triplicate and calculated by Equation (2).

$$PVA = \frac{e}{A \times \Delta p} \times \dot{M} \quad (2)$$

In which 'PVA' is permeability to water vapor (g.mm / m<sup>2</sup>.day.kPa), 'e' is mean film thickness, 'A' is permeation area (m<sup>2</sup>), 'Δp' is partial vapor pressure difference between two sides of films (kPa, at 25 °C), 'M' is absorbed moisture rate, calculated by linear regression of weight gain and time, in steady state (g/day).

#### 2.4.4 Statistical analysis

Significant differences between average results were evaluated by analysis of variance (ANOVA) and Tukey test at 5% level of significance, using SAS software (Cary, NC, USA).

### 3. Results and discussion

Differences in microstructure of the films can be visualized in Figure 1, by scanning electron microscopy (SEM). Control film (0%) presented organized and continuous polymer matrix and regular surface (Figure 1 A-C). Films developed with 40% of blackberry presented rougher and irregular surfaces and exhibited structural characteristics directly related to those observed for BL and ML powders, which consequently hampered its solubilization. The cross-section images of 40% BLD and MLD films (Figure 2 D-F and J-L, respectively), showed continuous regions and disorganized regions due to the presence of BL and ML particle within arrowroot starch matrix formed during the films drying. BL and ML particles were integrated in arrowroot starch matrix, showing good compatibility between materials. Using sieve to sprinkle BL and ML powder over the film-forming suspension allowed falling homogeneously over the entire surface area of films. It can be seen in Figure 2 G-I, in which, when 40% ML were sprayed under the film-forming suspension. Some regions with BL and ML agglomerations could also be observed in films for both types of incorporation. This may be due to poor dispersion of powders in high concentrations in the film-forming solution, given its high viscosity.

**Figure 1.** SEM images of the films with 0% and 40% of freeze dried blackberry pulp (BL) and freeze dried microencapsulated blackberry pulp (ML) incorporated directly (D) and by sprinkling (S): (A, B and C) surface and cross section of control film; (D, E and F) surface and cross section of 40% BLD film; (G, H and I) surface and cross section of 40% BLS film; (J, K and L) surface and cross section of 40% MLD film; (M, N and O) surface and cross section of 40% MLS film. Images A, C, F, I, L and O with 250x magnification and images B, D, E, G, H, J, K, M and N with 1000x magnification.

Thickness of films significantly increased ( $p < 0.05$ ) with increasing concentration of BL and ML powder incorporated directly (D) and by sprinkling (S) as compared to control film (0%) (Table 1), although, in all cases, the film-forming suspension volume by plate area remained constant. The increased solid content and possible agglomeration of BL and ML in polymer matrix, evidenced by prominences on the surface of films by SEM (Figure 1), could explain this result.

**Table 1. Thickness, solubility in water and permeability to water vapor of films with 0%, 20%, 30% and 40% of freeze dried blackberry pulp (BL) and freeze dried microencapsulated blackberry pulp (ML) directly incorporated (D) and by sprinkling (S).**

Films	Thickness (mm)	Solubility in water (%)	Permeability to water vapor (g.mm/m <sup>2</sup> .day.kPa)

\*Same letters in the same column show no statistical difference (p > 0.05).

Incorporated films with BL and ML by sprinkling were more water soluble than films with blackberry powder incorporated directly. Differently to direct incorporation, the incorporation by sprinkling allowed particles of powder stayed only in the surface of the films. As blackberry powders were porous and showed a high hydrophilicity, it is believed that, when the films were immersed in water, the particles rehydrated rapidly leading to their solubilization. Solubilization of the particles probably created holes in the surface of the films, which allowed the access of water molecules into the starch matrix facilitating their solubilization.

Films with only 20% BL and ML presented lower water vapor permeability rates than the 0% film. This behavior was attributed to a better dispersion of blackberry powder at low concentrations in the film-forming solution increasing compactness of the films, which may have hindered the passage of water molecules. It is also possible that presence of blackberry powder particles within the starch matrix, as well as on the surface, has introduced a tortuous path for the passage of water molecules, which may have led to a decreasing behavior in water vapor permeability. At concentrations above 30%, there was an increase in water vapor permeability due to the presence of agglomerated blackberry dust particles.

#### 4. Conclusions

The type of incorporation and concentration of the blackberry into filmogenic solution (directly or by sprinkling) influenced the structure, thickness, water solubility and permeability to water vapor of resulting films.

### **Abstract**

*Spray fluidized bed agglomeration is an important process in particle formation and is widely used in the chemical, pharmaceutical and food industry. In this study a continuously operated horizontal fluidized bed is employed to obtain a continuous agglomeration process. It is conducted with glass beads ( $d_{st}=200\ \mu\text{m}$ ) and water-based binder hydroxy-propyl-methyl-cellulose (HPMC) sprayed by three top nozzles. The steady state is reached and samples are taken periodically and analyzed. The influence of fluidization air temperature and configurations of internal weirs are studied.*

**Keywords:** horizontal fluidized bed, spray agglomeration, continuous process

---

## **1. Introduction**

Size enlargement processes have the purpose of changing the physical properties of powders in order to meet desired product specifications such as size, shape, flowability, density, solubility or porosity [1]. Among various heavily used apparatuses, spray fluidized bed agglomerator is an important one and widely used in the chemical, pharmaceutical and food industry. The most significant advantage of this apparatus is that it allows the combination of binder dispersion and drying in a single process [2]. In the agglomeration process, fluidized particles are wetted by spraying a liquid; agglomeration occurs when a wet particle collides with another particle forming initially a liquid bridge which solidifies by drying. A lot of attention has been paid on the study of this process but most of them are batch operated process. Among them the effect of process parameters such as binder addition rate, binder viscosity, fluidization velocity, air temperature, the morphology of agglomerates as well as the simulation based on population balance equation and Monte Carlo method have been studied [3,4,5,6]. However, many producers look for a continuous process for economic reasons instead of a batch process with high labor and dead-time. In this study, a horizontal fluidized bed is employed because it has several advantages such as the possibility to control different processes in separated chambers and possibility to control particle residence time distribution.

## **2. Materials and Methods**

### **2.1. Plant and materials**

In this paper, the agglomeration process was performed in a continuously operated horizontal fluidized bed (GF/Procell 20, Glatt GmbH, Weimar, Germany). A schematic flow diagram of the experimental fluidized bed is shown in Fig. 1. The dimensions of the horizontal fluidized bed are 1m in length and 0.2m in width. By installation of internal weirs, the bed can be separated into four chambers. With different settings of internal weirs, underflow and overflow can be achieved. To control the bed height, different heights of outlet weirs can be applied. The particles inlet speed was controlled by a twin screw feeder together with a rotary valve at the end of the feeding pipe which was used to isolate the bed from the atmosphere. The outlet was controlled by a rotary valve with constant rotation speed. The pulse injection of the tracer used in the residence time distribution measurement is enabled by an additional sewer port in the steady state of the system. The fluidization air was provided by two fans; one was at inlet and one at outlet. By adjusting the power of the two fans, the pressure inside the bed can be controlled. The fluidization air was heated by an electrical heater being separated into four pipes and entering the bed. The air speed and temperature in each pipes can be controlled by the open ratio of the two valves separately. Process parameters such as the fluidization air speed, the heater temperature, the open ratio

of valves, the spraying rate and etc. were controlled Distributed Control System station. The cross section of the upper side of the process chamber was expanded to reduce gas velocity and, thus, enforce the return of entrained particles in the fluidized bed. For the spraying system, maximum three top spray nozzles provided by Düsen-Schlick GmbH, Untertsiemau, Germany, model 940/3 with orifice diameter 0.8 mm, two-fluid nozzle, could be used. The nozzles are placed at a height of 320 mm from the distributor. The spray rate was controlled by a piston pump and the atomizing air pressure was controlled by an adjustable valve.

*Fig. 1 Schematic representation of the plant GF/Procell 20 (Glatt GmbH).*

The particles used for the experiments were glass beads (Sigmund Lindner GmbH, Germany), had a high sphericity of 0.89 and density  $2500 \text{ kg/m}^3$ , and were nearly mono-disperse. Measurements by Camsizer (Retsch Technologies GmbH, Haan, Germany) resulted in a very narrow range size distribution of the primary particles, with diameters between  $150 \text{ }\mu\text{m}$  to  $320 \text{ }\mu\text{m}$  and the Sauter diameter of  $200 \text{ }\mu\text{m}$ . The binder used was hydroxy-propyl-methyl-cellulose (HPMC, trade name Pharmacoat 606, from Shin-Etsus, Japan) water solution.

## 2.2. Experimental parameters

To study the influence of process parameters, seven experiments were carried out, denoted by No. 1-7 (Table 1). Reference Exp. NO. 2 was defined and then only one of the process variables was changed at a time. For all experiment, the feed rate was controlled at 400

g/min and fluidization air speed at 1.1 m/s. The binder used was 4wt% and relative air pressure in the nozzle was 1 bar. The influence of fluidization air temperature was studied by running experiments with different air temperature at 100, 80, 70 and 60°C. To study the influence of the configuration of internal wires, three internal weirs were employed and the gap height between the weirs and the air distribution plate were 10 and 5 mm. For all experiment, the outlet weir height was 200 mm.

To start the experiments, the plant was heated to the needed temperature then the feeder was started for the feeding. Apart from this metered feed, an initial feed of 6 kg of glass beads was fed instantly to promote the growth of the bed. The steady state was reached when the inlet and outlet mass flow rate of the particles were equal. After this stage, the binder pump was started. Samples were collected at the outlet periodically and used for analysis. The process time in each experiment was 130 -150 min.

*Table 1. Main experimental parameters*

Exp. NO.	Inlet Air Temperature $T_a$ [°C]	Spray rate $\dot{m}_b$ [g/min]	Number of internal Weirs	Gap height in underflow [mm]
1	100	72	-	-
2 (Ref.)	80	71	-	-
3	70	73	-	-
4	60	71	-	-
5	80	72	3	10
6	80	71	3	5

### 2.3. Experimental result analysis

In the first set of experiments the fluidization air temperature has been varied. As Fig. 2 displays, the largest Sauter diameters of agglomerates were obtained at the lowest air temperature experiment NO.4 at air temperature 60°C. Agglomeration rate decreased with the increase of air temperature. At lower temperature, the process took a longer time to reach the steady and the lower temperature also introduced more fluctuations because more particles stuck to the wall due to the higher moisture inside the bed. A decrease in agglomeration rate with increasing gas inlet temperature was also reported in batch operated agglomeration process [4,5]. At higher temperature binder droplets evaporate and shrink faster after having been sprayed from the nozzle, which decreases the height of sessile droplets. Some spray droplets may not even find a chance to hit the particle surface. In both cases, the number of particle collisions leading to agglomeration decreases [7]. From what showed in SEM pictures, at higher temperature despite using the same amount

of binder, there are more dried droplets layering on the outer surface of particles, meaning that the process tends to move from agglomeration towards coating.

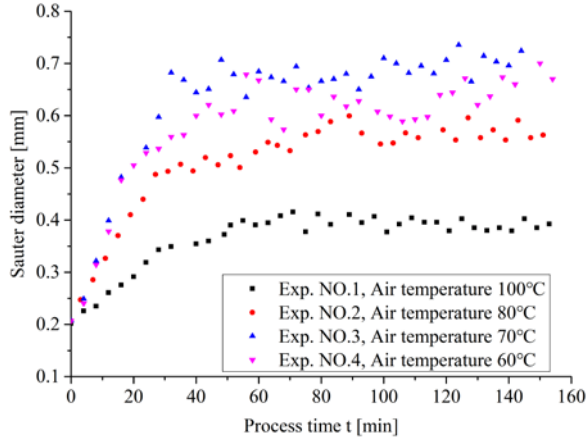

Fig. 2 Sauter diameter versus time at different air temperatures.

Fig. 3 shows the Characteristic diameters  $X_{10,3}$ ,  $X_{50,3}$ ,  $X_{90,3}$  and bed mass change during the process. Compared to the Sauter diameter the same trend was observed that at a lower temperature a higher agglomeration rate and bigger agglomerates are achieved, combined with a wider size distribution of agglomerates at the end of the experiment. With bigger agglomerates the process needs longer time to reach the steady state. There was a fast increasing of bed mass in the first 20 min of spraying. Bigger agglomerates also lead to a higher bed mass. When the air temperature was 70 and 60°C, a continuous increasing of bed mass was seen after 100-120 min which means that there is a high risk of defluidization in these two experiments.

In the second set of experiments, the internal weirs were used and the gap height was changed to see the influence of internal weirs on particle size distribution. The internal weirs are commonly used in such horizontal fluidized bed to control the flow behavior of particles. As Fig. 4 displays, the smallest Sauter diameter was achieved from the experiment with internal weirs which have the smallest gap height. During the present experiments, a slower rate of size increase was observed when the internal weirs were installed. The particle size distribution shows the internal weirs influence the flow behavior of the particles which could be shown more clearly in the residence time distribution measurement. By the installation of the weirs, more accessories were installed inside the bed which means more particles could stick. During the process, a hammer was used to knock the wall to clean the sticking particles on the walls and nozzles to prevent the formation of big lumps or the blocking of nozzles.

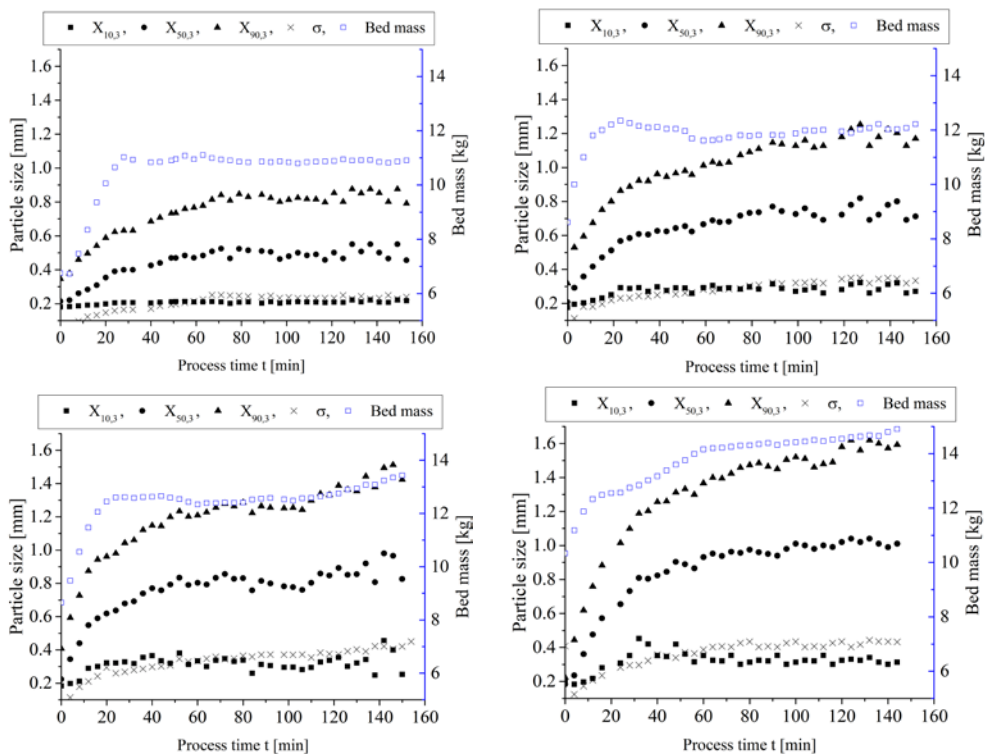

Fig. 3 Characteristic diameter  $X_{10,3}$ ,  $X_{50,3}$ , and  $X_{90,3}$ , the standard deviation  $\sigma$  and bed mass of experiments at temperature 100 (left, top), 80 (right, top), 70 (left, bottom) and 60°C (right, bottom).

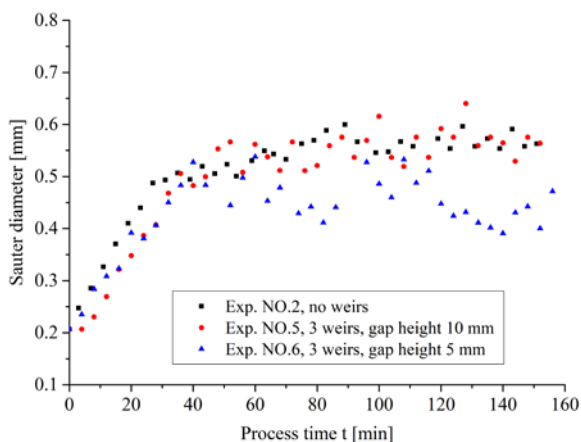

Fig. 4 Sauter diameter versus time with different internal weirs configurations.

**Fig. 5** Characteristic diameter  $X_{10,3}$ ,  $X_{50,3}$ , and  $X_{90,3}$ , the standard deviation  $\sigma$  and bed mass of experiments with internal weirs gap height 10 mm (left) and gap height 5 mm (right).

In Fig. 5, when compared to the reference experiment, it was observed that with internal weirs the starting bed mass of experiment is higher than without internal weirs because by separating process chambers, the spray has less influence on the fluidization of particles in last chamber. The internal weirs with gap height 10 mm have little influence on the size of agglomerates as well as on the width of size distribution. When the gap height was decreased to 5 mm, they decreased the size of agglomerates and a higher standard deviation of particle size distribution was observed which means a wider size distribution was achieved.

### 3. Conclusions

In this work, a continuously operated horizontal fluidized bed was used to conduct a spray agglomeration. The influence fluidization air temperature and configuration of internal weirs is presented. It was observed that an increase of air temperature results in decrease of agglomerate size and the width of size distribution combine with more fluctuations during the process. The internal weirs with gap height 10 mm have little influence on the size distribution of products, but when the height is decreased to 5 mm, they will decrease the size of products while increasing the width of size distribution. In future work, more parameters will be changed to study the influence the parameters such as particle feed rate, binder concentration and spray rate. To describe the continuous spray agglomeration, process a stochastic modelling approach based on a Monte Carlo method will be developed and compared with the experimental results.

### **Abstract**

*Bay leaves (Laurus nobilis L.) refers to aromatic leaves which are native to minor regions of Asia. In order to extend the shelf life of the bay leaves its water activity and the surface micro-organisms were reduced using microwave heating at different power densities in the range 32.14 to 142.85 Wg<sup>-1</sup>. Treatment time at each power level was maintained constant at 150 s. The maximum reduction in water activity and moisture content occurred at highest power density. The heating time-temperature profile was obtained at all power levels. TPC, color change and browning index (BI) of bay leaves were measured in order to determine the effect of microwave treatment on microbial reduction and quality. The highest reduction in TPC was found in leaves heated at 142.85 Wg<sup>-1</sup> power density along with acceptable quality parameters of the treated bay leaves.*

**Keywords:** Bay leaves; Microwave heating; TPC; Colour change.

## **1. Introduction**

Bay leaves hail from the bay tree and originally belongs to the family Lauraceae which is scientifically known as *Laurus nobilis*. It is believed to have been originated in Asia minor region, from where it is distributed to all over Mediterranean region and other parts of Asia. Bay leaves began to find its medicinal use during the European Middle Ages. Bay leaves belonging to various different origins were studied by different researchers for its chemical composition. In almost all the cases, 1,8-cineole was found to be the major component with percentages ranging between 31.4% and 56% [1,2]. Other compounds that are also present in appreciable amount include trans-sabinene hydrate, linalool,  $\alpha$ -terpinyl-acetate, sabinene, methyl eugenol and eugenol [3]. The various benzene compounds like eugenol, methyl eugenol and elemicin, present in bay leaves with percentages ranging between 1% and 12%. These compounds are responsible for the sensory qualities of bay leaves [4]. The essential oil content of bay leaves varies with the source of origin of the bay leaves and it is different for bay leaves obtained from different resources. Generally, the essential oil content of bay leaves ranges from 1% to 3% on a fresh weight basis. Bay leaves have a strong aroma but are also quite bitter. The bitterness of bay leaves can be reduced to an acceptable extent by drying. Thus the essential oils in dried bay leaves contribute to a strong, spicy aroma and are widely used throughout the world as a flavor enhancer in varieties of foods. Being one of the best-known flavoring leaves all over the world, they find their use in soups, sauce, sausages, stews, pickles and also act as an essential ingredient of the herb mixes. As a medicinal plant, bay leaves have been used as a cure for rheumatism, earaches and skin rashes. In addition, it has been also employed as a stomatic, carminative, astringent, stimulatory, emetic, emmenagogic, diaphoretic, abortifacient agent, and as an insect repellent. Essential oil obtained from bay leaves has also found its use in the cosmetic industry. Micro-organisms exist in the dried bay leaves which affects the shelf life. In order to extend the shelf life of the bay leaves its water activity must be decreased and the microbes present in the surface must be inactivated. Thus, it requires finished drying and surface sterilization. Recently, microwave heating has gained popularity due to its various advantages like quick and uniform heating, high-temperature short time treatment, inactivation of microbes without much damage to food quality [5]. Considering all the above reviews, this study aims to carry out microwave finish drying and surface sterilization of bay leaves.

## 2. Materials and Methods

### 2.1. Raw materials

The bay leaves were collected from the local market of Rourkela, Odisha, India. The samples collected were stored in a refrigerator (4°C) until usage to prevent any type of quality deterioration in the product.

### 2.2. Determination of moisture and water activity

Moisture content and the water activity were determined for both the control untreated samples and the microwave treated samples. For determination of the moisture content, vacuum oven method was used. The water activity of the conditioned sample was measured using water activity meter (Rotronic, HC2-AW, Rotronic measurement solution, Switzerland) at initial temperature 20.02 °C and relative humidity 53%.

### 2.3. Microwave finish drying

#### 2.3.1. Experimental Setup

Finished drying and surface sterilization of the bay leaves were carried out in a microwave oven. A programmable domestic microwave oven (Samsung, Model-CE73JD) with a maximum output of 800 W at 2450MHz was used for the experiments. The dimensions of the microwave cavity were 310 mm width, 290 mm height, and 220 mm depth. The oven was fitted with a fan, a glass turntable (30 cm diameter) and a digital controller to adjust the pulsation of microwave power and total heating time. Schematic diagram of the microwave heating system is shown in Fig. 1. The efficiency of the microwave oven was calculated according to USFDA (United State Food and Drug Administration) procedure at different power levels and the average efficiency was determined. The heat absorbed by water (220 g) was equated to the input energy[6]. During the drying process, the microwave oven was operated at five different power densities 32.14, 53.57, 80.35, 107.14 and 142.85 Wg<sup>-1</sup> and a constant treatment time was maintained at 150 s. The surface temperature of the bay leaves was regularly measured at an interval of 10 s using infrared sensor (IRL380-KUSAM MECO, India) up to 150 seconds at each power density. For accuracy in results, the temperature was measured at three different points each time and its average was taken as the final temperature.

*Figure 1. Schematic diagram of the microwave heating system*

## 2.4. Microbial analysis

Microbial analysis was performed on the bay leaves in order to find the effect of microwave treatment on the reduction of microbial contamination. In this regard, the Total Plate Count (TPC) per gram was done both for the control sample and the final samples treated at different microwave power densities.

### 2.4.1. Culture Preparation

Firstly, the culture media was prepared by mixing 28g of nutrient agar with 1000 mL of distilled water. It was then properly mixed with help of a stirrer and heated up to 60°C for proper dissolution of the nutrient agar in the distilled water. Media was then transferred to the glass bottles leaving some headspace at the top. Glass bottles were autoclaved at 15 psi at 121°C for 15 minutes. After completion of the autoclave heating, the media was allowed to cool below 50°C. The media was then poured into pre-sterilized Petri dishes such that a uniform layer of culture (2-3 mm) was obtained. The whole pouring process of the culture media was carried out under laminar flow hood in order to prevent any kind of contamination.

## 2.5. Color analysis

The color of the fresh and treated bay leaves was measured by scanning them with help of HP scanner. The scanned samples were then analyzed with help of Adobe Photoshop software. The color value of samples was measured at three different points for accuracy and expressed as L (whiteness or brightness/darkness), a (redness/ greenness) and b (yellowness/ blueness) at any time, respectively. The total color change ( $\Delta E$ ) indicates the overall color change and quantification was done using the equation given below [7]:

$$\Delta E = [(L-L^*)^2 + (a-a^*)^2 + (b-b^*)^2]^{0.5} \quad (1)$$

where  $L$ ,  $a$ , and  $b$  are respective values measured during high power short time microwave finish drying. The  $L^*$ ,  $a^*$ , and  $b^*$  are values of the fresh sample (before microwave finish drying). The browning index ( $BI$ ) were calculated from  $L$ ,  $a$ ,  $b$  values and used to describe the brown color produced due to heat accumulation during the decontamination process. The equation to calculate  $BI$  is given below:

$$BI = [100(x - 0.31)]/0.17 \quad (2)$$

Where

$$x = (a + 1.75 L)/(5.645L + a - 3.012b) \quad (3)$$

### 3. Results and Discussion

#### 3.1. Effect of power density on moisture content and water activity

The moisture content and the water activity was measured for both the control and treated samples. The results obtained showed that the average initial moisture content of bay leaves was 10.68% (wb) which was reduced up to safe moisture content. The maximum reduction in the moisture level occurred when bay leaves were treated at the power density of 142.85 Wg<sup>-1</sup>. In this case, final moisture content obtained was 1.24% (wb). Similar trends were obtained for the water activity of bay leaves; initial average water activity of bay leaves was measured to be 0.89. The maximum reduction in the water activity occurred at 142.85 Wg<sup>-1</sup> and reached to 0.18. Table 1 gives the moisture content and the water activity for bay leaves treated at different power densities.

**Table 1. Final moisture content, water activity and TPC log reduction in the microwave treated bay leaves**

Power Density (W g <sup>-1</sup> )	Final Moisture Content (% , wb)	Water activity	Log Reduction	$\Delta E$	BI
32.14	2.23	0.41	0.115	0.58	49.90
53.57	1.87	0.35	0.291	0.65	55.78
80.35	1.75	0.27	0.532	1.20	58.92
107.14	1.66	0.23	0.780	1.39	63.59
142.85	1.24	0.18	1.069	1.62	69.92

### **3.2. Effect of microwave power density on product temperature and microorganisms**

Bay leaves samples were treated for 150 seconds at each of the five microwave power densities. The surface temperature of the bay leaves was measured regularly during the microwave treatment of bay leaves. The time-temperature profile obtained at different power densities showed that maximum surface temperature reached was 101.6°C in the case when bay leaves were treated at 142.85Wg<sup>-1</sup> for 150 s. While minimum surface temperature reached was 75.85°C when bay leaves were treated at 32.14 Wg<sup>-1</sup> for 150 s. Total plate count (TPC) was done for both control and microwave treated samples of bay leaves. Results showed that plate count was minimum for the sample treated at 142.85Wg<sup>-1</sup>. While the treatment at 32.14Wg<sup>-1</sup> obtained a maximum number of plate counts. Total log reduction was also calculated for samples treated at different power densities and it ranged from 0.115 to 1.069. The log reduction at different power densities is given in Table 1.

### **3.3. Effect of microwave power density on color change and browning index**

Color analysis was performed to determine the color change ( $\Delta E$ ) which was encountered during the microwave treatment of the bay leaves. Browning Index (BI) was also calculated for both initial and the microwave treated samples. Results obtained showed that maximum color change of 1.62 was obtained when the sample was treated at 142.85 Wg<sup>-1</sup>. Similar results were obtained for Browning Index (BI) that is a maximum BI value of 69.92 was obtained for microwave treatment at 142.85 Wg<sup>-1</sup>.

## **4. Conclusions**

Maximum water activity reduction from 0.89 to 0.18 occurred at 142.85 Wg<sup>-1</sup> power density. Microbial analysis was performed in order to determine the effect of microwave treatment on microbial reduction of bay leaves. TPC was obtained for fresh as well as microwave treated samples. Maximum log reduction (1.069) was achieved in the sample treated at 142.85 Wg<sup>-1</sup> power density for 150 seconds. The color change was also quantified and the Browning Index (BI) was measured which indicated the less effect of microwave treatment on the color of the product. It can be concluded from the results that high power density short time microwave finish drying turns out to be an effective alternative for drying and surface sterilization of bay leaves with acceptable quality parameters.

### **Abstract**

*In this study, the moisture adsorption isotherm of pistachio was determined at 25°C and relative humidity (10-90%), using the standard static, gravimetric method. Eleven sorption models were tested to fit the experimental data. A non-linear regression analysis method was used to evaluate the constants of the sorption equations. The GAB equation gave the best fit to the experimental data for a wide range of water activity, while BET gave the best fit for a water activity range of 0.1-0.5. The agreement between experimental and predicted values of these models was found to be satisfactory.*

**Keywords:** *Moisture adsorption isotherm; Sorption model; Pistachio*

---

## 1. Introduction

Pistachios are one of the oldest edible nuts known to mankind, which are originated from Asia Minor, and are cultivated from Pakistan to Greece and even Italy and U.S.A. But pistachios originated from Gaziantep Region of Turkey, are worldwide known with its high quality and rich distinctive flavor. Pistachios are subjected to various processes after they are harvested. Proper harvesting and postharvest handling are two key activities in achieving maximum yield of good quality pistachio nuts, which effect marketability and profit. Process steps may vary with respect to desired product. For consumption as snack, processing of the nuts includes dehulling, washing, drying to 60–80 g/kg moisture (related to whole kernel) in dryers at 65°C for 6 to 7 h or by sun-drying for 3 to 4 d, salting by immersion in 100 g/kg sodium chloride solution for 15 min, roasting at 150 to 180°C for 30 min and packaging [2]. In this operation, water absorption and water vapor adsorption and desorption processes are very important, the air-watersolid equilibrium relations in the pistachio nuts determine the optimal conditions of post-harvest physical treatments and storage [3]. The water activity ( $a_w$ ) of food describes the energy state of water in the food, and hence, its potential to act as a solvent and participate in chemical/ biochemical reactions and growth of microorganisms. It is an important property that is used to predict the stability and safety of food with respect to microbial growth, rates of deteriorative reactions and chemical/physical properties [4]. Sorption isotherms can also be used to design their suitable packaging and storage conditions, and to select proper ingredients for preparation of a formulated intermediate moisture food. However, very limited data are available on sorption isotherms of different pistachio varieties [1]. It is well known that sorption isotherms of foodstuffs are very important for design, modelling and optimization of many processes. Hossain et al. [5] pointed out the importance of those data in drying, aeration, predicting of stability and quality during packaging and storage of food. Moisture sorption isotherms of foods provide critical information that can be used in predicting shelf-life by theoretical calculation. Moisture sorption isotherms can also be used to investigate structural features such as specific surface area, pore volume, pore size distribution, and crystallinity of food products. Many research studies on the sorption isotherms of certain foods, temperature dependence of isotherms, determination of heat of sorption, and mathematical models to represent sorption isotherms have been reported in the literature [6]. Many theoretical, semi-theoretical and empirical sorption models to describe the sorption behavior of foods other substrates have been proposed in the literature [7]. The objectives of this study were to determine the water sorption behavior of the pistachios originated from Gaziantep Region of Turkey at 25°C and relative humidities ranging from 10 % to 90% to propose a mathematical model for prediction of its sorption behaviour as a function of temperature, to evaluate the constants of sorption isotherm models.

## 2. Materials and Methods

### 2.1. Materials

Roasted pistachio sample was obtained from a local market at Gaziantep. All chemicals used in the preparation of saturated salt solutions were reagent grade (Merck) and water used was deionized distilled water.

### 2.2. Determination of Sorption Characteristics of Roasted Pistachio

A static gravimetric method was used to determine the sorption isotherms at 25 °C of the roasted pistachio nuts. 10 saturated salt solutions with an average water activity of between 0.10 and 0.90 were prepared for the glass jars which can be closed to prevent air ingress. 0.3g pistachio samples were weighed and placed together with two witness samples to each jar. A small amount of toluene was placed in jars with saturated salt solutions with high water activity to prevent microbial spoilage. After the jars were closed tightly, they were placed to an oven set at a constant temperature of 25 °C. Samples were weighed at 1-week intervals. The weighing continued until no difference more than 0.001 g it was found. The equilibrium moisture content of the samples was determined by drying at 105 °C for 4 hours. The equilibrium moisture content was plotted against the water activities to form the moisture sorption isotherms. The water activity values of the saturated salt solutions at 25°C are given in Table 1.

*Table 1. Water activity values of the saturated salt solutions at 25°C used in the experiment*

SALT	aw (25 °C)
LiCl	0,1130
CH <sub>3</sub> COOK	0,2251
MgCl <sub>2</sub>	0,3278
K <sub>2</sub> CO <sub>3</sub>	0,4316
Mg(NO <sub>3</sub> ) <sub>2</sub>	0,5289
NaBr	0,5757
SrCl <sub>2</sub>	0,7085
NaCl	0,7529
NH <sub>4</sub> SO <sub>4</sub>	0,8099
KCl	0,8430

The experimental sorption data of all samples at three different temperatures was fitted to sorption equations (with six two-parameters, five three-parameters and one four parameter) shown in Table 2. The parameters of the sorption models were estimated from the experimental results using nonlinear regression analysis (SPSS 13.0 for Windows), which

minimizes the residual sum of squares. Best-fitting equations were evaluated with the mean relative percentage deviation (P) value and the percentage root mean squares error (RMSE) value. P value and RMSE value are defined as

$$P = \frac{100}{N} \sum_{i=1}^N \frac{|M_{exp} - M_{cal}|}{M_{exp}} \quad (6)$$

$$RMSE = 100 \sqrt{\frac{\sum (M_{cal} - M_{exp})^2 / M_{exp}}{N}} \quad (7)$$

where  $M_{exp}$  and  $M_{cal}$  are experimental and predicted moisture content values, respectively, and  $N$  is the number of experimental data. A model was considered acceptable if the P values and RMSE values were below 10% and  $R^2$  values were higher than 0.90.

**Table 2. Equations describing the sorption equilibrium isotherms**

Name of the Equation	Equation
BET (Brunauer, Emmet and Teller) [8]	$M = \frac{M_0 c a_w}{[(1 - a_w) + (c - 1)(1 - a_w)a_w]} \quad (1)$
GAB (Guggenheim-Andersen-de Boer) [9]	$M = \frac{M_0 C K a_w}{[(1 - K a_w)(1 - K a_w + C K a_w)]} \quad (2)$
Halsey [10]	$a_w = \exp[-k/M^n] \quad (3)$
Henderson [11]	$1 - a_w = \exp(-k T M^n) \quad (4)$
Oswin [12]	$M = k \left( \frac{a_w}{1 - a_w} \right)^n \quad (5)$

### 3. Results and Discussion

Sorption isotherms are graphs that provide very useful information about the state of the food, determined by plotting the water content of the food at constant temperature versus the water activity of the food. These isotherm graphs are basically as follows; adsorption or desorption isotherms obtained by demonstrating the increased water content of the dry food at constant temperature or the decreasing water content of the wet food against the changing water activity [7]. The sorption data of whole pistachio nuts shows remarkable hysteresis in the multimolecular range and in the capillary condensation range (between  $R = 0.10- 0.80$ ). Above this region the difference between adsorption and desorption tends to disappear [3]. Several sorption equations (GAB, BET, Simit, Halsey, Henderson, Iglesias-Chirife, Chung-Pfost, Oswin, Caurie, and Langmuir et al.) that considered the relationship between water activity, moisture content of food and water binding energy, were developed to represent the sorption isotherms of the foods. However, these equations do not adequately represent all the food. The reason for this is the high heterogeneity of foods in structure and composition. The

BET equation, which is one of the first sorption equations and widespread employed, can successfully represent the isotherm when the water activity is less than 0.50 [7]. GAB model is about monolayer moisture concept and provides the value of monolayer moisture content of the material, as most other models not have this parameter. The monolayer moisture content ( $M_0$ ) indicates the amount of water that is strongly adsorbed to specific sites on the surface of food and is regarded as the moisture content affording the longest time with minimum quality loss at a given temperature [13].

The adsorption isotherm of pistachio at 25°C is shown in Fig. 1. The equilibrium moisture content at each  $a_w$  represents the mean value of three replications. The standard deviation of each experimental point (kg/kg dry solids) was within the range of 0.003 to 0.05.

*Fig.1 Adsorption isotherms of roasted pistachio 25°C.*

The adsorption isotherms of pistachio showed type II behaviour according to the BET classification, typical of the many sorption isotherms of food [14]. The equilibrium moisture content increases with increasing  $a_w$ , at constant temperature. Similar results have been reported in literature for the sorption curve of pistachio [14].

The results of non-linear regression analysis of fitting the sorption equations to the experimental data are presented in Tables 3. The mean relative percentage deviation (P), the percentage root mean squares error (RMSE) and correlation coefficient ( $R^2$ ) values are also given in Tables 3.

The GAB equation (Table 3) gave the best fit to the experimental adsorption data of pistachio for a wide range of water activity (0.10-0.9). This observation is consistent with the results obtained by Maskan [14]. Constant K value for pistachio in the GAB equation was 0.821. The value of K provides a measure of the interactions between the molecules in multilayers with the adsorbent and tends to fall between energy value of the molecules in the monolayer and that of liquid water. The monolayer moisture content ( $M_0$ ) helps to define physical and chemical stability of foods since it has a direct influence on lipid oxidation, enzyme activity,

non-enzymatic browning, flavour preservation and product structure. The BET and GAB monolayer moisture contents for pistachio were 0.038 kg/kg dry solid and 0.046 kg/kg dry solid, respectively (Tables 3).  $M_0$  value obtained by the GAB equation was higher than those obtained by the BET model. Moreover, the Oswin, Halsey and Henderson equations (Table 3) gave a satisfactory prediction of the adsorption equilibrium moisture content of pistachio.

**Table 3. Estimated parameters and P (%), RMSE (%), R<sup>2</sup> values of the sorption equations**

Model	Parameters	Temperature 25 (°C)
BET <sup>a</sup>	$M_0$	0.038
	C	22.79
	P (%)	4.439
	RMSE (%)	0.028

<sup>a</sup>  $a_w$  range for BET equation was 0.11-0.5, only the first four data points were used.

As seen in Table 3, the BET equation gives the lowest P % and RMSE % value in the water activity range 0.11-0.5. Furthermore, the GAB equation representing multi-layer adsorption gave the best fit to the experimental data for pistachio. The experimental adsorption data and the predicted values obtained from different sorption models at 25°C are shown in Fig. 2.

It should be noted that, the goodness of fit of any sorption model to the experimental data shows only a mathematical quality and not the nature of the sorption process [15].

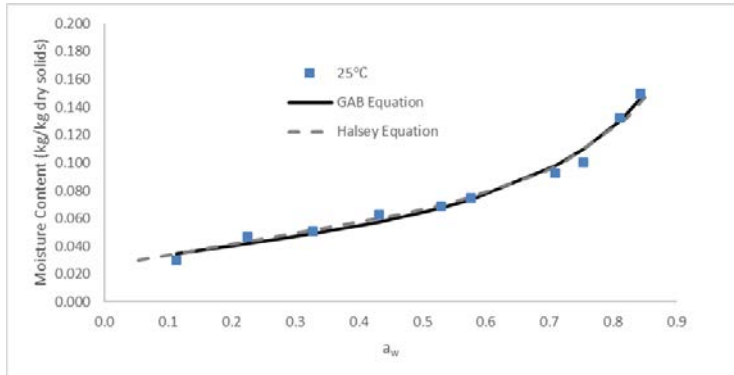

Figure 2. Comparison of experimental and predicted adsorption equilibrium moisture contents of pistachio at 25°C.

#### 4. Conclusions

The equilibrium moisture content of pistachio increased with increasing water activity at constant temperature. Among the sorption models tested, the GAB equation was recommended for characterising the adsorption behaviour of pistachio in the water activity range of 0.11-0.87. The adsorption data were also expressed by the Halsey equations in the wide range of water activity and by the BET equation in the range of water activity 0.1-0.5.

### **Abstract**

*Presented in this article studies show the investigation of ultrasound application as a new method for improvement of ceramic materials processing and their influence on mechanical properties of dried samples. Ultrasound were applied during convective and convective-microwave processes carried out in two different temperatures. Obtained results indicate increase of drying rate due to sonification and what's more interesting they affect the material strength parameter. The experiments indicate that the effectiveness of ultrasound assist depends on the drying temperature and such dependency is observed mainly when considering dry product quality parameter.*

**Keywords:** *ceramics; hybrid drying; material strength*

---

## **1. Introduction**

Drying of clay like materials is a very important industrial process which allow to achieve ceramics with very useful, specific properties like, e.g. high durability, electrical and thermal resistance and other. It is the first step after molding or casting which lead to reduction of the moisture content and gives a possibility to further calcination of such products. Dry product before calcination needs to have not only very limited moisture content but also can not have fractures. Thus why drying process is so important as it contributes into final product quality or possibility for postprocessing of such product.

To achieve a good quality of dried products the drying process needs to be carried out in the way which allow to reduce internal drying stresses, the main cause of material destruction<sup>[1-4]</sup>. Tension which appears in dried products are mainly the result of highly nonuniform distribution in temperature and moisture content throught the material, thus why using several drying techniques simultaneously or using nonstationary drying is presented as a method to diminish unwanted effects<sup>[5-7]</sup>. Application of such drying programs not only allow to achieve better quality of dry products but also if appropriately determined lead to reduction in energy consumption, which is one of the most important parameter considered when presenting new drying solution affecting their economical effectiveness.

In the mentioned hybrid drying processes in last years ultrasound were applied as one of the method to enhance the drying process, however they were considered mainly for thermal sensitive products like fruits and vegetables<sup>[8]</sup>. Nevertheless, described in the literature interaction with the material in the form of, e.g. heating or vibrating effect<sup>[9]</sup> could affect positively also other than biological products like for example ceramics<sup>[10]</sup>. The processes proposed in this work present modern drying technique in which high power ultrasound are used to affect drying kinetics and processed material propertiess.

## **2. Materials and Methods**

The investigated material was kaolin KOC clay produced by Polish company Surmin Kaolin S.A. The material before preparing a moulding mass was dried for 24h in 120°C. Next, a dry powder was mixed with a specific amount of demineralized water which allows to achieve an initial moisture content of 40% <sub>d.b.</sub>. Wet material was closed in a sealed box and left for 48h, so the moisture distribution in the mass became uniform. After that time the mass was portioned into 200g batch and stored separately in a sealed containers at temperature of 5°C. For each experiment from single 200g batch 7 samples in the form of cylinders with a diameter of 21mm and a height of 26mm were molded and placed in a dryer trace. The experiment were performed in a hybrid dryer according to 6 drying

schedules presented in Table 1. The apparatus allowed to control and collect all important process parameters and is described in detail in other author work<sup>[9]</sup>.

*Table 1. Drying processes and parameters*

<b>Drying program</b>	<b>Convection</b>	<b>Microwaves</b>	<b>Ultrasound</b>
CV <sub>80</sub>	80°C air flow 4m/s	-	-
CVUS <sub>80</sub>	80°C air flow 4m/s	-	200W
CVMWUS <sub>80</sub>	80°C air flow 4m/s	100W in 2 cycles	200W
CV <sub>50</sub>	50°C air flow 4m/s	-	-
CVUS <sub>50</sub>	50°C air flow 4m/s	-	200W
CVMWUS <sub>50</sub>	50°C air flow 4m/s	100W in 3 cycles	200W

Application of microwaves was performed periodically in a given number of cycles which last 5 minutes with the following 30 minutes relaxation periods. Such procedure allows not to destroy ceramics samples during processing with microwave application.

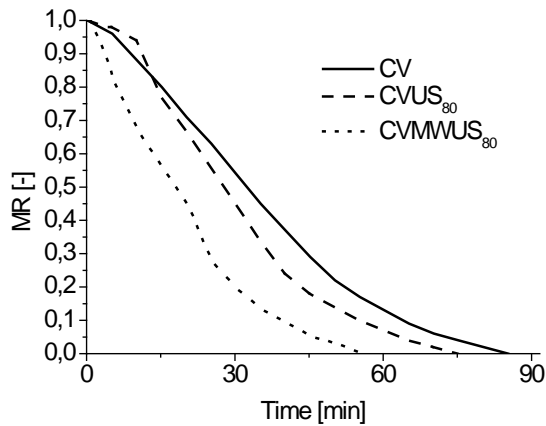

As drying processes were carried out till the material reach 2%<sub>d.b.</sub> moisture content, before mechanical tests the samples were placed for 48h in exsiccator, so all examined cylinders would had exactly the same parameters. Compression tests were carried out axially on Cometech strength machine with 20mm/min compression speed.

### 3. Results and discussion

The first series of experiments was carried out for higher drying temperature both as a single convective process as also with application of ultrasound and microwaves. The kinetics of such processes is presented in figure 1 and was evaluated on the basis of MR(time) curves where MR is defined as follows:

$$MR = \frac{X_t - X_{eq}}{X_0 - X_{eq}} \quad (1)$$

In the above equation X value indicates the material moisture content (kg/kg d.b.) and subscripts specify the time at which they were determined, that is: t - given time of the process, eq is the end of process (equilibrium moisture content) and 0 is at the beginning of the process (initial value).

**Fig. 1 Kinetics of processes carried out at 80°C**

In Figure 1, one can see the characteristic behaviour of material dried only with ultrasound assist at the beginning of the process. In the heating period the water loss is visibly lower as compared to the CV process, however in the next period the drying rate increases significantly and leads to reduction of the overall drying time up to 11 minutes. This characteristic kinetics was observed in number of repeats thus why it can be stated that for such processes ultrasound application could be applied after heating period what allows to additional improvement of drying kinetics. In the second process assisted with ultrasound (CVMWUS<sub>80</sub>) the kinetics shows the influence of short application of microwaves which allows to reduce the drying time significantly. Longer application of microwaves was not justified as earlier work of autor<sup>[10]</sup> indicates their negative effect on the material structure as also its strength.

The next series of experiments was performed in a lower drying air temperature to verify if ultrasound assist in other conditions transfer onto the drying kinetics and material properties differently. Figure 2 presents the drying curves achieved for processes carried out in 50°C. In opposite to process carried out in higher temperature, the CVUS<sub>50</sub> process do not show very slow drying tendency during heating period but from the beginning offer higher drying rates than pure convection. This reflects in higher reduction in drying time even up to 85 minutes. So high reduction in drying time could results also from the fact that a lower temperature of processing affects the air density which influence greatly the reduction of acoustic wave attenuation.

**Fig. 2** Kinetics of processes carried out at 50°C

Additional periodical application of microwaves in the CVMWUS<sub>50</sub> process allows to increase the average drying rate and in total reduces the drying time to the level achieved during CVUS<sub>80</sub>. Similar drying time for those processes affects also similar appearance of the sample surface with small number of narrow cracks. The samples achieved after drying are presented in Figure 3.

**Fig. 3** Dry samples structure achieved after different drying processes; a) CV<sub>80</sub>, b) CVUS<sub>80</sub>, c) CVMWUS<sub>80</sub>, d) CV<sub>50</sub>, e) CVUS<sub>50</sub>, f) CVMWUS<sub>50</sub>

The presented above pictures show that ultrasound application affects positively the sample quality, however better results were observed at higher drying air temperature, especially without microwave application. Slightly other influence of ultrasound was observed at

lower air temperatures where the best quality was observed in case the samples dried by CVMWUS<sub>50</sub>. In this temperature application of ultrasound itself do not cause visible improvement of product structure. The above investigation of samples appearance does not however investigate their mechanical properties, thus why the results of strength tests for the dried samples are tabulated in Table 2.

*Table 2. Material strength and energy consumption in different drying processes*

<b>Drying program</b>	<b>Strength [N]</b>	<b>Standard deviation [N]</b>	<b>Energy consumption [kWh]</b>	<b>Standard deviation [kWh]</b>
CV <sub>80</sub>	180,38	23,78	2,28	0,01
CVUS <sub>80</sub>	199,77	13,51	2,44	0,08
CVMWUS <sub>80</sub>	196,27	22,61	1,87	0,18
CV <sub>50</sub>	260,06	15,57	1,95	0,04
CVUS <sub>50</sub>	203,38	23,42	2,07	0,17
CVMWUS <sub>50</sub>	206,15	17,96	1,63	0,28

The results of compression test correlates fully with a sample appearance for processes carried out at temperature of 80°C. In those processes ultrasound assist reflects in the increase of material strength both for pure convective drying and also for the process enhanced with microwaves. However the mechanical properties determined during strength tests do not cover with visual quality determination for samples dried at a lower temperature. It is observed that application of ultrasound as also microwaves during convective drying in 50°C affects significantly reduction of material strength, nevertheless without negative influence on product appearance. The reason of such specific behaviour could be tracked back into varied acoustic wave propagation and attenuation in different air temperatures, however it exact explanation is very difficult. From one side the vibration carried by mechanical wave could affect the clay particles arrangement and its strength, but from the other side it do not explain why the improvement of drying rate at lower temperature is greater. Nevertheless, when considering the material strength and drying time for particular processes it can be stated that CVUS<sub>80</sub> and CVMWUS<sub>50</sub> give almost identical, very good results. Thus why to indicate the most effective process in which ultrasound are applied it is necessary to consider the energy needed to remove a specific amount of water from the material. As all samples have the same volume and initial moisture content the overall energy consumed during specific process can be compared directly. The energy consumption presented in Table 2 shows that the most similar processes from quality and kinetic point of view (CVUS<sub>80</sub> and CVMWUS<sub>50</sub>) differ

significantly by the energy consumption. The process carried out at a lower temperature consumes more than one third less energy what shows its great advantage. Also other processes carried out at a lower temperature are more effective from energy point of view comparing with the ones carried out at 80°C, where the only exception is the CVMWUS<sub>80</sub> process which offers similar energy consumption.

#### **4. Conclusions**

The application of ultrasound shows different influence on both drying kinetics and material strength depends from temperature in which they were applied. Application of acoustic waves in all cases affects in reduction of processing time, however at a lower air temperature their influence on drying rate is greater probably due to a lower wave attenuation. Ultrasound affect also the material strength, however their influence is ambiguous and depends on drying air temperature. At a lower temperature sonification affects negatively on the material resistance, whereas at a higher temperature it improves product strength. However, for both temperatures ultrasound improve the product appearance as the sonificated samples had a better surface quality with a lower amount of narrow cracks.

Considering all of the processes and material parameters the CVMWUS<sub>50</sub> program can be pointed as the best drying process due to a quite short drying time and also a lower energy consumptionless energy, and a reasonable material strength and product appearance. Nevertheless, the ultrasound enhancement during all drying schemes brings some advantages in the process, but sonification should be applied with a grate care and determination of the most important parameters onto which we would like to affect using ultrasound.

### ***Abstract***

*Anthocyanins pulp and peel passionfruit extracted by leaching using water as a solvent where the operating conditions of spray drying were evaluated for a microencapsulated. The variables were temperature input (180,200 and 220 ° C), MD (6,8y10%), AP (1,3y5%) and outlet temperature 80 ° C, was achieved noted that during the drying process moisture decreased to 85% due to this high in MD and AP, this also increases the content of ST. Color significantly was not affected by spray drying..*

**Keywords:** *Passionfruit, abstract, encapsulants, spray microencapsulation.*

---

## 1. Introduction

Passionfruit (*Passiflora biflora*) is a wild fruit ovoid neotropical as shown in (Fig 1) and belongs to the Passifloraceae family, is a liana with smooth variable leaves are generally wider than long, with two lobes that occur with the cut end, rounded or slightly stippled. [n1] In recent years it has sought ways to replace artificial pigments thus has opted for extraction of certain natural pigments from different plants and fruits, is why in the present research, the extraction process is evaluated own compounds of passion fruit by microencapsulation technique by spray drying.

*Fig. 1 Passiflora biflora*

Microencapsulation by spray drying corresponds to the transformation of a fluid into a solid material, shaped by atomizing minute droplets into a hot drying medium. One of the great advantages of this process, besides its simplicity, is suitable for heat sensitive materials because the exposure time at elevated temperatures is very short ranging between 5 and 30 seconds [n3, n5]. Anthocyanins belong to the flavonoid family, composed of two aromatic rings,  $\alpha$  and  $\beta$  joined by a chain of 3 carbons [n2], these pigments are widely distributed in fruits and flowers, offering attractive colors such as orange, red and blue [n6]. One of the most important and studied food characteristics is the color, the Interest in anthocyanin pigments in scientific research have increased in recent years, due not only to the color that give products that contain them but its likely role in reducing heart disease, cancer, diabetes, anti-inflammatory, improvement of visual acuity and cognitive performance; these preventive and therapeutic effects are mainly associated with its antioxidant properties [n4] The objective of this research was microencapsulated anthocyanins pulp and peel passion fruit by spray drying with maltodextrin and potato starch, evaluating the influence of the conditions drying.

## **2. Materials and Methods**

### **2.1 Raw material**

Passionfruit (*Passiflora Biflora*) was harvested and collected in the high mountains, Cordoba, Veracruz, Mexico

### **2.2 Fruit packaging.**

The fruit was placed at room temperature (25 ° C) for 2 hours to return to its initial state, the subsequent detachment of the peduncle performed and seed making a homogenization between the pulp and peel of the fruit into a sterile glass papillary.

### **2.3 Extraction of anthocyanins.**

Once homogeneous mixture extraction was performed by placing the fruit in water at 30 ° C for 2 hours, to obtain the anthocyanins in the solvent, filtration was performed on Whatman paper to remove solids from the extract.

### **2.4 Experimental design.**

The amounts used were determined by an Box-Behnken experiment design have three variables to consider: Inlet temperature, % maltodextrin and potato starch %. □

Box-Behnken desings always have 3 levels per factor, is a type of design response surface that does not have an embedded fractional factorial design, where the design points are in combinations of high and low levels of factors and their midpoints [n8].

### **2.5 Determiation of moisture.**

Moisture determiation of passion fruit extract was performed in a thermobalance of Sartorius, Model MA35 brand. At a temperature of 121 ° C.

### **2.6 Determiation of Total Solids.**

It was determined by weight difference according to the result of % moisture.

### **2.7 Determiation of color.**

The color measurement was performed to extract Colorquest XE colorimeter for liquids where “L”, “a” and “b” values were obtained. Determining color for dry passionfruit was performed with a colorimeter MiniScan XE plus the mark Hunterlab obtaining values “L”, “a” and “b”.

### **2.8 Determiation of water activity (aw).**

The water activity (aw) was measured with an Aqualab, model series 3 computer.

### 3. Results and discussions

#### 3.1 Fruit Yield

In (Table 1). integral yield mature fruit, which is formed by 8% shell, 80% pulp and 10% seed and the other 2% is the organic waste [n1] is shown.

*Table 1. Performance passionfruit (Passiflora biflora)*

Sample	Total weight (g)	Pulp weight (g)	Seed weight (g)	Shell weight (g)	Shell yield (%)	Seed yield (%)	Pulp yield (%)
A	104.5698	83.5903	9.8471	7.7998	7.4589	9.4167	79.9377
B	108.6584	86.6302	9.2321	8.5462	7.8651	8.4964	79.7271
C	112.9454	87.5682	10.9358	8.5821	7.5984	9.6823	77.5314

Source: [n1]

*Table 2. Results obtained from the extract in different concentrations*

Sample	Temperature (°C)	Maltodextrin (% m/v)	Potato Starch (% m/v)	Humidity (%)	ST (%)
1	180	6	3	92.11	7.89
2	180	10	3	87.81	12.19
3	220	6	3	91.71	8.29
4	220	10	3	85.83	14.17
5	180	8	1	87.64	13.36
6	180	8	5	90.30	9.70
7	220	8	1	90.81	9.19
8	220	8	5	87.81	12.19
9	200	6	1	89.05	10.95
10	200	6	5	86.85	13.15
11	200	10	1	91.82	8.18
12	200	10	5	82.12	17.88
13	200	8	3	86.23	13.77
14	200	8	3	89.22	10.78
15	200	8	3	89.56	10.44

In (Table 2). Results show the humidity and ST obtained extract at different concentrations which shows that the amount of maltodextrin and starch added potato is directly proportional to the % obtained, showing that the higher the added amount increases occurs in solids and a decrease moisture.

In (Fig. 2) is observed that a high level of MD and an average level of AP the highest content of total solids in the samples are present, this may be due to the degree of solubility of potato starch samples, since increasing this concentration could suffer saturation in the solution, affecting the homogeneity of the sample.

*Fig. 2. Correlation of TS content*

In (Fig. 3) the graphical response surface moisture, it is clear that its content decreases until 85% with a content of, high MD and low AP, as the one that is shown to microencapsulated ascorbic acid by spray drying with two matrices maltodextrin and soluble potato starch, the moisture value reported is  $0.038 \pm 1.5\%$ , which is low by these drying conditions.[n9]

*Fig 3. Correlation of moisture content*

In (Table 3) results according to the color parameters are shown, the luminosity (L), chromaticity (a\*, b\*) in the extract, the changes (L) clearly observed were diminished as

was increased the number of solids, however parameters ( $a^*$   $b^*$ ) had a trend toward red and blue, which notes the presence of anthocyanins which are responsible for the red, orange, blue and purple colors fruits, flowers and other plant products.

**Table 3.- Results of chromaticity in different concentrations extract**

Sample	Chromatic parameters		
	L	$a^*$	$b^*$
1	1.71	-0.05	-0.35
2	1.46	-0.43	-0.17
3	1.26	-0.34	-0.07
4	1.21	-0.39	-0.43
5	1.39	-0.29	-0.05
6	1.45	-0.90	0.20
7	1.34	-0.66	-0.74
8	1.38	-0.17	-0.29
9	1.47	-0.52	-0.30
10	1.31	-0.25	0.13
11	1.69	-0.91	0.13
12	1.43	-0.28	-0.14
13	1.57	-0.80	0.06
14	1.31	-0.40	-0.31
15	0.83	-0.90	-0.71

**Table 4. Results obtained after performing spray drying**

Sample	H (%) $\pm$ DS	ST (%) $\pm$ DS	aw $\pm$ DS
1	5.04 $\pm$ 0.06	94.97 $\pm$ 0.06	0.308 $\pm$ 0.03
2	7.07 $\pm$ 0.64	92.94 $\pm$ 0.64	0.411 $\pm$ 0.01
3	5.06 $\pm$ 0.18	94.94 $\pm$ 0.18	0.308 $\pm$ 0.03
4	5.15 $\pm$ 0.12	94.86 $\pm$ 0.12	0.345 $\pm$ 0.01
5	8.28 $\pm$ 0.49	91.72 $\pm$ 0.49	0.380 $\pm$ 0.01
6	6.87 $\pm$ 0.19	93.14 $\pm$ 0.19	0.327 $\pm$ 0.01

In (Table 4) the results obtained are shown after performing spray drying which shows that in runs 3 and 4 there is a lower moisture content 5.06% and 5.15% respectively, resulting in

a greater amount of ST, is therefore it is considered that in a matter of performance is optimal to use an amount of maltodextrin 10% because this presents better results.

In (Table 5) color results obtained in the pigment are shown, where the parameters (L, a\*, b\*) had a color trend toward red and blue resulting in the run, number 2 and 6 have a higher intensity is the color, which results show the presence of anthocyanins, demonstrating that the spray drying does not alter the anthocyanins present in the fruit.

**Table 5. Results of chromaticity obtained after performing spray drying**

Sample	Chromatic parameters		
	Luminosity L ± DS	Chromaticity a ± DS	Chromaticity b ± DS
1	46.87 ± 0.21	6.65 ± 0.13	-5.16 ± 0.05
2	42.50 ± 0.18	8.36 ± 0.04	-3.14 ± 0.19
3	39.95 ± 0.21	5.45 ± 0.49	-3.06 ± 0.08
4	45.42 ± 0.49	5.18 ± 0.04	-2.35 ± 0.21
5	46.06 ± 0.44	7.37 ± 0.21	-1.60 ± 0.47
6	44.22 ± 0.30	8.26 ± 0.10	-1.73 ± 0.49

#### 4. Conclusions

From the extract obtained color leached from fruit of the passion fruit one microencapsulado product was achieved maltodextrin by spray drying, where according to the experiment performed and the results obtained it is established that the optimum conditions for the pigment are the runs 3 and 4 with an inlet temperature of 180 ° C, MD 10% D10, 5.1% of AP and a temperature of 80 ° C outlet, because in these higher performances are obtained and although They do not exhibit the greatest color intensity but they present a good one, which represents the existence of anthocyanins, which makes them be suitable for obtaining the pigment by spray drying.

### **Abstract**

*Alginate microcapsules containing cell yeasts of the species *Saccharomyces cerevisiae*, used as a reference microorganism, were studied here to improve the protection of cell activity during food processing. Here a novel drying process was proposed to optimize processing conditions.*

*The dehydration of microcapsules by microwaves and under near fluidizing conditions (NFMD), allows performing dehydration employing lower temperatures to maintain high viability levels and a high quality end product. Thus, strategies based on the combination of different thermal gradients and processing temperatures were analysed through a series of NFMD experiments.*

**Keywords:** *microwave drying, fluidization, probiotics, cell viability.*

---

## 1. Introduction

In this work, the novel Near Fluidizing Microwave Drying (NFMD) process is studied to avoid some of the problems with lyophilization and spray drying. Microwave heating adequately controlled is specially recommended for drying. Through this process, the heat is generated inside the microcapsules, causing a thermal gradient from inside out, which favours the elimination of the moisture [1]. Microwave drying is a technology that is being developed widely in the food industry [2]. Drying of the microcapsules through the application of microwaves presents as primary characteristic, the inverse temperature gradient, favouring the drying of the microcapsules from inside out, as opposed to conventional drying methods. The application of this inverse temperature gradient involves much lower temperatures and operating times [3]; [4]. Based on previous kinetic studies of the microwave drying operation, three perfectly differentiated phases during the dehydration of microcapsules have been found [5].

As an extension of the study, here the effect of control variables in the applied energy for the drying process of microcapsules were studied. Several operating conditions were analysed combining different values of thermal levels of control variables: air and product temperature. Finally, the viability of each thermal level applied by microwaves was compared with the results obtained by freeze-drying.

## 2. Materials and Methods

### 2.1. Preparation of microcapsules and viability analysis

Microcapsules were prepared following a variant to that indicated in the bibliography [6]. In this work, dry yeast extract (*Saccharomyces cerevisiae*, ZYMAFLORE®) supplied by LAFFORT (France), containing an active cell concentration higher than  $2 \cdot 10^{10}$ /g, was used as cell culture material. Capsules were extracted from the solution by filtration and, once eliminated the superficial water, they were conveniently packaged and stored for 18 h in covered trays during 18 h in a freezer at 4 °C until the start of the drying experiment. This leads to initial moisture content between 7.1 and 7.3 g water/g d.s. in all the cases.

The evaluation of viable encapsulated yeast was carried out by homogenizing 0.1 g of filtered microsphere slurry in 10 mL of sodium citrate 0.1 M for 10 min and stirred. The plates were incubated for 2 days at 37 °C and the encapsulated yeast enumerated as cfu/g d.s.

### 2.2. Drying experiments

The experiments were carried out according to the procedure NFMD, consisting of dry cell capsules, under fluidizing conditions, through the supply of heat by microwaves. Microwave power was regulated during the drying process in order to achieve certain values of temperature in the microcapsules and the temperature of the air being introduced into the bed of particles.

Nine thermal strategies were tested in this study combining three levels for the air temperature with other three levels for the product surface temperature through temperature  $T_f$  (Table 1). The inlet air temperature levels considered were: 5°C, room temperature (20°C) and 40°C. The different experiments were defined on the basis of combining these three air temperature levels with three different target surface temperatures of the microcapsules. Since it was difficult to measure the temperature of the microcapsules directly,  $T_f$  was controlled instead, measuring the temperature of the air film in contact by a fiber optic probe placed inside the microcapsules bed.

**Table 1** Definition of the thermal levels in the NFMD experiments.

Exp.	Phase I			Phase II			Phase III	Code
	$T_{in}^*$	$T_f^*$	$T_s^*$	$T_{in}^*$	$T_f^*$	$T_s^*$		
1	5	10	15	5	17.5	30	5 °C/h decreasing rate of $T_{in}$ (from 40 °C)	LI/MI
2	5	17.5	30	20	25	30		MI/Mm
3	5	10	15	40	27.5	15		LI/Lm
4	20	25	30	5	17.5	30		Mm/HI
5	20	17.5	15	20	25	30		Lm/MI
6	20	17.5	15	40	42.5	45		Lm/Hm
7	20	17.5	15	20	32.5	45		Lm/Hh
8	40	27.5	15	40	42.5	45		Lh/Hh
9	40	35.5	30	20	32.5	45		Mh/Hm

The code used in Table 1 refers to the thermal conditions employed in Phases I and II. The first two letters correspond to Phase I and the other two, separated by a slash, to Phase II. At each phase, the first capital letter refers to the target temperature for the surface ( $T_s^*$ ): L=15°C (Low), M = 30 °C (Medium), and H = 45 °C (High). The second letter refers to the inlet air temperature  $T_{in}^*$  using the same but in small letters: l = 5 °C, m = 20 °C and h = 40 °C. Thus, in Experiment 3 (LI/Lm), low thermal level was applied either for Phase I or II, except for the thermal gradient in Phase II, where a 40 °C inlet air temperature was applied.

### 3. Results and discussion

The air velocity was used as indicator variable to define the phase boundaries, rather than the water content, which would have been much less accessible for following the process.

### 3.1. Variation of the minimum fluidization velocity

The microcapsules obtained as described in the previous section had an initial moisture content of around 85% ( $X=0.85\pm 0.03$ ) at the beginning of the drying. Under these conditions, microcapsules have a high adherence so that, initially, the experimental minimum fluidization velocity  $u_{mf}^*$  of the bed was considerably higher than that obtained theoretically.

Initially, the experimental minimum fluidization velocity,  $u_{mf}^*$ , was 1.39 m/s, about 3 times higher than the theoretical minimum fluidization velocity,  $u_{mf}$ , obtained in accordance to the previous equations. Velocity decreases rapidly as drying progresses, while the theoretical value  $u_{mf}$  decreases slowly only affected by the decrement in density and particle size  $d_p$  along the drying. When the humidity of the particles reaches a value around  $X = 0.5$ , the microcapsules lose the adherence shown at the beginning of the process so that the experimental minimum fluidization velocity becomes equal to the theoretical. In such a situation:  $u_{mf}^*=u_{mf}=0.29$  m/s (see Table 2) and it was set in this study as a reference for the definition of the end of Phase II or beginning of Phase III. From this moment, the residual moisture of the particles is removed exclusively by convective heating (microwave is off).

Table 2. Data of  $X$ ,  $u_{mf}$ ,  $d_p$  and time in the transition Phase II-III, in the different NFMD strategies

Heatings strategy	Phase II				Phase III		
	t(min)	$X^{(1)}$	$d_p$ (m)	$u_{mf}^*/u_{mf}^{(2)}$	t(min)	$X^{(1)}$	$d_p$ (m)
Ll/Ml	35	0.44	1.69E-03	0.30/0.32	275	0.045	1.13E-03
Ml/Mm	30	0.49	1.76E-03	0.30/0.30	195	0.070	1.16E-03
Ll/Lm	18	0.55	1.86E-03	0.38/0.28	240	0.072	1.16E-03
Mm/Hl	25	0.49	1.76E-03	0.30/0.30	240	0.070	1.16E-03
Lm/Ml	25	0.57	1.88E-03	0.40/0.30	235	0.070	1.16E-03
Lm/Hm	20	0.39	1.63E-03	0.30/0.30	210	0.071	1.16E-03
Lm/Hh	23	0.48	1.75E-03	0.28/0.32	240	0.078	1.17E-03
Lh/Hh	15	0.54	1.84E-03	0.28/0.36	240	0.081	1.18E-03
Mh/Hm	20	0.5	1.78E-03	0.32/0.30	240	0.072	1.16E-03

<sup>1</sup>Units of  $X_{in}$  and  $X$ : g water/g w.b. <sup>2</sup>Units of  $u_{mf}^*$  and  $u_{mf}$ : m/s

An acceptable correspondence of the moisture content  $X$  with the minimum fluidization velocity values used in each phase can be seen in Table 2. Thus, the average values of  $X$  corresponding to the end of Phase I and II, for all the experimental conditions tested, were 0.75 and 0.49 with a standard deviation of 0.040 and 0.051, respectively.

### 3.2. Drying kinetics analysis

In Figure 1, the mass loss profiles of NFMD Experiments 1 and 2, in terms of *MR* (moisture ratio dry basis), are compared with spray-drying and freeze-drying of product with similar water content. The drying time spent in the NFMD is clearly lower than freeze-drying and only a few minutes longer than the time observed in spray drying (about 100 min) but the thermal levels applied are considerable. Consequently, NFMD presents very favourable characteristics for the drying of thermosensible materials with similar efficiencies to those obtained by spray-drying, taking into account the duration of cycles and power consumption [7].

Figure 1. Drying kinetics of NFMD compared to freeze-drying (Rudy et al., 2015) and spray-drying.

When analyzing the thermal profiles, it is necessary to take into account the strong reduction of mass during Phases I and II that directly affects the thickness of the bed through a reduction of the particle size, as shown in Table 2 above. An idea of the reduction of the size associated with the water loss is shown in Figure 2 for Experiment 7 (Lm/Hm). Thus, Figure 2a and 2b correspond to the start and end of Phase I, where one can see the important size difference with respect to the rest of the drying (Figure 2c and 2d). As a result, an important reduction

in the thickness of the bed, up to a 25% of the initial value, was observed at the end of Phase II.

Fig. 2 Micrograph of the microcapsules at different drying times for Experiment 7 (Lm/Hm): a)  $X_{in}=0.80$ ,  $dp=2.12$  mm; b)  $X=0.51$ ,  $dp=1.8$  mm; c)  $X=0.24$ ,  $dp=1.4$  mm; d)  $X=0.05$ ,  $dp=1.1$  mm.

### 3.3. Quality of the dehydrated product

The lower the water activity, the better the stability of the dry food product, but in very low water activities, the oxidisation of membrane lipids can also reduce viability [8].

The moisture content was determined by the Karl-Fischer method. Results were obtained on wet basis, expressed as percent ( $KF$ ) that permits to determine the dry solid fraction taking into account the mass loss during drying. The results of  $KF$  from each experiment were used to confirm the dry solid fraction of capsules.

The probiotic viability or survival ratio (in %) of the microorganisms in each experiment is defined according to Chávarri *et al.*[6]. It is based on a count of colony forming units (cfu), taking the log values in the initial sample ( $cfu_0$ ) and after drying ( $cfu_{fin}$ ). According to Table 3, the average data of drying rate for each experiment, the time of processing, water activity,  $KF$ , and the survival % of the overall process are shown at the end of each drying conditions. The NFMD experiments were made by triplicate in order to analyse the effect of possible process variability on the viability results. In Table 3, one can see that the standard error of the survival values were in all cases lower than 1.6%. This proves a good process control with the used operating variables and the subsequent reproducibility of experiments.

**Table 3** Quality parameters obtained for all experiments.

Exp.	$r_{I-II}$	$M_{fin II}$	$r_{global}$	time (min)	KF	Survival (%)	Code
1	0,114	0,783	0,017	275	6,726	74.42±1.01	LI/MI
2	0,126	0,946	0,024	195	7,522	96.00±1.37	MI/Mm
3	0,219	1,245	0,021	240	7,706	93.83±0.28	LI/Lm
4	0,184	0,945	0,023	240	7,577	88.65±0.04	Mm/HI

9	0,254	0,992	0,025	240	7,726	55.00±0.98	Mh/Hm
<b>Lyo.</b>			0,007	720	8,855	91.18±1.44	-

\*Units:  $r_{I, II}$  and  $r_{global}$ : g H<sub>2</sub>O/g d.s. min,  $M_{fin II}$ : g H<sub>2</sub>O/g d.s.

#### 4. Conclusions

The NFMD process has proved to be a feasible technology for microencapsulated microorganisms dehydration. The global value of drying rate was in all NFMD cases around 0.02 g water/g d.s., spite of the significant differences when referring Phases I and II. The long duration of Phase III dilutes somehow the differences of preceding phases.

The operating conditions applied and the temperature gradient from product to air or viceversa generate a convective heat flow that leads to an extra heat contribution (medium air temperature; i.e. Experiment 1) or heat loss (low air temperature; i.e. Experiment 9). Despite the negative effect on energy consumption that occurs when the air temperature is low or medium, this circumstance seems to favour the quality of the dehydrated product as in Experiment 2, showing high survival values of 96%.

### **Abstract**

*The great amount of waste produced by food industry contains interesting bioactive compounds. The extraction of these compounds requires the by-products previous stabilization being the convective drying one of most used techniques to this end. Drying conditions can affect both drying kinetics and final quality of products. The apple skin, byproduct of apple juice or cider industries, is rich in functional compounds such as polyphenols or vitamin C. The main goal of this contribution was to quantify the influence of temperature and ultrasound application in drying kinetics of apple skin. For this purpose, drying experiments at different temperatures (-10, 30, 50 and 70 °C) and with (20.5 kW/m<sup>3</sup>) and without application of ultrasound were carried out. Drying kinetics were modelled by using a diffusion based model. As can be expected, the higher the temperature the faster the drying. Ultrasound application accelerated the process at every temperature tested being the influence slightly lower than found from the literature for other products. This can be attributed at the physical structure of the apple skin, less porous than the pulp. In any case, the application of ultrasound significantly reduced the drying time.*

**Keywords:** *by-products; dehydration; diffusivity; mass transfer.*

---

## **1. Introduction**

The food industry generates a great amount of waste that produces an important environmental impact. However, these by-products could be considered as a source of interesting bioactive compounds.[1] Apple is one of the most consumed fruits in the world.[2, 3, 4] The main by-product generated by juices and cider industries is the apple skin. This by-product presents a very important antioxidant activity [5] containing flavonoids such as cyanidin glycosides and quercetin glycosides which are not present in the pulp.[6, 7] Therefore, it can be used as a source of these compounds or directly as a functional ingredient.[7, 8]

Convective hot air drying is one of the most applied methods to stabilize products and by-products [9] facilitating their management, storage and transport. However, drying can induce significant changes in product quality.[4, 9, 10] Thus, the influence of drying process on antioxidant capacity of apples [11, 12, 13] and apple skin [4] has been already studied. The drying processes at low temperature emerges as an excellent way to preserve the thermal-sensitive compounds.[14] However, at these conditions, the low rate of drying must be intensified to avoid long processing times. [15] In this sense, ultrasound application comes up as an efficient alternative to intensify drying process.[16]

The aim of this work was to assess the influence of the drying temperature and ultrasound application on drying kinetics of apple skin.

## **2. Materials and Methods**

### ***2.1 Sample preparation***

Apple fruits (Royal Gala var.) were selected with a similar maturation degree, washed and peeled. Apple skin was blanched in boiling water for 30 s to inactivate the enzyme polyphenol oxidase.[17] Moisture content was determined by differential weighing between fresh and dried samples in a vacuum oven at 60°C.[18]

### ***2.2 Drying***

The drying processes were carried out by an atmospheric freeze-drying and a hot air drying process.

#### ***2.2.1 Atmospheric freeze-drying experiments***

Samples were placed in a sample-holder, frozen in a blast freezer (HIBER, mod. ABB BF051, Italy) at  $-35 \pm 1^\circ\text{C}$  and placed in an ultrasonically-assisted convective drier.[15] Drying process was carried out at  $-10^\circ\text{C}$ , 2 m/s, without (AIR-10) and with (US-10) ultrasound application (electrical input of 50 W) by triplicate. The process finished when samples lost 85% of its initial weight.

### 2.2.2 Hot air drying experiments

These experiments were carried out at 30, 50 and 70°C with (US30, US50, US70) and without (AIR30, AIR50, AIR70) the ultrasound application (electrical input of 50 W).[19] All the runs were performed by triplicate at 2 m/s and until samples lost 85% of initial weight.

### 2.3 Modelling

An unidimensional diffusion-based model was considered for modelling the experimental drying kinetics (Eq. 1).

$$\frac{\partial W(x, t)}{\partial t} = D_e \frac{\partial^2 W(x, t)}{\partial x^2} \quad (1)$$

Where  $W$  is the local moisture content of sample (kg water/kg dry matter, d.m.);  $D_e$  is the effective moisture diffusivity ( $\text{m}^2/\text{s}$ );  $x$  is the direction of the moisture transport (m);  $t$  is the drying time (s). Effective moisture diffusivity was considered constant during the process and it was assumed isotropic and uniform samples. Although, at atmospheric freeze-drying conditions, this fact is far from the reality, the model allowed to quantify the influence of the studied process variables and to compare the drying kinetics.[11] The external layer of apple peel was considered a waterproof surface. The external resistance to mass transport was included in the model by means of Eq. 2.

$$-D_e \rho_{ss} \frac{\partial W_p(L, t)}{\partial x} = k(a_w(L, t) - \varphi_{air}) \quad (2)$$

where  $a_w$  is the water activity of samples,  $\rho_{ss}$  is the density of the dry solid ( $\text{kg d.m./m}^3$ ),  $L$  is the experimental average thickness of the apple peel samples,  $\varphi_{air}$  is the relative humidity of the drying air and  $k$  is the mass transfer coefficient ( $\text{kg water/m}^2\text{s}$ ). An implicit finite difference method was chosen to estimate the model parameters,  $D_e$  and  $k$ , using Matlab 2011B® (The Mathworks, Inc, Natick, USA).

The percentage of explained was used to measure the goodness of the model fitting.

$$\% VAR = \left( 1 - \frac{S_{xy}^2}{S_y^2} \right) \cdot 100 \quad (3)$$

$S_{xy}^2$  and  $S_y^2$  are the calculated moisture content of apple peel the variance of the experimental, respectively.

### 3. Results and Discussion

#### 3.1 Experimental drying kinetics

The initial moisture content of apple skin was  $4.99 \pm 0.07$  (kg water/kg d.m.). Only the falling rate of moisture content was considered in drying kinetics.

As expected, temperature significantly affected the process kinetics; the higher the temperature the faster the drying (Table 1). Thus, the average time needed to reach a moisture content of 1 kg of water/ kg of dry matter at 30°C was 4.6 times greater than those needed at 70 °C. The atmospheric freeze-drying experiments were the slowest processes due to the low level of energy available for moisture transport at these conditions.

Ultrasound application significantly shorten the drying processes (Fig. 1). The influence in time process reduction was higher as lower the drying temperature. Thus, the drying at atmospheric freeze-drying conditions (-10 °C) assisted by ultrasound was 3.2 times faster than without ultrasound. At 30 ° C, ultrasound application produced a 2.4 times shortening of drying process.

*Table 1. Drying time needed to achieve a moisture content of 1 kg water/kg dry matter during drying of apple peel at different temperatures without ultrasound application.*

Treatment	Drying time (h)
AIR-10	$68.1 \pm 23.4$
AIR30	$4.1 \pm 0,92$
AIR50	$1.3 \pm 0,29$
AIR70	$0.9 \pm 0,10$

#### 3.2 Drying kinetics modeling

Taking into account the limitation of the model used, the modelling permitted to quantify the influence of the process variables on drying kinetics. The figure of the explained variance obtained showed the goodness of the model fit to the experimental data (Table 2).

Temperature significantly affected the values of  $D_e$  identified. Thus, the higher the temperature the greater the  $D_e$  figure. It can be highlighted the fact that the value of  $D_e$  found at atmospheric freeze-drying conditions (-10 °C) was one order of magnitude smaller than those identified at temperatures above freezing point (Table 2). As a general rule, the identified  $D_e$  were in the range than those found by others authors drying apple flesh at similar temperatures.[11, 12, 13]

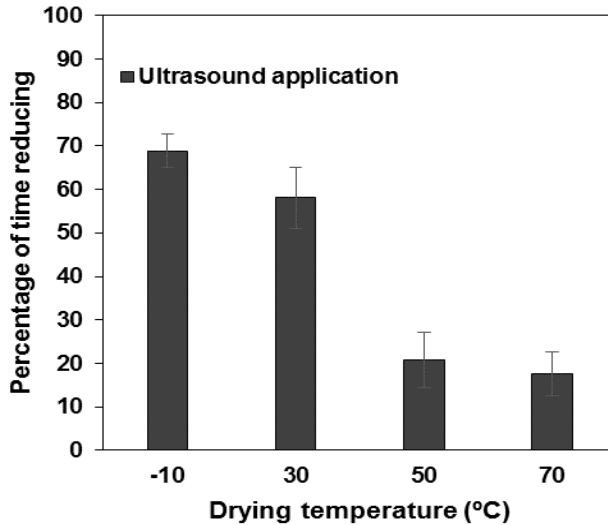

Figure 1. Percentage of time reduction by the application of ultrasound (50 W) during apple skin drying at different temperatures.

The relationship between  $D_e$  and temperature was modeled using an Arrhenius type equation (Eq. 4).

$$D_e = D_0 \exp\left(\frac{E_a}{RT}\right) \quad (6)$$

Where  $D_0$  is a pre-exponential factor ( $m^2/s$ ),  $E_a$  is the activation energy (kJ/mol),  $R$  is the universal gas constant (kJ/mol K) and  $T$  the absolute temperature (K). The fit for AIR experiments was adequate ( $r^2 > 0.99$ ) and the  $E_a$  obtained, 32.51 kJ/mol, was in the range of products such as passion fruit peel [20].

Ultrasound application increased the identified  $D_e$  value being this increase higher as lower was the drying temperature. Thus, at -10 °C, ultrasound application increased 74% the  $D_e$  while this increase was only 10 % at 70 °C. This fact has been previously observed in other products such as apple flesh [12] or passion fruit peel [20]. The  $D_e$  observed in the US experiments at -10, 30 and 50 °C also followed an Arrhenius type relationship ( $r^2 > 0.99$ ). The  $E_a$  obtained for these experiments was slightly lower than those found for AIR experiments (25.86 kJ/mol for US vs 32.51 kJ/mol for AIR) that would indicate that the US assisted drying will could be a less temperature dependent process than the AIR experiments. This fact means that the ultrasound application can make possible the

lowering of the drying temperature. The pre-exponential factor was also lower for US ( $1.6 \cdot 10^{-5} \text{ m}^2/\text{s}$ ) than for AIR experiments ( $8.6 \cdot 10^{-5} \text{ m}^2/\text{s}$ ).

As for the mass transfer coefficient (k) neither temperature nor ultrasound application significantly affected the figures identified (Table 2). However other authors have found significant influence of these variables on k [11, 12]. This fact could indicate that, at the drying conditions tested, the influence of external resistance compared with the internal one was negligible. Therefore, the effect of studied variables on internal resistance could mask the effect on external one and then, the model can not identify any influence on k.

*Table 2. Effective diffusivity and mass transfer coefficient identified by using a diffusion model. Percentage of variance explained by the model. Letters in the same column show homogenous groups determined for Least Significance Difference ( $p < 0.05$ ) intervals.*

Treatment	$D_e$ ( $\times 10^{-10} \text{ m}^2/\text{s}$ )	k ( $\times 10^{-3} \text{ kg water}/\text{m}^2/\text{s}$ )	% var
AIR-10	$0.3 \pm 0.1^a$	$1.9 \pm 0.4^a$	98.7
AIR30	$1.7 \pm 0.6^b$	$0.8 \pm 0.2^b$	99.1
AIR50	$5 \pm 3^c$	$1.9 \pm 0.5^a$	99.6
AIR70	$9 \pm 2^d$	$2.3 \pm 0.2^a$	99.9
US-10	$1.16 \pm 0.02^b$	$2.0 \pm 0.4^a$	98.4
US30	$5.49 \pm 0.02^c$	$1.8 \pm 0.3^a$	99.4
US50	$10 \pm 2^d$	$2.0 \pm 0.3^a$	99.8
US70	$10 \pm 1^d$	$2.4 \pm 0.7^a$	99.8

In view of the results obtained, the ultrasound application can be considered as an interesting means of intensify drying processes at moderate temperatures.

#### 4. Conclusion

Temperature and ultrasound application are able to significantly affect the apple skin drying. The higher the temperature the faster the process. The ultrasound application can also reduce the drying process time being this reduction more significant as lower the temperature. The atmospheric freeze-drying of apple peel was a very time consuming process even when was intensified by an ultrasound application.

### Abstract

*Vibration is a promising way to intensify the drying process through heating-up due to viscous dissipation, activation of internal liquid transfer and increase of external transfer. To better assess the possible contribution of these effects, we choose a multiscale approach.*

*This paper is focused on the pore scale, simulated by a capillary tube partially filled with water subjected to sinusoidal vibrations. We studied the displacement of water inside this tube through image analysis. This configuration mimics the moisture transfer inside the pores of a porous media during drying.*

*The experimental device developed in this study is applicable to a wide range of configurations, such as symmetrical or asymmetrical vibrations.*

**Keywords:** *drying intensification, acoustic vibration, pore scale, symmetrical and asymmetrical signals, image processing.*

---

## 1. Introduction

Vibration is a promising way for the intensification of drying [1], especially for porous media. The present work is focused on the study of the effect of vibration to assist moisture migration inside these materials. Several phenomena may be involved [2,3] such as internal heat generation by viscous dissipation, intensification of transfer at the exchange surfaces, activation of vapor diffusion by oscillating bulk velocity, change of wetting angle, etc. In this paper, we focus on the liquid water behavior inside a unique pore during vibration.

## 2. Materials and Methods

The experimental set consists of a capillary glass tube partially filled with water, a vibration chain and an optical bench controlled by a PC.

*Fig. 1 A general view of the experimental device.*

### 2.2 Capillary tube and water index

Capillary tubes – inner diameter ( $ID$ ) = 0.6 or 2.2 mm, length = 15 cm, carefully cleaned with Mucosol solution (3 %, ROTH) – are used for simulating a unique pore. Considering the difficulty of tracking the position of a smooth tube, a notch is machined on the top external wall as a mark to observe its movement. An index of distilled water is placed in this tube. In the present work, a constant index length was used, in the range 10.1 to 10.2 mm.

### 2.3 Vibration chain

A Brüel & Kjær vibration chain (Fig. 1) vibrates the capillary tube horizontally. A power supply (type 2718) amplifies the signal from the generator (LDS LASER<sub>USB</sub>, 64 bits) to the vibration exciter (type 4809, maximum 8 mm peak-to-peak displacement, from 10 Hz to 20 kHz). An impedance head (type 8001, with a piezoelectric accelerometer and force gauge sharing the same housing, operating frequency range up to 10 kHz) – fastened between the

exciter and the tube, and connected to the signal generator – allows a feedback control. At the other end of the tube, a 3D-printed holder reduces the vertical oscillations due to the gravity and possible resonances. Series of tests were performed with sinusoidal vibrations:

$$x_{cap}(t) = A \sin(\omega t) \quad (1)$$

where  $A$  is the amplitude,  $\omega$  the angular frequency and  $f$  the frequency ( $\omega = 2\pi f$ ).

## 2.4 Image acquisition system

The tube and liquid movement are monitored thanks to an optical bench, comprising a high-speed camera (FASTCAM Mini AX100, by Photron: up to 4000 fps at full resolution of 1024×1024 with a grey level coded on 12 bits), controlled by a PC, and a backside illumination. The perpendicularity of the tube and the optical bench axis is calibrated using two line lasers.

Fig. 2 Water index meniscus inside a capillary tube.

## 2.5 Image processing

The behavior of the water index is studied by image processing through the displacement of the meniscus (Fig. 2), *i.e.* the interface between water and air. Obtained images are analyzed using a custom Matlab program. The core of the program consists in the recognition of the inner wall, the meniscus and the notch. The boundaries between phases are characterized by a transition from light to dark. Point B is the intersection of the tube axis and the meniscus. The coordinate of the mass center of the notch (white area in Fig. 2) is used to follow the position of the capillary tube.

## 3. Raw data

For each test, we register 50 pictures per period over a total of 7 periods. Fig. 3 presents images obtained for  $ID = 2.2$  mm,  $f = 30$  Hz and  $A = 2$  mm. Red arrow depicts the tube direction and the blue one shows the water direction compared with the previous position.

For this test, we notice that the menisci are not perfectly symmetrical to the horizontal plane: gravity is not negligible anymore for the 2.2mm-inner diameter tube.

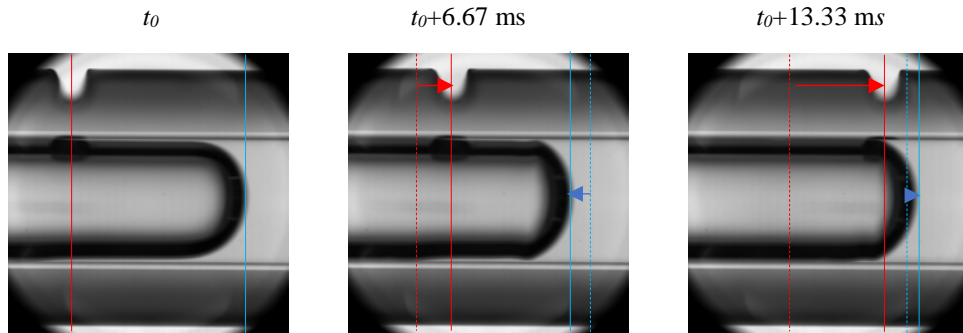

Fig. 3 Displacement of the water index during half period ( $ID = 2.2 \text{ mm}$ ,  $f = 30 \text{ Hz}$ ,  $A = 2 \text{ mm}$ )

Fig. 4 Absolute displacements of water and tube vs. time ( $ID = 2.2 \text{ mm}$ ,  $f = 30 \text{ Hz}$ ,  $A = 2 \text{ mm}$ )

We can also notice that the absolute displacement amplitude of the water index is lower than the one of the capillary tube. At this high frequency, inertia dominates the forces acting on the system (viscous and capillary forces). This observation is confirmed by all positions determined by image processing. In this case, as the absolute movement of water (Fig. 4) is much smaller than the tube movement, the relative movement of water inside the tube has almost the same amplitude as the imposed movement. For these parameters, the phase change of water movement is about  $\pi/2$ .

#### 4. Results

In order to study a wide range of contrasted situations, the values of three parameters were systematically tested: inner diameter (0.6 and 2.2 mm), frequency (10, 20 and 30 Hz) and amplitude (0.5, 1, and 2 mm). Thus, we obtained a dataset of 18 experiments. The images

analysis for all tests depicts a high diversity of water index behavior, especially for menisci shape and displacement amplitude. To explain this variability, it is mandatory to quantify the relative importance of three parameters: surface tension, viscosity and inertia. For this purpose, we introduce two dimensionless numbers:

#### 4.1. The capillary effect

$N_c$  is the ratio of capillary force  $F_c$  over inertia  $F_i$ :

$$F_c = 2\pi R\sigma \quad (2)$$

$$F_i = ma = \pi R^2 l \rho A \omega^2 \quad (3)$$

hence 
$$N_c = \frac{2\sigma}{Rl\rho A\omega^2} \quad (4)$$

where  $R$  is inner radius of capillary,  $\sigma$  the surface tension,  $l$  the length of the index, and  $\rho$  the water density.

Fig. 5 Representation of all tests performed in the present study according to their respective effects of capillary forces and viscosity; One marker size per signal amplitude, (small = 0.5 mm, medium = 1 mm and large = 2 mm)

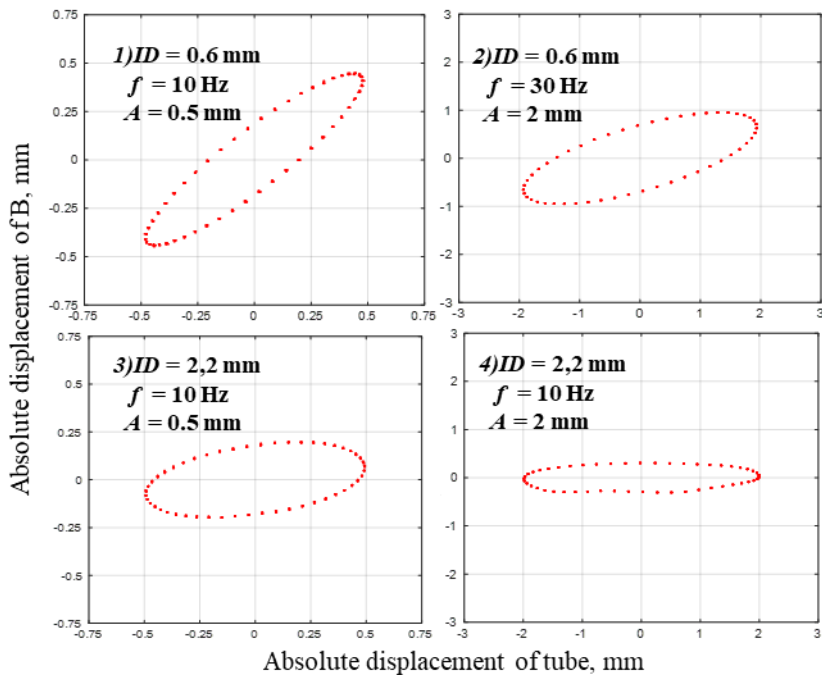

#### 4.2. The viscous effect

$N_v$  is the ratio of the characteristic time of the signal (half-period) over the characteristic diffusion time:

$$N_v = \frac{\mu}{2f\rho R^2} = \frac{\delta^2}{R^2} \quad (5)$$

where  $\mu$  is the dynamic viscosity of water and  $\delta$  the thickness of the Stokes boundary layer.

All tests performed in this study can therefore be represented by one marker in the plane defined by the values of  $N_c$  and  $N_v$  (Fig. 5). From all these tests, four contrasted situations are selected for an in-depth study.

*Fig. 6 Lissajous curves (absolute displacement of point B plotted versus tube displacement) for the four configurations selected for the in-depth analysis (points in Fig. 5)*

### 4.3. Focus on contrasted situations

In order to provide a more in-depth analysis of the relative effects of the physical phenomena (viscosity, surface tension, inertia), Lissajous curves were plotted for each selected test (Fig. 6). These curves consist in plotting the absolute displacements of the water index (point B) as a function the tube displacement. On these closed curves, we can easily observe the ratio between the tube and water amplitude (respectively width and height of the ellipse according  $x$  and  $y$ ) and the phase change between the signal (twice the angle between the first bisector and the main axis of the ellipse)

For test 1, the capillary effect dominates inertia and the viscous effect is not negligible (see the position of point 1 in Fig. 5). As a result, the water index flows the tube movement with a slight hysteresis. This explains why the curve is long and narrow along the direction 45°: almost same amplitudes and same phase. For the same tube diameter (0.6 mm) but a larger frequency and a larger amplitude (test 2),  $N_c$  is smaller than the unit. Consequently, the water index is not able anymore to follow the tube movement: the water index amplitude is ca. half the signal amplitude and the phase change increases. For test 3, as seen in Fig. 5, the capillary effects are quite important, but the viscous effects are now negligible, due to the larger tube diameter. Finally, test 4 lies at the very bottom-left of Fig. 5, which means very weak viscous and capillary forces. Accordingly, the water index is almost at rest in spite of the tube movement.

## 5. Conclusions and perspectives

In this work, we highlighted on the effect of vibrations on the movement of a water index in a capillary tube.

Then, various parameters were tested: tube diameter, frequency and amplitude of the tube movement. In order to quantify the effects of the parameters, two dimensionless numbers were introduced to see the effect of viscous and capillary forces compared to the index inertia. All data collected in four contrasted selected tests are perfectly explained by these dimensionless numbers.

*Fig. 7 Absolute displacements of B and tube (ID = 2.2 mm,  $f = 1$  Hz,  $A = 1.03$  mm)*

Finally, by using an asymmetrical signal, we prove that the index movement can be forced in a chosen direction. In this sense, Fig. 7 depicts a preliminary, but promising test. Using a saw-tooth wave at low frequency, we obtained an obvious global movement of the index to the right along the successive periods. This trend was inverted when changing the phase of the signal, which proves that the water movement is really due to the asymmetric signal.

Additional tests as well as modeling approaches are in progress in our team to further investigate the effect of vibrations on liquid movement, and the numerical validation of some experimental results has also been done.

## 6. Nomenclature

$a$	acceleration	$\text{ms}^{-2}$	$m$	mass	kg

### **Abstract**

*Wall deposition tests have been conducted on a new spray-drying system. Solutions of salt and skim milk powder have been dried with different inlet temperatures (170 °C and 230 °C) and solid contents (8.8 wt% and 30 wt%). The experiment showed that increasing the temperature caused a decrease in the amount of deposition for salt solution, but an increase for skim milk. The experiments also showed that a higher solid content caused an increase in deposition. The trends agreed with the studies using a conventional spray dryer, but the amount of deposition appeared to be lower in the new spray dryer at the same operating conditions*

**Keywords:** *Spray drying; wall deposition*

---

## 1. Introduction

Spray-drying techniques have been applied in a wide range of industries. One of the key issues that occurs when using spray dryers for food materials is wall deposition. During the drying process, the particles, especially if they contain sugar-rich and fat-rich food materials, may stick on the wall of the drying chamber [1]. Many workers have focused on the effects of operating conditions on the degree of wall deposition, such as the temperatures and the solid content. At a certain moisture content, the sticky point is the critical temperature at which particles transform into a sticky state due to the increase in the molecular mobility and the formation of solid bridges between particles. Studies by Roos & Karel [2] showed a close relationship between the sticky point and the glass-transition temperature  $T_g$  of the dried materials. Solid content is another important factor affecting the formation of deposits. Goula & Adamopoulos [3] have suggested that, for food products with higher hygroscopicity (e.g. skim milk, sucrose, tomato pulp), increasing the feed concentration increases the moisture adsorption rate on the surface of particles. Another possible effect of increasing the feed concentration is to change the particle moisture content. The moisture content within each droplets may vary with feed concentration, depending on the droplet sizes [4].

A new spray-drying system has been established in the School of Chemical and Biomolecular Engineering in the University of Sydney. The preliminary studies on the flow pattern of the spray dryer have shown that the design improved the stability of the flow field near the chamber wall, which may help to reduce wall deposition. The aim of the project is to evaluate the wall deposition performance of the new spray dryer using different feed materials and operating conditions, including inlet temperatures and feed concentrations. The experiment also compared results with previous studies using spray dryers of conventional designs.

## 2. Materials and Methods

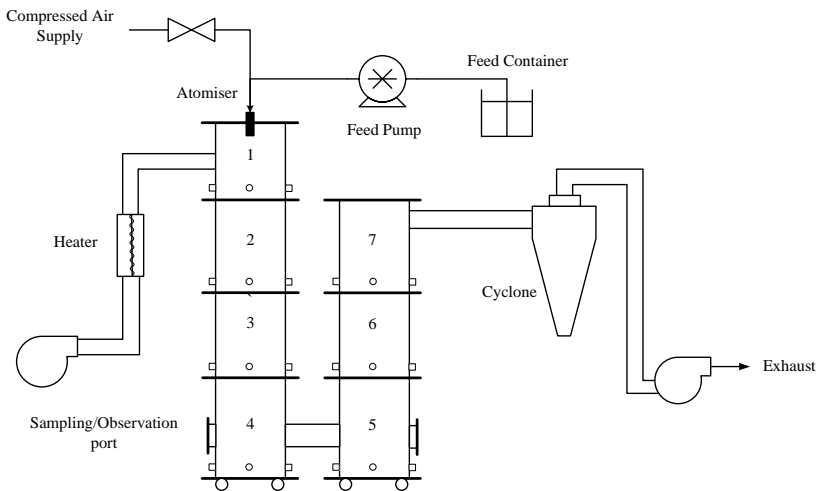

A schematic diagram of the system is shown in Figure 1. The stainless steel chamber is insulated using glass wool insulation blankets. The drying chamber consists of two drying columns of 30 cm in diameter. Chamber one is 2.2 m, and chamber two is 1.6 m in height. The columns comprise seven detachable sections in total, with the actual drying process starting from section 2. The chamber is fitted with a two-fluid nozzle atomizer (Buchi B-290, Switzerland). Feed solutions of all the tested materials have been introduced through the atomiser using a liquid flowrate of 27 ml/min and an atomising air flowrate of 10 L/min, which were selected according to previous experimental studies using a conventional spray dryer [5], [6]. The operating conditions for different materials have been shown in Table 1. Multiple stainless steel plates have been placed at the side wall of each section of the chamber as well as the bottoms of both columns, in order to measure the deposition fluxes. After removing the plates from all the sections, each section has been washed with water to

dissolve all the remaining deposits. Portions of the wash solutions have been dried at 80 °C for 24 h, in order to calculate the total mass of deposits based on the weight of the collected solutions. The total mass of deposits has been used to calculate the deposition rate, which is the total mass of deposits divided by the total sprayed solids.

*Table 1 Operating conditions for different feed materials applied in the experiment.*

Feed material	Inlet temperature (°C)	Feed concentration (wt%)
Salt	170/230	8.8
Skim milk	170/230	8.8/30

*Figure 1 Schematic diagram of the new spray-drying system.*

### 3. Results and Discussion

#### 3.1. Investigation of the influence of inlet temperature using salt and skim milk

The inlet temperature was chosen to be the first parameter to be investigated, because it was noticed that the design features and the insulation of the new spray-drying system provided a relatively low heat loss to the environment (around 20 W/K). The difference in temperature profile could lead to different wall deposition behaviour compared with conventional spray-dryer designs. The qualitative observations of the deposition patterns at different sections of the drying chamber have been shown in Table 5. The measurements of deposition fluxes and deposition rates have been shown in Table 2.

For the salt solutions, it can be first observed from Table 5 that there appeared to be no severe formation of wall deposits on the chamber wall, with only a thin, dusty layer observed in sections 3, 4 and 5. Increasing the inlet temperature from 170 °C to 230 °C has shown no

significant effect on the deposition pattern. It should be noted that, at the bottom of section 4, the deposition tended to form an evenly distributed layer, whilst at the bottom of section 5, the deposition pattern changed into spotted deposits. Such differences between indicated two different processes of forming wall deposits in the drying chamber. Kota & Langrish [6] suggested that deposition could be formed by two mechanisms: inertial deposition, caused by the inertia of particles, and turbulent deposition, caused by the random movement of particles due to turbulence in the air flow. In chamber one (section 4), the particles from the atomiser travelled directly towards the chamber wall/bottom, then formed an evenly-distributed deposit, mainly due to particle inertia. As the particles proceeded to chamber two (section 5), the recirculation flow caused the particles to agglomerate into large particles and formed spotted deposits. From Table 2, it can also be observed that the the deposition fluxes were higher on the bottom of sections 4 and 5, which indicated that the inertial deposition may be the dominant mechanism causing deposition. At a higher temperature of 230 °C, the measurements have shown slight reductions on both the side walls and the chamber bottoms. Such reductions could be caused by a lower moisture content, thus less adhesive forces caused by liquid bridges [7].

*Table 2 Wall deposition fluxes and deposition rates of 8.8 wt% salt and skim milk feed solutions at different sections of the drying chamber.*

		Salt (170 °C)	Salt (230 °C)	Skim milk (170 °C)	Skim milk (230 °C)
<b>Side wall Deposition Fluxes (g·m<sup>-2</sup>·h<sup>-1</sup>)</b>	<b>Section 2</b>	0.5	0	0.3	0.5
	<b>Section 3</b>	2.0	0.7	2.7	3.0
	<b>Section 4</b>	1.5	0.3	1.0	1.0
	<b>Section 5</b>	2.0	1.6	5.5	3.5
	<b>Section 6</b>	1	0	1.3	0.7
	<b>Section 7</b>	0	0	0	0
	<b>Bottom Deposition Fluxes (g·m<sup>-2</sup>·h<sup>-1</sup>)</b>	<b>Section 4</b>	10	11	7.0
<b>Section 5</b>		22	15	12	14
<b>Overall average (g·m<sup>-2</sup>·h<sup>-1</sup>)</b>		4.9	3.6	4.0	4.0
<b>Side wall average (g·m<sup>-2</sup>·h<sup>-1</sup>)</b>		1.2	0.4	2.0	1.4
<b>Bottom average (g·m<sup>-2</sup>·h<sup>-1</sup>)</b>		16	13	9.3	12
<b>Chamber 1 deposition rate (%)</b>		2.0	1.8	2.8	3.2
<b>Chamber 2 deposition rate (%)</b>		3.4	1.3	3.3	4.4
<b>Cyclone deposition rate (%)</b>		2.3	1.5	1.4	2.9
<b>Total deposition rate (%)</b>		7.7	4.6	7.6	10.5

In comparison with salt solutions, skim milk showed some differences in response to the increase in the inlet temperature. From Table 5, it can be seen that the deposition produced by the skim milk at 170 °C appeared to be similar to that produced by salt. As the temperature

increased to 230 °C, however, colour changes could be observed in the deposition. The brownness of the deposition indicated that Maillard reactions and possibly caramelisation may have occurred at the higher temperature. Previous studies using a conventional spray dryer [5] reported a deposition flux of around 16 g·m<sup>-2</sup>·h<sup>-2</sup> at the inlet temperature of 170 °C, which was higher than the values measured in this work (maximum of 12 g·m<sup>-2</sup>·h<sup>-2</sup>). The lower deposition in the new spray dryer could be caused by a more stable flow pattern and relatively smaller heat loss of the new system. However, as the inlet temperature increased to 230 °C, the deposition flux in the conventional spray dryer was reported to be 8 g·m<sup>-2</sup>·h<sup>-2</sup>, lower than the values measured at the bottoms of the new system. Maillard reactions and caramelisation could cause such higher deposition flux in the new dryer, as the reactions produced complex compounds [8], thus led to changes in the particle compositions and the glass transition temperature.

### 3.2 Investigation of the influence of feed concentration using skim milk

From the comparison of the wall deposits obtained at different inlet temperatures, it was strongly suggested that the higher drying temperature of 230 °C could lead to changes in the particle compositions. To avoid introducing additional variables, the investigation of the effect of feed concentration was conducted at the inlet temperature of 170 °C. The qualitative observations of the deposition pattern have still been shown in Table 5, and the measurement of deposition fluxes and deposition rates have been shown in Table 3.

From Table 5, it can be observed that the bias in the deposition became more obvious at the higher feed concentration in sections 3 and 4 than that in section 5. Four plates were placed in each of section 3, 4 and 5 in order to better interpret the distribution of the wall deposition, and the percent deviations for each section have been shown in the brackets of Table 3. It can be seen that for the feed concentration of 8.8 wt%, the percent deviation was found to be the highest in section 3 (96%), and sections 4 and 5 showed a similar degree of deviation (57% and 54%). At the higher feed concentration, no apparent change was observed in the percent deviation in section 3 and 4 (90% and 52%), but a reduction was seen in section 5 from 54% to 17%. Such changes in section 5 suggested that the formation in section 5 underwent a different process from that in sections 3 and 4. The inertial deposition due to the direct impact of the spray appeared to be the main cause of the deposition, as well as the biased deposition pattern in sections 3 and 4, regardless of the feed concentration. By contrast, with a higher feed concentration, particle of larger sizes may be less influenced by the turbulent flow, thus forming the deposition around section 5.

The deposition fluxes measured in this experiment were again compared with the results using a conventional spray dryer [5], [6]. As shown in Table 4, the new spray dryer showed lower deposition fluxes at the same operating conditions, with the average deposition fluxes reported to be 16 g·m<sup>-2</sup>·h<sup>-1</sup> compared with 4 g·m<sup>-2</sup>·h<sup>-1</sup> at a concentration of 8.8 wt%, and 130

$\text{g}\cdot\text{m}^{-2}\cdot\text{h}^{-1}$  compared with  $50 \text{ g}\cdot\text{m}^{-2}\cdot\text{h}^{-1}$  with a 30 wt% feed solution. Despite the overall lower deposition flux, the new drying system showed the increasing trend similar to the previous studies, as shown in Table 4. There are several reasons that could lead to the increasing wall deposition fluxes: 1) higher the specific moisture content due to larger droplet sizes; 2) the hygroscopicity of skim milk increases with the solid content, which could hinder the drying process; 3) particles with higher solid content tended to form crust of higher thickness, which could reduce the evaporation of moisture within the crust.

**Table 3** Wall deposition fluxes and deposition rates of 8.8 wt% and 30 wt% skim milk feed solutions at different sections of the drying chamber. Inlet temperature = 170 °C.

#### 4. Conclusion

Wall deposition tests have been conducted on a new spray dryer in order to investigate its performance at different operating conditions, and compare it with a conventional design. The increase in the inlet temperature from 170 °C to 230 °C has caused a slight reduction in wall deposition rate for salt solutions, but an increase in the value for skim milk solutions. Such a difference could be caused by the change in the composition of skim milk deposits as a result of Maillard reactions. The experiments with different feed concentrations showed an

increase in wall deposition when the solid content increased from 8.8 wt% to 30 wt%. Such an increasing trend agreed with the previous studies using a conventional spray dryer, although the actual amount of wall deposition appeared to be lower in the new spray dryer. Overall, the experiments provided some valuable information to improve the design of the new system.

### **Abstract**

*A one stage drying process for dried cranberry production, employing a vacuum microwave technique, is proposed. The process consists of a specific sequence of microwave energy dosage at a given vacuum level. During the 60 minute process, three sub-stages can be identified: osmotic dehydration, intensive water evaporation and stabilization. Mass transfer, as well as quality changes during the process, has been described, and the final product quality compared to purchased control. The proposed method of dried cranberry production resulted in a microbiologically stable product ( $a_w=0.62$ ) of a decent sensory quality, with an antioxidant potential three times higher than traditional products.*

**Keywords:** *Vaccinium macrocarpon; microwave-vacuum drying; ready-to-eat snack*

## **1. Introduction**

The cranberry (*Vaccinium macrocarpon*) fruit is recognized worldwide as a rich source of numerous phytonutrients with confirmed pharmacological and antioxidant properties [1]. Due to a high acid content, as well as an astringent taste, the fresh fruits are unacceptable for direct consumption. In an effort to make cranberries more appealing to consumers, one idea is to dry them, which unfortunately also means adding sugar. The traditional method of dried cranberry production is a time and energy-consuming process, which is realized in three stages: skin pre-treatment, sugar infusion by osmotic dehydration and final drying. Cranberry fruits, like many other fruits are covered by a cutin layer consisting of fatty acid polymers which exist to protect the fruit from losing water. Although the wax layer is beneficial in plant biology, it restricts processing by inhibiting osmotic dehydration and further drying processes. Cutting the fruits into halves allows the interior fruit tissue to be exposed to osmotic solution as well as increasing the evaporation surface during final hot air drying. Sadly, cutting the fruit also leads to several negative consequences, such as a higher leakage of sap or an increase in nutrient oxidation during the final drying. Available literature documents numerous attempts to intensify the osmotic dehydration of cranberries through various pre-treatments [2–3], as well as attempts to accelerate the drying process by applying new drying techniques [4–6]. Among the new techniques, a hybrid technique including microwave technology has been intensively investigated [7]. According to the latest reports the drying time can be reduced to less than 100 min [3]. The other problem associated with dried sweetened cranberry production is the time needed to infuse sugar, which can take up to 24 hours [8]. Despite the introduction of some new ideas to reduce the osmotic dehydration process [3,5], the waste sucrose syrup collected after the process, remains a serious technological and environmental problem.

The aim of this paper is to present an idea combining sugar infusion and final drying of freshly cut cranberry fruit, which can be realized within 60 min in the same reaction chamber by using a vacuum microwave technique.

## **2. Materials and Methods**

Cranberry fruits ('Ben Lear' cv) taken out of cold storage (2°C) were thoroughly washed with tap water and cut in half. The osmo-dried cranberry production was realized using a laboratory vacuum-microwave dryer (PromisTech, Wrocław, Poland). The standard polypropylene reaction chamber was replaced with a glass drum, which allowed the management of liquid medium. Just before drying, a batch of 100 g freshly cut cranberry fruit halves were placed into a 2 L capacity glass drum and mixed with 80g of 40% sucrose solution. When the system reached the ambient temperature ( $20.0 \pm 2.0^\circ\text{C}$ ), the process was started. The drying procedure was developed using a specific sequence of microwave energy

dosage at a given vacuum level. The drying period lasted 60 min, within which, three sub-stages can be identified, as is presented in Table 1 (PL, Patent Pending, 2018).

**Table 1. The technical parameters of the vacuum microwave drying of halved fresh cranberries**

Stage	Duration [min]	Operation	Pressure [hPa]	Max sample temperature [°C]	Microwave power [Watt/g]
1	15	Osmotic dehydration	30 ± 2	34.0 ± 0.8	1.00
2	30	Evaporation	30 ± 2	57.0 ± 3.0	3.25
3	15	Stabilization	6 ± 2	30.0 ± 1.0	0

The density of microwave power introduced into the drying chamber ensured that the material temperature was kept below 60°C. The mass transfer, and the quality changes of the material, was monitored in 7 mid-points, after 5, 10, 15, 20, 30, 35, 45 min and after process completion. To follow real drying dynamics, the process was terminated after a given time, and the material collected for analyses, after which a new procedure with a new batch of raw material was begun. For each mid-point of the process water removal rate was determined as the difference between the total weight of material at the given point. The material temperature was measured by a manual pyrometer, and then the material was checked for moisture content, density, anthocyanin content and antioxidant capacity. The appearance of the material was captured by a camera. The fruit samples taken between 5-30 min of the process, prior to measurement, were gently rinsed with water to remove residual syrup and blotted with paper towels. A fresh portion of fruit was used to obtain each sample taken for each time interval. The final product quality was also evaluated by a sensory panel, and the experimental dried fruit were compared to dried cranberries purchased in the market (one bulk product and one commercially packed). The experiment was carried out in two technological repetitions.

### 2.1. Physical, chemical and sensory analyses

The *dry matter content* was determined using the gravimetric method by drying the sample to a constant weight at 70°C under vacuum conditions (3 kPa) according to PN-90/A-75101/03 [9]. The density of the dried berries was determined using hydrostatic scales (Radwag) and calculated using the following formula:

$$\rho_s = \frac{ms_1}{ms_1 - ms_2} * \rho_t$$

where,  $\rho_s$  indicated sample density (g/cm<sup>3</sup>),  $ms_1$  sample mass in the air (g),  $ms_2$  sample mass in toluene (g), and  $\rho_t$  density of toluene (g/cm<sup>3</sup>). For each experimental point the measurements were repeated for 6 individual fruit halves.

*Water activity* was measured 24 h after drying, using HC2-AW-USB station probes connected to a PC running HW4-P-QUICK-V3 software (Rotronic, B&L, Poland).

*Antioxidant activity* was determined according to the method described by Re et al. [10]. Measurements were recalculated to micromoles of Trolox equivalents per gram of dry weight ( $\mu\text{mol Trolox/g DW}$ ).

*Total anthocyanin* content was quantified using the pH differential method [11]. The results were calculated as cyanidin-3-glucoside, and expressed in mg/100 g DW of the analyzed sample. For each mid-point of particular technological repetition, two independent analytical replicates were carried out.

*Sensory analysis.* Both experimentally dried fruit and the commercially purchased products were assessed by a well-trained panel using a profiling method. The samples were evaluated in individual sensory booths under white light (6500 K). All samples, marked with 3-digit codes, were served in duplicate in random order. Panelists were asked to evaluate fifteen sensory attributes: three aroma attributes (fruity, untypical, overall), two textural attributes (hardness and overall), five flavour/taste attributes (fruity, sweet, sour, astringent, bitter, and off-flavour) and overall flavour, as well as overall quality. The results were finally expressed in 10-point scale.

## **2.2. Statistical analysis**

The data was processed using the STATISTICA 13.0 software package (StatSoft Inc., Tulsa, USA). To determine the difference between experimental and commercial products the analysis of variance (ANOVA) and a Duncan's multiple range test at  $p = 0.05$  was used.

## **3. Results and Discussion**

The dehydration kinetics of the fresh cranberry halves subjected to the one stage process realized in a vacuum- microwave reactor is illustrated in Fig. 1. Along with the parameters outlining the mass transfer intensity, the sample temperature is also given (Fig 1A). As the drying process proceeded simultaneously with osmotic dehydration, the obtained drying kinetics presents an untypical shape. In the first 15 min of the process, the drying rate gradually decreased (Fig. 1B), probably due to the effect of the increase of the syrup viscosity surrounding the surface of the fruit. During this stage the soluble solids of the fruit increased from  $8.9 \pm 0.1$  to  $15.1 \pm 1.1^\circ\text{Brix}$ , which was also reflected by the increase of the sample dry matter (Fig. 1A), caused mainly by the infusion of sugar into the fruit. The predominant effect of the osmosis mechanism at this stage, is indicated by the very low WRR (Water Removal Rate), which after 15 min of the process reached the minimum.

When the residue of syrup liquid had run out, the second stage of drying was initiated by a microwave power increase up to 3.25 Watt/g of the initial sample weight. Immediately, the

**Fig. 1** Diagram of changes monitored for osmo-dehydrated cranberries during drying process (A) material temperature and dry matter contents (B) water removal rate, MEAN ± SD (n=2)

WRR accelerated, and the water evaporation intensity increased for about 20 min, until it gained a maximum value of 0.094 g H<sub>2</sub>O/g DM/min, after which the WRR started to decline, and despite the still relatively high water content (2g H<sub>2</sub>O/g DM) in the dried material, the sample temperature continued to rise. When the temperature was approaching 60°C, the MW power was automatically reduced to avoid overheating. The temperature limit was set on the basis of other authors work [12], where 60°C is reported as crucial in polyphenol degradation in sour cherries subjected to microwave-vacuum drying. After 45 min of the process the microwave power was switched off, but water evaporation still occurred, with a steadily decreasing WRR, which can also be attributed to the low water content in the sample. These observations follow the typical pattern of sample temperatures when fruits are subjected to microwave drying [8,13].

In Fig. 2 the quality changes of the dried material during the dehydration process are presented. During the first twenty min the sample density rose from the initial value of 0.87

**Fig. 2** Trends in the quality changes of osmo-dehydrated cranberry fruit during the drying process: (A) fruit density; (B) anthocyanin content and antioxidant activity (ABTS<sup>+</sup>), MEAN ± SD (n=2).

$\pm 0.02$  to over  $1 \text{ g/cm}^3$  (Fig. 2A), which indicates slight material shrinkage, as is illustrated in Photo 1 (B).

**Photo 1. Cross-section and outside appearance of raw material (A), osmotically infused fruits after 15 min (B) and final product (C).**

To some extent, the increase in the density of the material can be explained by the fact that the intercellular spaces were replaced by the infused sugar syrup. In the next 40 min the fruit density decreased steadily, by up to  $0.48 \pm 0.02 \text{ g/cm}^3$ , which represents almost half the initial density of the fresh material. This phenomena is typical for vacuum drying, where rapid mass transfer is accompanied by a typical expansion in a so-called “puff up” effect [14]. In Fig 2B, the effect of process time on the bioactive component content is presented. The raw material used in the study contained on average  $220 \pm 4 \text{ mg/100 g DW}$  of total anthocyanins, which means that cranberries grown in Poland are able to accumulate as much anthocyanin as the Canadian clones [15]. Although the drying process lasted only 60 min, and the sample temperature did not exceed  $60^\circ\text{C}$ , the evident negative effect on both anthocyanin content and antioxidant activity ( $\text{ABTS}^{+}$ ) was observed. When compared to fresh fruit, the loss of anthocyanins reached almost 50%, and its final content in dried product amounted to  $119 \pm 10 \text{ mg/100g DW}$ . A similar pattern was found for antioxidant activity, which decreased from  $127 \pm 0.2$  to  $57 \pm 1.3 \text{ } \mu\text{mol Trolox/g DW}$  (Fig. 2B). According to data in literature, anthocyanin degradation in halved cranberries is higher than for sour cherries dried in similar microwave-vacuum conditions [15]. As is clearly presented in Fig. 2B, the antioxidant activity of dried cranberries expressed by  $\text{ABTS}^{+}$ , corresponds with the gradual decrease in anthocyanins. Similar findings have been reported by other authors [13,16] who indicated the anthocyanin content as having a major impact on the total antioxidant capacity of the cranberry fruits.

To be able to identify the advantages of our product, the experimental material (Photo 1, C) was compared to commercially available product. The comparison comprised sensory attributes, antioxidant properties and water activity. The results are gathered in Table 2. Sensory evaluation of the product showed that, when compared to commercial products, the experimental cranberry (MW-V) was characterized by a more intensive fruity aroma, but unfortunately, despite higher water activity, also by an inferior texture. It was also perceived

as less sweet, which resulted in a rating of only 4.8 (out of 10) in the overall quality assessment.

**Table 2. The comparison of chosen quality characteristics of dried cranberries available in the market and the experimental product (MW-V).**

Product type	Sensory attributes (0-10 points)						ABTS [μmol Trolox/g fresh weight]	Water activity
	Fruity aroma	Fruity flavour	Sourness	Overall texture	Sweetness	Overall quality		
Bulk product	2.8 <sup>b*</sup>	4.8 <sup>b</sup>	3.3 <sup>a</sup>	7.4 <sup>b</sup>	6.2 <sup>b</sup>	6.8 <sup>b</sup>	15.0 <sup>b</sup>	0.55 <sup>a</sup>
Commercially packed	1.5 <sup>a</sup>	3.7 <sup>a</sup>	2.7 <sup>a</sup>	7.1 <sup>b</sup>	6.2 <sup>b</sup>	4.9 <sup>a</sup>	9.9 <sup>a</sup>	0.54 <sup>a</sup>
MW-V	3.1 <sup>b</sup>	4.9 <sup>b</sup>	5.8 <sup>b</sup>	4.9 <sup>a</sup>	4.4 <sup>a</sup>	4.8 <sup>a</sup>	51.8 <sup>c</sup>	0.62 <sup>b</sup>

\*Means in columns marked with the same letter do not differ significantly according to Duncan MRT at  $p = 0.05$ .

Surprisingly, the highest overall quality was indicated for commercial, unpacked cranberries, which were expected to be of lower quality than the packed ones, which were assessed as having an untypical aroma and being off-flavour, which can be attributed to the flavor of oxidized oil, resulting in a low sample acceptance. Despite a slightly lower sensory appreciation than the commercial product, the dried cranberry produced using our method was characterized by three times more antioxidant potential. The ABTS<sup>+</sup> values seen in the experimental product were on average  $51.9 \pm 5.5$  (Table 2), whereas for cranberries purchased in the market the values were as low as  $15.02 \pm 0.2$  and  $9.88 \pm 0.2$  μmol Trolox/g fresh weight for the bulk product and commercially packed, respectively.

#### 4. Conclusions

The proposed method of sweetened dried cranberry production resulted in a microbiologically stable product ( $a_w = 0.62$ ) after a 60 min process. Sensory evaluation of the product showed that compared to commercial products, the experimental cranberry was characterized by a richer fruit aroma, but unfortunately, also by an inferior texture and lower sweetness sensation, which resulted in a rating of only 4.8 (out of 10) in the overall quality assessment. Despite a unfavourable sensory appreciation, the dried cranberry produced using our method was characterized by three times more antioxidant potential, thus further process optimization seems advisable.

We can summarize, that the presented idea of production sweetened ready-to-eat dried cranberries using a one stage process combining osmotic treatment with a vacuum microwave dehydration technique can be considered as an alternative to traditional dried cranberry production.

### Abstract

*Drying process directly affect in structure of the silica support for catalysts . Therefore, we herein prepared bimodal meso-macropore structure of silica by sol-gel method and investigated the silica support obtained from various drying techniques, namely, hot air drying (HA), microwave drying(MW)and freeze drying (FD)by means of BET and BJH N<sub>2</sub>-sorption, and SEM. The results showed a significant effect of drying technique on the textural properties of the dried bimodal porous silica support. In addition, it was found that freeze drying could enhance surface area of silica support with higher than 500 m<sup>2</sup>/g.*

**Keywords:** *bimodal meso-macropore structure silica support: drying technology: freeze drying: hot air drying: microwave drying*

---

## **1. Introduction**

Silica supports are widely used in field of catalysis. High surface area, large pore size and large pore volume of silica are often desired for catalyst supports in many reactions. Bimodal meso-macropore structure of silica is suitable for use as support in aspect of high dispersion of metal catalyst and good mass and heat transfer [1]. Generally, alkyl orthosilicates are used as a silica source for the preparation of silica support. Moreover, organic surfactant are also used as the pore structure-directing agent (template) of silica support. However, they are not appropriate in term of commercial, safety and green approach production due to their high cost, flammability, difficulties in handling or storage, and toxic to environment [2-3]. Therefore, sodium silicate is an interesting as silica source and chitosan is an alternative bio-template, in aspect of lower cost and cleaner production of silica support. In order to modify the textural properties of silica support, especially in preparing the meso-macro structure of silica, is always conducted by chemical techniques. For example, Li et al. [4] had prepared meso-macroporous structure of silica by using tetrametoxysilane (TMOS) as silica source and polyethylene glycol (PEG) as template, Blin et al. [5] proposed the usage of decane as an effective expander to enlarge the pore size of mesoporous silica. It is found that these techniques are not only use more expensive chemicals but also impractical in green processing which effected to the environment. Besides, it is found that the preparation methods are more complicated for industrial scale [6].

However, many previous researches have been suggested that drying is a physical process that directly affects on structure of the prepared silica support [7-9]. The hot air drying is the process that thermal energy is transferred to the interior of the wet-gel silica via conduction, depends on the thermal conductivity of the wet-gel silica [2]. While, in the microwave drying, water, presented in the wet-gel silica, absorbs the microwave throughout the entire mass, causing molecular vibration with respect to the oscillating electric field of the microwave and the generated heat is transferred homogenously to a molecular scale throughout the bulk [2,10]. Whereas, freeze drying, moisture is removed by sequentially freezing the water/solvent and subliming it at low pressure [10]. As per the abovementioned, we interested and attempt to apply the drying techniques in term of physical techniques to modify textural properties of silica support instead of those chemical techniques. Due to the drying is easier and effective method with lower cost [6].

Therefore, we herein prepared bimodal meso-macropore structure of silica supports by sol-gel method using sodium silicate as a silica source and chitosan as a template, and investigated comprehensively the properties of silica support obtained from various drying techniques, namely, hot air drying (HA), microwave drying (MW) and freeze drying (FD).

## **2. Materials and Methods**

The silica supports were prepared using sol-gel method. Firstly 0.4 g of chitosan was dissolved in 100 mL of 2% v/v acetic acid in deionized water under continuously stirred at 300 rpm and control temperature using water bath at 40 °C for 30 min. Then, 5.4 g of sodium silicate solution (based on 1 g of SiO<sub>2</sub>) were primarily diluted with 10 mL of deionized water and added to the chitosan solution. The solution was adjusted to pH of 6 by dropwise addition of 2 M hydrochloric solution. After that, the hydrolysis-condensation reaction was carried out at 40 °C with continuously stirred for 3 h, and then the resulting mixture was aged in the Teflon-lined autoclave at 100 °C for 24 h. The precipitated wet-gel silica products were filtered, washed several times with distilled water. Then, the washed wet-gel silica cake was dried using different drying techniques (hot air drying, microwave drying and freeze drying). Dried-gel silica were finally ground and calcined at 600 °C with the heating rate of 2°Cmin<sup>-1</sup> for 4 h in order to remove chitosan template. The obtained white silica powder was kept in vacuum container. Hot air drying was carried out in a hot air dryer (Binder GmbH, RedLine RF115, Tuttlingen, Germany) at the operating temperature of 80, 100 and 120 °C for 120, 90 and 60 min, respectively. Microwave drying was carried out in a microwave oven (Samsung, MS28H5125BK, Seoul, Korea). The oven was operated at a frequency of 2.45 GHz and a power of 600, 850 and 1000 W for 40, 30 and 20 min, respectively. Freeze drying was carried out in a freeze dryer (Thermo Fisher Scientific, Supermodulyo-230, Waltham, MA) with vacuum pressure for 24 h. Prior to use the freeze dryer, the wet-gel silica cake was freeze in the freezer at -20°C for 24 h. The prepared silica support obtained from various drying techniques were characterized by means of Brunauer, Emmett and Teller (BET) and BJH N<sub>2</sub>-sorption (Quantachrome Instruments, Autosorb-1C, Boynton Beach, FL) and Scanning electron microscopy (SEM) (FEI, Quanta 450, Hillsboro, OR).

## **3. Results and discussion**

The results of textural properties (BET specific surface area, average pore diameter and cumulative pore volume) of silica supports prepared by various drying techniques were summarized in Table 1. It was clearly noticed that the largest BET specific surface area was obtained for dried silica support by using freeze dryer. Whereas, silica supports, dried by using hot air and microwave dryer, were relative lower BET surface area. In addition, the average pore diameter and cumulative pore volume for freeze dried silica support were much greater than those of hot air and microwave dried silica support.

**Table 1. Textural properties for silica supported dried by using microwave, hot air and freeze drying**

Sample	Surface area <sup>a</sup> (m <sup>2</sup> g <sup>-1</sup> )	Pore diameter (nm)		Pore volume (cm <sup>3</sup> g <sup>-1</sup> )
		Mesoporous <sup>b</sup>	Macroporous <sup>c</sup>	
<b>HA80</b>	376	13.1	~400	1.23
<b>HA100</b>	401	12.6	~250	1.24
<b>HA120</b>	406	12.4	~150	1.28
<b>MW600</b>	414	12.6	~150	1.30
<b>MW850</b>	390	13.3	~350	1.30
<b>MW1000</b>	413	12.5	~250	1.30
<b>FD</b>	700	17.0	171.6, 500<	2.18, 4.05

<sup>a</sup> Specific surface area calculated by BET method.

<sup>b</sup> Pore diameter (mesopore) measured by BJH desorption method.

<sup>c</sup> Pore diameter (macropore) estimated from SEM.

The N<sub>2</sub>-sorption isotherm results for silica supports dried by using MW, HA and FD were given in Fig.1. It was found that HA and MW dried silica sample showed similar isotherm although differences in surface area, pore volume and pore size were observed. These isotherms exhibited hysteresis loop which correspond to the type IV isotherms at high relative pressure range of 0.75-0.9. It was due to the capillary condensation of N<sub>2</sub> gas occurring in the mesopores. Therefore, the type IV isotherm was considered as the characteristic of mesoporous materials [2,11]. In addition, it was clearly noticed that the isotherm for freeze dried silica support exhibited significant difference hysteresis loop, which corresponded to the composite isotherm type IV-II. The sharp increase of N<sub>2</sub>, at relative pressure range of 0.8 to above 0.9, indicated the presence of large meso-macropores or interparticle adsorption and condensation [3,12].

Pore size distribution of silica supports dried by using various drying methods were presented in Fig.2. It was found that the pore size distribution for silica supports corresponded to the results of pore size of silica listed in Table 1. It can be seen that hot air and microwave dried silica supports also showed similar and uniform pore size distribution with mesopores diameter of around 12 nm. While freeze dried silica support showed broader pore size distribution with mesopores diameter of 17 nm and clearly showed macropores diameter of 171.6 nm. The SEM image for silica support obtained by different drying techniques were

presented in Fig.3. It was clearly observed that the texture of HA dried silica support are closely packed particles when drying temperature increased from 80 to 120°C. It was due to the water molecules were constantly eliminated during the drying process. It led to the increasing of sol concentration, increasing in the capillary force and also created fluid drag which caused the particles to come closer to each other and forms aggregate to achieve greater stability [2,6,13]. In comparison with MW drying found that, the MW dried silica support had the higher porous of structure with larger pore size and pore volume. This could be due to fusion of some of the smaller particles during microwave drying [10]. The freeze dried silica support exhibited the lossely packed, highly porous and sponge-like particles with the macropore of interparticle voids. In the FD process, the effect of capillary force was avoided due to it involves solid-gas transition. The volume expansion occurred during the liquid water transformation to solid in the freezing process also could contribute to the loose packing [13]. In addition, the macropore diameter estimated by SEM images (Fig.3) for all of silica samples listed in Table 1.

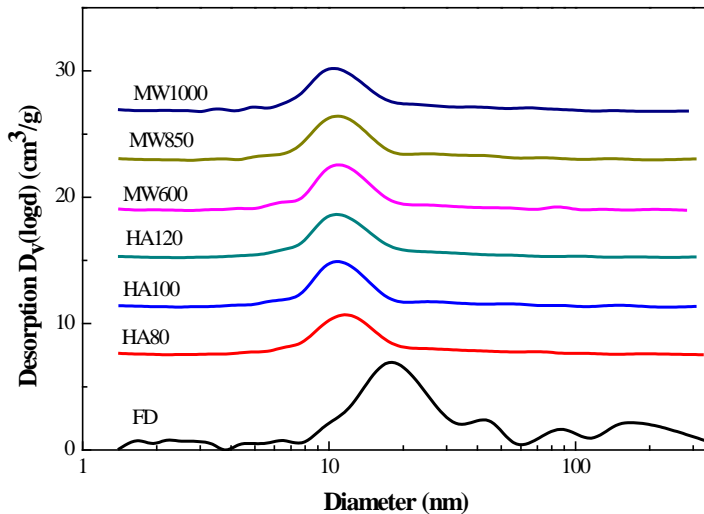

Fig. 1 *N*<sub>2</sub>-sorption isotherm for silica supports dried by using microwave, hot air and freeze drying.

*Fig. 2 Pore size distribution for silica supports dried by using microwave, hot air and freeze drying.*

#### **4. Conclusion**

The bimodal meso-macropore structure of silica supports were successfully prepared by sol-gel method using sodium silicate as a silica source and chitosan as a template. The textural properties of the prepared silica supports obtained from various drying techniques were investigated comprehensively. The freeze drying technique led to the highest surface area, largest pore size and pore volume of silica support among the hot air and microwave drying techniques. In addition, the application of the prepared bimodal porous silica support in catalysis field is based on kind of reaction, that should be further studied.

### ***Abstract***

*Swedish Exergy AB commercialised superheated steam drying technology – an invention from Chalmers University of Technology. New application for drying and valorisation of DWGS has been successfully developed and deployed at one of the sites in Europe. The technology has been adapted to this application. Key development includes novel and innovative concept of back-mixing in pressurised loop.*

***Keywords:*** Super-heated steam drying; PSSD, DWGS, DDGS, Back-mixing.

---

## **1. Introduction**

Pressurised Super-heated steam drying (PSSD) technology was re-invented by Claes Svensson Münter at Chalmers University of Technology, Gothenburg, Sweden. This novel and innovative technology found commercial application from research laboratory. In 1979, first full scale commercial plant was built and commissioned for drying of CTMP at a small paper mill in Sweden. Many other premier institutions have done research work on use of steam for drying and modification of product properties. TNO in Holland has done notable work on modification of product properties using steam at different pressures and conditions. NUS under leadership of Dr Mujumdar [1] has done extensive research work in the field of superheated steam drying and product quality modifications. All the research shows tremendous benefits for the technology. With net heat consumption 150 kWh/ton water evaporation; PSSD is world's most energy efficient drying process. Swedish Exergy AB since inception has been working on commercializing this technology with mixed success. High capital expenditure is biggest hinder. However, Swedish Exergy has successfully applied PSSD in one of the most difficult applications. Purpose of this paper to present this application and highlight results achieved.

## **2. Materials and Methods**

### **2.1. Application Industry and Process Description**

The application industry is grain based distillery plant. Process of ethanol from grain based distillery is briefly described below.

Grain from storage silos is milled either as dry milling or wet milling. Fig.1 shows process with wet milling. Slurry after wet milling is cooked in jet cookers before fermentation process. Sugar are converted into alcohol in fermentation and separated in distillation process. Remains from bottom of distillation process containing solids rich in protein is de-cantered. Separated solids are mixed with thin phase concentrated in an evaporator plant. This mix (DWGS) with 75% moisture content is dried in PSSD. Heat energy to PSSD is supplied from high pressure steam, thermal oil, natural gas or bio-gas. For every ton evaporated water, 750 kW thermal energy is put into the PSSD indirectly. Out of this 600 kW is recovered as low pressure (2-4 barg) steam and used for jet cooking, distillation and evaporation. Dried product (DDGS) with 10% moisture content is cooled after the dryer and sold as animal feed.

**Fig. 1: Grain based distillery integrated with PSSD.**

PSSD technology is closed loop system consisting of a circulation fan, heat exchanger, drying conduits, cyclone, feeding rotary valve and discharge rotary valve. Drying media is kept in closed loop circulation and drying energy is added indirectly through the heat exchanger. We product is fed through feeding rotary valve to the closed loop system. Drying takes place in drying conduits in very short time of less than 10 seconds. Product is separated in a cyclone from circulating drying media and discharged through bottom of the cyclone via discharge rotary valve. Separated drying media is circulated back to the heat exchanger for addition of drying energy. The process continues in this manner. As more and more moisture is evaporated in the closed loop, pressure increases inside the closed loop. Some of the evaporated moisture is bled-off through a control valve keeping constant pressure inside the closed loop. See fig. 2 for PSSD components.

Sticky and pasty material is handled in the dryer by back-mixing system. Fig 3 is picture of commercial plant installed in an ethanol plant in Italy.

*Superheated Steam Dryer application for drying of sticky and pastry materials – particular referents to distillers wet grain and soluble (DWGS)*

**Fig. 2: Schematic of PSSD used for DDGS production**

**Fig. 3: Picture of PSSD commercial plant**

## 2.2. Process Integration and energy efficiency

PSSD energy recovery potential makes it best candidate to integrate with other processes in the distillery. Steam generated from DWGS moisture is used for jet-cooking, distillation and evaporation processes in the plant. A typical energy and mass balance for a 10 ton/h DWGS plant is shown in table 1.

*Table 1: Heat and Mass Balance for 10 ton/h DWGS plant*

Media	Input to PSSD			
	Pressure, MPa	Temperature, °C	Mass, kg/h	Heat, kW
DWGS – 75% moisture	-	70	10 000	685
Net heat input	-	-	-	4 911
Heat from electricity used for rotating machinery	-	-	-	150
<b>Total</b>	-	-	10 000	5 746
Output from PSSD				
DDGS – 10% moisture content	-	100	2 777	136
Steam generated in the dryer and recovered as low pressure steam	0,3	145	7 000	5 341
Flash off and leakages	0	100	223	169
Thermal losses	-	-	-	100
<b>Total</b>	-	-	10 000	5 746

## 2.3. Product Quality Improvements

### 2.3.1. Sterilization

Closed loop PSSD works as continuous autoclave and product is 100% sterilized at the end of the PSSD process. Live tests with salmonella has been done to demonstrate this. This means product can be sold with guarantees which means higher value product.

### 2.3.2. Protein digestibility and by-pass protein

Product when used as animal feed for animals with multiple stomachs like cows, DDSG produced with PSSD process offers additional product quality benefits of improved protein digestibility and by-pass protein [2]. Product gets cooked during drying process.

### 2.3.3. No oxidation

Closed loop PSSD does not allow ingress of atmospheric air inside the PSSD which provides oxygen free process medium ensuring that product is not oxidized. O<sub>2</sub> measurements conducted using sensitive O<sub>2</sub> measuring probes have confirmed oxygen free media inside the PSSD. Product maintains excellent uniform color and texture. See product picture shown in fig 4.

*Fig. 4: Picture of DDGS produced from PSSD process*

#### **2.4. Novel and innovative back mixing system**

Swedish Exergy has developed and implemented at commercial stage a novel and innovative back mixing system operating at same pressure as PSSD operating pressure (fig 5.0). This unique back-mixing method offers many benefits over traditional back-mixing methods.

1. Very short mixing time.
2. Excellent mix production
3. Smaller equipment
4. Very uniform product dryness

*Fig. 5: Picture of novel and innovative back-mixing system as part of PSSD process*

### 3. Conclusions

Commercialization of PSSD has been a challenge and still is. Swedish Exergy has successfully commercialized PSSD for production of animal feed from waste stream in ethanol production process. Valorization of waste streams or by-products is big focus for the industry. PSSD has big potential to help industry to valorize the waste and by-products.

Example illustrated in this paper is concrete evidence. Other potential industries who can benefit from PSSD technology are breweries, food and feed industry, oil seeds industry etc.

### 4. Nomenclature

CTMP	Chemical Thermo Mechanical Pulp
SHSD	Super-heated steam drying
DWGS	Distiller Wet Grain and soluble
DDGS	Distillers Dry Grain and Soluble
PSSD	Pressurised Super-heated steam dryer

### **Abstract**

*The Municipal Solid Waste of Agareb (Sfax –Tunisia), characterized by high organic fraction and moisture contents is the most worrying pollution source that must be managed by innovative treatment and recycling technologies. Bio-drying, as a waste to energy conversion technology, aims at reducing moisture content of this organic matter. This concept, similar to composting, is accomplished by using the heat generated from the microbial degradation of the waste matrix, while forced aeration is used. The purpose of this work was to reduce the moisture content of the waste, by maximizing drying and minimizing organic matter biodegradation, in order to produce a solid recovered fuel with high calorific value.*

**Keywords:** *Municipal solid wastes; organic matter; biodrying; composting; energy recovery.*

---

## **1. Introduction**

The accumulation of municipal solid waste (MSW) is a matter of concern for the developing countries in the present time. The rapid urbanization followed by the industrial development and construction activities is supposed to be the major reason for MSW accumulation [1]. Waste to energy (WTE) technology has the potential to reduce the volume of the original waste by 90%, depending on the composition by recovering the energy [2, 3]. But the net energy yield from waste to energy conversion processes depend upon the density, composition and relative percentage of moisture of the waste [4]. Here comes the importance of biodrying process for the treatment of municipal solid waste with high moisture content. The biodrying process can be promising for treating mixed municipal solid waste containing large proportion of organic compounds, since high moisture content of the organic materials will increase the wetness of the entire MSW matrix. Biodrying is a suitable method to treat very humid waste, which would release high quantity of leachate if waste is directly burned without any pre-treatment [5].

Biodrying is an aerobic convective evaporation process which reduces the moisture content of the waste, with minimum aerobic degradation. The major difference of biodrying from composting is that the major objective is not to maximise the degradation process of organic material, but only to degrade the waste enough to generate biological heat to dry the waste [6]. The biodrying process is distinct from composting in that the output of composting process is stabilized organic matter, but the output of biodrying is only partially stabilized. Also biodrying process is of short duration one and hence the emission factors are also short lasting. Process of biodrying utilizes the auto thermal heat generation due to microbial action on waste material instead of thermal treatments in conventional drying process. Hence this is an energy saving process when compared to drying since it effectively utilizes the biological heat energy [7, 8].

Biodrying reactor aims to pre-treat the waste at the lowest possible detention time in order to produce a high quality refuse derived fuel (RDF). Biodrying process increases the energy content of solid waste by maximising removal of moisture present in the waste matrix and preserving most of the gross calorific value of the organic chemical compounds through minimal biodegradation [9]. The solid derived fuel from biodrying process is the best renewable fuel [9, 10, 11, 12, 13]. The strategy based on temperature feedback control will be more promising for biodrying technology and the issue of homogeneity of the output of the biodrying process is a subject need to be improved and hence to be investigated in future ([14]. In biological stabilization processes the temperature parameter is more qualitative than quantitative [15]. The biodrying process is critical for control of physical and mechanical properties [6].

In Tunisia, environmental preoccupations are among the priorities of the Government. Since 1990, Tunisia has triggered an environmental assessment process targeting the definition and implementation of a proactive national strategy and safeguarding the environment. This strategy dealing with the environment preservation was established and strengthened with the implementation of sustainable development. The municipal solid waste (MSW) management, an important task to protect human health, the environment and to preserve national resources was taken into account by the Government. Indeed, the Tunisian Government allocates a huge budget for MSW management and treatment. According to National Agency of Solid Waste Management (ANGed), 2.2 M of tons of household waste are annually generated (0.5 kg/inhabitant/day). These wastes are dumped in the landfills (9 in the country). Such strategy is cost and inefficient solution considering the large dumping land needed and the loss of available resources (68% organic matter in MSW) that could be recycled based on circular economy. Consequently, the ANGed started implementing a strategy where recycled waste is reconsidered, allowing waste reduction and incomes. Also, to boost the waste reduction and the materials recycling, political programs were set in the five-year program of the development plan (2016-2020). Moreover, the Ministry of Environment and Sustainable Development was engaged to improve the solid waste valorization all over the country, based on a partnership between public and private sectors. The Government announced its investment for waste valorization by giving financial support to encourage such strategy, reducing the landfilling of biodegradable waste. The recovery of MSW will reduce greenhouse gas emissions and increases the use of renewable fuels in energy production.

The objective of this work was to conceive a laboratory prototype for the treatment and the recovery of the organic fraction from MSW by an innovative bio-drying process, in order to produce a solid fuel recycling (CSR). In this new bio-drying technology, the exothermic reactions were recycled for the evaporation of the highest part of the waste humidity, with the lowest bioconversion of organic carbon to produce a dry high-calorific fraction. This is usually shredded and can be used either in densified or bulk form as fuel in industrial boilers or in furnaces such as those in the cement plant.

## **2. Materials and Methods**

### **2.1. Raw material**

The studied waste was collected from the municipality of Agareb (region situated at 20 km in the West of Sfax city (Tunisia). After removing glass and metal debris from this municipal solid waste the organic fraction and the moisture content were 59% (w/w, in wet weight) and 70% of total solids (w/w) respectively.

## **2.2. Experimental setup and operation**

The conceived prototype (figure 1) is a bed plexiglass reactor of internal dimensions (1 m x 0.5 m x 0.6 m) with a support made of a stainless steel grid to support a capacity of about 60 kg of solid waste.

The drying air is blown by a centrifugal fan of 0.75 kW power, controlled by a timer allowing the automatic operation fuction and shutdown of the system in order to maintain a defined air flow rate. The air flow crosses upward the waste from the bottom, activating the biological reactions and goes out of the biological reactor from the upper side. Finally, the process-air is discharged into the atmosphere after progressin through the bed. The experimental study evaluated and compared different tests according to the air flow rate and the stirring frequency, in order to choose the best working conditions.

*Fig.1 The prototype of bio-drying*

Each trial lasted approximately 10 days. After adequate waste mixing, the reactor was fed by 45 kg of the selected and homogeized MSW organic matter fraction, having a density of 450 kg/m<sup>3</sup>. The airflow was set at 0.7 m<sup>3</sup> per kg of wet waste per hour for the first test and 0.4 m<sup>3</sup> per kg of wet waste per hour for the second and third trials. The temperature was measured by thermometers set inside the bed reactor, at 5 points scanning all the bed. The ventilation was set on a mode working at a frequency ventilation of 10 min on/20 min off. The waste was manually agitated every 2 days for the first 2 tests (tests 1 & 2) and then

every 4 days for the last test (test 3). The waste was sampled every two days. The humidity rate and the organic matter degradation were determined gravimetrically after drying at 105 °C.

### **2.3. Sampling methods**

Waste samples were collected from the bed reactor for analysis 2 days during the biodrying process. The moisture content was determined as quickly as possible to limit evaporative losses. The organic matter, total organic carbon, kjeldahl nitrogen and metals are measured later in the laboratory. All these analyzes are carried out in duplicate. Leachte and condensate water were collected every day and analysed for volume, ph, total organic carbon (TOC) and ammonia concentration.

### **2.4. Analytical methods**

- The moisture content of solid samples was determined by gravimetric method.
- According to the standard (JIS K0102.14.4, 1995), the same crucible used for dry matter determination is placed in a muffle furnace at 550°C for two hours for calcination. The residual mass is weighed and the organic matter and the ASH will be calculated.
- The nitrogen content was measured with Kjeldahl nitrogen analyser.
- The TOC concentration was measured by a total carbon/total nitrogen (TC/TN) analyser.
- In order to get an idea of the lower heating value (LHV), we have chosen to estimate this value by using the CHANNIWALA correlation [16], and which requires knowledge of the composition of the product in carbon, nitrogen and other compounds:

$$\text{LHV (MJ/kg)} = 0.3491 \text{ C} + 1.1783 \text{ H} + 0.1005 \text{ S} - 0.1034 \text{ O} - 0.0151 \text{ N} - 0.0211 \text{ ASH}$$

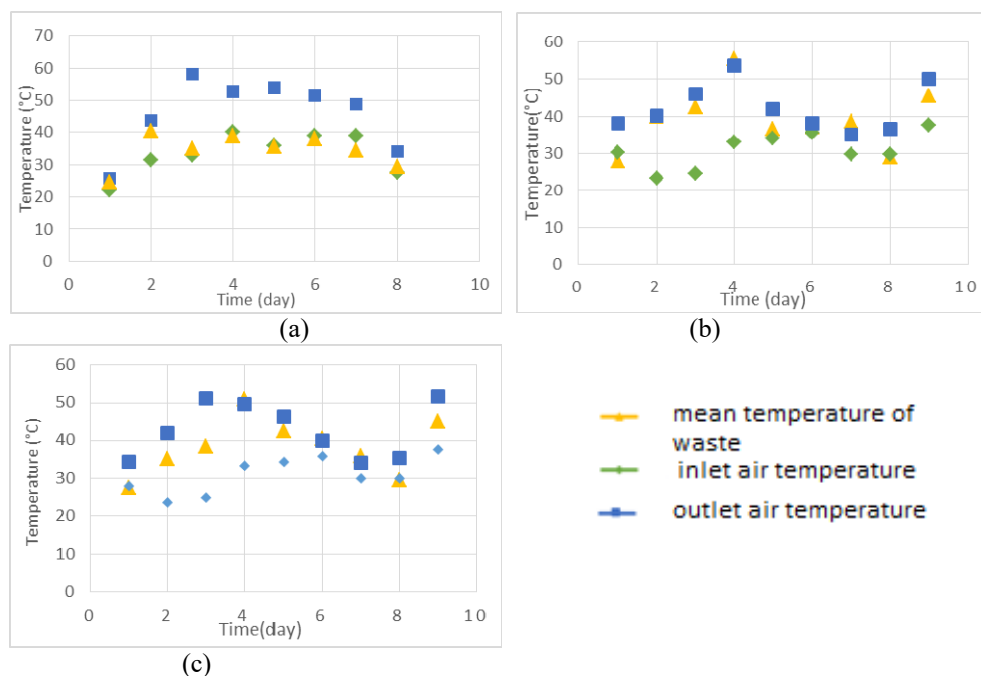

with C, H, O, N, S, ASH: product composition of carbon, hydrogen, oxygen, nitrogen, sulfur and ASH in %.

## **3. Results and discussion**

Three tests were carried out in this work: the first has an air flow of 0.7 m<sup>3</sup>/h kg<sub>MSW</sub> under a capacity of 46 kg of waste with a manual turning every 2 days. The second and third tests were carried out at a rate of 0.4 m<sup>3</sup>/h kg<sub>MSW</sub> under a 50 kg daily turning load every 2 and 4 days respectively for the second and the third test. The three tests were carried out at a ventilation frequency of 10 minutes “on” / 30 minutes “off”, that is to say, the fan runs for a period of 10 minutes and stops for 30 minutes before to start the cycle again.

### **3.1. Temperature evolution**

Figure 2 illustrate the evolution of the inlet and outlet air temperature as well as the mean temperature of waste for three tests.

**Fig.2 Temperature evolution versus time**  
*a (trial 1) - b (trial 2) – c (trial 3)*

For the first (Figure 2-a) test with the highest air flow rate ( $0.7 \text{ m}^3/\text{h kg}_{\text{MSW}}$ ), the waste temperature is practically equal to the temperature of Air at the inlet and does not exceed  $40^\circ\text{C}$ , the air is cooling the waste and the phenomenon of bio-drying didn't take place.

For the second (Figure 2-b) and the third test (Figure 2-c) the temperature changes are quite similar. At the end of the 4<sup>th</sup> day, the waste temperature reached  $51^\circ\text{C}$  and  $55.5^\circ\text{C}$  respectively in the 2nd and 3rd tests due to the fermentation of waste.

By comparing test 1 and test 2, we find that for an air flow equal to  $0.4 \text{ m}^3/\text{h kg}_{\text{MSW}}$  the waste temperature is quite similar to the outlet air during the first days of the experiment. From the 4<sup>th</sup> day The fermentation phenomenon is reduced and the temperature of waThese results show that the fermentation effect is more figured when using a low air flow rate.

### 3.2. Degradation of organic matter

Degradation of organic matter is well sought in the case of the composting process, but it has an undesirable effect in the bio-drying process. So we must minimize this degradation. Analyzes were carried out every 2 days to monitor the mass fractions of dry matter, organic matter and mineral matter (ASH content) of the solid waste in Figure 3 illustrates the evolution of degraded organic matter per kilogram of waste. The highest air flow gives the highest degradation of organic matter. Tests 2 and 3 have the same air flow rate but a

different frequency of agitation, the one having the high frequency, undergoes the slight degradation. These results are similar to other research (Zhao et al., 2011).

Fig. 3 The evolution of degraded organic matter versus time

#### 4. Conclusions

During the biodrying process, the temperature evolution showed an increase in the second and third trials, and reached 51.0°C and 55.5°C respectively in these experiments, because of the fermentation held. Consequently, the water content was reduced from 70% to 9.0 and 9.1% and 21.4 % (respectively for the three trials. A significant decrease in water was noticed during the 2 first-days, the water evaporation rate begins to decrease from the third day and that with low agitation frequency. The final product 'CSR' has the best water content compared to that of higher agitation. The assessed calorific value of the three trials were 17.1, 19.66 and 19.16 MJ/kg respectively for the three experimented air-flow rate and agitation frequency.

### Abstract

*The energy performance and carbon footprint associated with the fluidized bed drying of petals of *Echium amoenum* Fisch. and *C.A. Mey* are experimentally evaluated at three temperatures (40,50,60°C) and air velocities (0.50,0.75,1.00m/s). The maximum and minimum specific energy consumption are observed to occur at 40°C and 1ms<sup>-1</sup> (79.18MJ/kg) and 60°C and 0.5m/s (22.60MJ/kg), respectively. The greenhouse gas emission is in the range, 0.10-8.40kgCO<sub>2</sub>eq, varying with drying conditions in the same manner as energy consumption, with natural gas-fired systems performing better than oil-fired systems. High-temperature, low-air velocity drying is thus, favourable for energy-efficient and sustainable fluidized bed drying of the petals.*

**Keywords:** *fluidized bed dryer; greenhouse gas; specific energy consumption; Iran.*

## 1. Introduction

*Echium amoenum Fisch. and C.A. Mey* grows in a narrow region of northern Iran and the Caucasus [1]. Its dried violet-blue petals have medicinal (demulcent, anti-inflammatory, analgesic, sedative tonic, tranquillizing and diaphoretic) properties, and are useful as remedies for cough, sore throat and pneumonia [2, 3]. Hence, it is important for the drying of these petals to be energy-efficient and sustainable, while yielding high-quality products.

From ancient times, solar energy has been used to dry agricultural products. However, sun drying has several disadvantages such as poor food quality, insufficient control over the drying process, long drying times and contamination, all of which, could be avoided using industrial dryers [4]. The control of thermal treatment conditions is important during industrial drying of medicinal plants as the final product quality largely depends on the treatment conditions. In general, the drying temperature of medicinal plants should not exceed a certain level, to retain active compounds [5]. In this regard, drying in the fluid bed is attractive due to the homogeneous heat treatment of products, which allows better control of the conditions even at temperatures higher than those that cause thermal degradation of the product [6, 7].

Fluidization also has several other benefits such as increasing moisture uniformity, facilitating the use of higher drying temperatures and hence, increasing drying capacity, allowing for better mass and heat transfer, smaller-size dryer chambers, lower costs and higher-quality products [8].

As drying is an energy-intensive process, accounting for about 10-25% of the national industrial energy of the developed world [9, 10], it is very important that drying processes are energy-efficient. It is therefore not surprising that energy efficiency has over the years been a key driver of research and development in drying technology [10]. Preserving limited fossil fuels, reducing carbon footprint to combat climate change and improving the economics of drying-related processes are clear motivations for reducing energy consumption in drying [11]. The first step in identifying opportunities to save energy in drying processes, is an in-depth analysis of energy use. The evaporation load to remove water from the product under different drying conditions indicates energy consumption [11].

Energy consumption affects global warming, which in turn, affects humans and ecosystems in different ways: rising temperatures, changes in rainfall and rainfall rates, changes in the rate of melting of snow and ice, rising sea levels, changes in the geographical population distribution and even the extinction of some animals and plants [12].

Actions aimed at reducing energy usage must therefore be taken urgently in all processing activities. For drying in particular, using renewable energy sources, optimizing every part of

the process and using control devices to detect and minimize GHG injection into the atmosphere are some of the possible actions.

Singh *et al.* [13] studied CO<sub>2</sub> production during potato slice drying. They compared the CO<sub>2</sub> emissions of the sun, fossil fuels (coal, diesel fuel, natural gas) and electricity. Results showed that replacing coal with solar energy significantly reduced carbon emissions.

Kumar and Kandpal [14] analyzed the carbon emission potentials of drying various products using solar energy and other fuels in India. It was reported that increasing the proportion of solar energy, relative to the other fuels (coal, natural gas, wood) during agricultural product drying could lead to significant reductions in carbon emissions.

Piacentini and Mujumdar [12] studied climate change due to the drying of agricultural products. Given the high energy-demand of the drying operation, the authors proposed the use of renewable sources, optimizing the drying process and adopting energy efficient practices to reduce GHG emissions.

Motevali and Tabatabaei [15] studied SO<sub>2</sub>, CO<sub>2</sub> and NO<sub>x</sub> emissions during the drying of dog-rose using hot-air, infrared, hybrid hot air-infrared, microwave, hot air-microwave, vacuum, and hybrid photovoltaic-thermal solar dryers. The results showed that GHG emissions increased with temperature and air velocity in the hot air dryer, and reduced when infrared and hybrid hot air-infrared energy are used instead of hot air. The GHG emissions of hybrid photovoltaic-thermal solar dryers were less than the emissions of the hot air dryer.

The literature review shows little research on the GHG emissions of dryers. The aim of this research is to explore the energy consumption and effects of different drying conditions on greenhouse gas emissions for petals of *Echium amoenum* Fisch. and *C.A. Mey.*

## 2. Materials and Methods

### 2.1. Experimental procedure and energy analysis

A laboratory-scale fluidized bed dryer (details can be found in [16]) constructed at the Department of Agricultural Machinery Engineering of Azadshahr University, Iran, was used to conduct the drying experiments. It consisted of an air-heating device, chamber, and control systems for air and temperature. The fluidized bed chamber, made of stainless steel with inside dimensions of 250 mm×250 mm×300 mm, is connected with a fan, a duct made of stainless steel to supply air, while the distributor plate, with thickness of 1 mm and holes of 3 mm in diameter, was tightly fixed to the bottom of the chamber. The fluidizing air is supplied by a 1.5-kW blower, while an anemometer is used to regulate the air velocity manually. The heating unit consists of three fin heaters each of 800 W power, using thermostat-type temperature controls in order to adjust the desired drying temperature.

Fig. 1 Fluidized bed dryer

The total energy consumed during the experimental drying operation was estimated from the sum of the thermal and mechanical energies. Equation (1) was used to calculate the thermal energy for different temperatures.

$$E_{th} = (A \cdot v \cdot \rho_a \cdot C_a \cdot \Delta T) \cdot t \tag{1}$$

where,  $A$ ,  $v$ ,  $\Delta T$ ,  $t$ ,  $\rho_a$  and  $C_a$  are the cross-sectional area of the distributor plate, the air flow rate, temperature difference between the dryer inlet and ambient air, drying time, density and specific heat capacity of the inlet air, respectively. The density and specific heat capacity of the air were respectively calculated [17] as:

$$\rho_a = \frac{353.049}{T_a} \tag{2}$$

$$C_a = 1.04841 - \frac{3.83719T}{10^4} + \frac{9.45378T^2}{10^7} - \frac{5.49031T^3}{10^{10}} + \frac{7.92981T^4}{10^{14}} \tag{3}$$

The mechanical energy used to move the air by the blower was determined by [18]:

$$E_{mec} = \Delta P v A t \tag{4}$$

where  $\Delta P = 0.5 f h v^2 \rho$ , with  $\Delta P$  as the pressure drop,  $h$ , product thickness, and  $f$ , the resistance to airflow.

Specific energy consumption SEC (kJ/kg) is the total energy required to remove 1kg of water from the product during the drying process and is expressed by the following equation.

$$SEC = \frac{E_{th} + E_{mec}}{m_w} \quad (5)$$

where,  $m_w$  is the mass of removed water from the product during the drying operation. It is obtained from equation (6).

$$m_w = \frac{W_0 (M_0 - M_f)}{100 - M_f} \quad (6)$$

where  $W_0$  is initial weight,  $M_0$  is initial moisture content and  $M_f$  is final moisture content.

## 2.2. GHG emissions

The main source of power in many dryers is electricity [15]. Hence, the GHG emissions from the driving power plant indicates the amount of energy consumed during the drying process. The conventional power generation system in Azadshahr city, courtesy of Neka Power Plant, is a combined-cycle and steam system, and this study analyzes GHG emissions of this power plant. The mean GHG emissions (CO<sub>2</sub>) from the Neka Power Plant (steam and combined-cycle) using primary fuels (natural gas and heavy oil) for generating 1 kW energy are shown in Table 1. As the fluidized bed dryer used in this experiment is driven by electricity from this power plant, the total CO<sub>2</sub> emissions due to the drying process is evaluated under the different power house/fuel type scenarios in Table 1. In each case, the total CO<sub>2</sub> emissions is the product of the conversion factor and the corresponding total energy consumption ( $E_{th}+E_{mech}$ ), in kWh, with allowances made for power plant, transmission line and distribution losses (a total of 16.45%).

*Table 1. CO<sub>2</sub> emissions and pollutants from power plant of Neka*

Power House Type	Fuel type	CO <sub>2</sub> Conversion Factor (g/kWh)
Combine-cycle	Natural Gas	450
	Gas oil	622
Steam	Natural Gas	63
	Heavy Oil	1025

## 3. Result and discussion

### 3.1. The effect of drying conditions on specific energy consumption

The specific energy consumption and the total energy required under the different conditions of fluidize bed drying *E. amoenum* petals are presented in Fig. 2. An analysis of the results shows that the minimum specific energy consumption of 22.56 MJ/Kg occurs at 60°C air temperature and 0.5 m/s air velocity, while the maximum specific energy consumption of

79.18 MJ/Kg occurs at 40°C air temperature and 1 m/s air velocity. This implies that, the maximum specific energy consumption is approximately 3.5 times the minimum specific energy consumption. The energy required for fluidized bed drying of *E. amoenum* petals is observed to decrease with temperature, and increase with air velocity. This is partly attributable to the reduction in drying time with increasing air temperature, Also, at any given temperature, the specific energy consumption and the total energy required were higher at higher fluidization velocity, because higher air velocity did not reduce the drying time considerably due to the fact that the moisture transfer inside the material was controlled by the diffusion process. Similar findings have also been reported by other researchers. A higher air velocity reduces the proportion of the input energy utilized by the dryer, thus, increasing the heat losses in the dryer exhausts. This implies increased energy consumption.

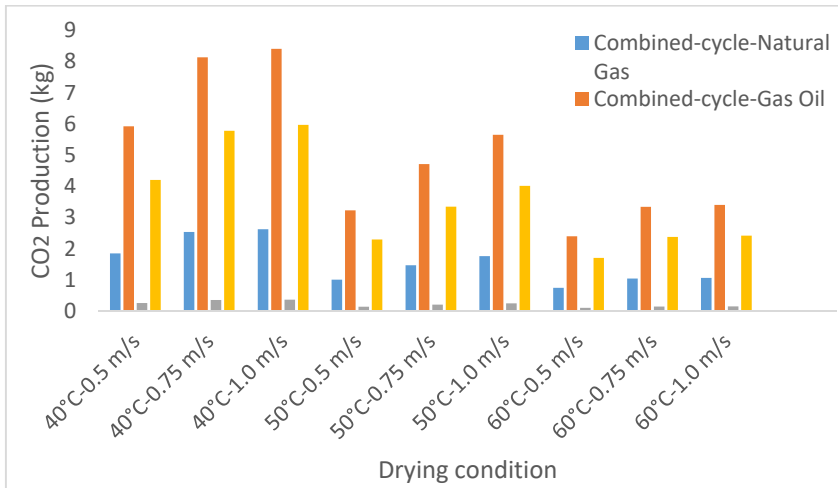

Fig. 2 The effects of different drying conditions on the specific energy consumption

### 3.2. The effects of drying conditions on CO<sub>2</sub> emissions

Fig. 3 shows the CO<sub>2</sub> emissions by the Neka Power Plant, which is a combined-cycle and steam plant, using different fuels for drying 1 kg of *E. amoenum* petals. This figure shows the variations in temperature and air velocity in a fluid bed dryer and the corresponding CO<sub>2</sub> emissions. Increasing the air flow leads to increased CO<sub>2</sub> emissions due to the corresponding increased energy consumption. The emissions however, decrease with temperature as a result of the corresponding drop in the energy consumption. The least CO<sub>2</sub> emissions occur at 60°C and 0.5m/s, while the maximum occurs at 40°C and 1m/s. As Fig. 2 shows, the maximum CO<sub>2</sub> production for all the studied drying conditions occurs for the combined-cycle-gas oil power plant, while the minimum occurs for the steam-natural gas plant. The maximum CO<sub>2</sub>

emissions recorded for the combined-cycle-gas oil power plant at 40°C and 1m/s was approximately 80.3 times, its level at the steam-natural gas plant at 60°C and 0.5m/s.

**Fig. 3** The effect of in temperature and air velocity variations in a fluid bed dryer on carbon emissions of power plants

#### 4. Conclusion

In this study, the effect of drying air velocity and temperature on energy consumption and greenhouse gas (CO<sub>2</sub>) emissions from a fluidized bed dryer was evaluated. From the results, the total energy consumption increased with air velocity for each drying temperature, and decreased with temperature for each air velocity. The GHG (CO<sub>2</sub>) emission levels also varied with drying air temperature and velocity in the same manner. The lowest carbon footprint occurs when the natural gas-fired steam plant is used, while the highest corresponds to the use of oil-fired combined-cycle power plant. High-temperature, low-air velocity drying is thus, advantageous for the fluidized bed drying of *Echium amoenum* Fisch. and *C.A. Mey* petals, from a sustainability viewpoint.

### **Abstract**

*While anaerobic digestion is a reliable method that treats the waste and produces renewable biomethane fuel, the necessary sludge in liquid form is difficult to handle due to the constant biogas generation. Therefore, this study investigates the possibility of convective air drying, namely heat pump and hot air circulation oven as preservation methods for anaerobic microbial sludge. Drying was conducted at various temperatures, ranging from 22°C to 70°C. The study found that heat pump drying at 22°C resulted in highest COD removal of 55.3% as well as the least log reduction in methanogens and anaerobes at 1.4 and 2.4, respectively.*

**Keywords:** *Chemical Oxygen Demand (COD); Heat pump drying; Hot air drying; Log reduction; Methane yield*

## 1. Introduction

Palm oil mill effluent (POME) is liquid waste containing oil, plant debris, and nutrients produced from palm oil milling process. In Malaysia, the most widely used effluent treatment scheme is the anaerobic/facultative ponds. Anaerobic digestion is the decomposition of organic material whereby the end products are biogas and sludge. This process is desirable due to low costs and low energy demand involved besides producing a biologically stable final product with good fertilizing properties as well high nutrient content. However, Difficulty in supplying the solid-liquid mixture of microbial seed sludge for anaerobic treatment of POME has raised several issues that must be overcome in order to promote the practicality of this treatment option. Main concerns include limitations in storage and transportation due to constant biogas generation from the anaerobic digestion<sup>[1]</sup>. Drying of the seed sludge allows easier storage of additional sludge as the mass and volume are greatly reduced due to majority of water content evaporated<sup>[2]</sup>. In addition to space conservation, the dried product can be more easily transported in its inactive form, where biodegradation and biogas production is halted in its dormant form which prevents fire hazard and risk of over-pressurisation<sup>[3]</sup>. There have been many studies conducted for the preservation of microorganisms. Numerous studies have shown that high cell viability of pure cultures can be achieved using freeze drying technique<sup>[4]</sup>. Despite its wide applicability, this method is cost intensive and requires long drying time which could be harmful to several delicate microorganisms<sup>[5]</sup>. Thus, relatively inexpensive convective air drying has been considered as promising alternative to address problems encountered in freeze drying.

To date, research on the application of convective air drying for microorganism preservation, or more specifically for mixed culture preservation, is rather scarce and largely limited to agricultural and dairy industry. Hence, this study aims to develop dried mesophilic mixed culture from economical convective air drying methods, namely heat pump and hot air circulation oven. Various drying conditions were also investigated to achieve the highest possible cell survival, methane yield, and treatment performance during treatment of POME.

## 2. Materials and Methods

### 2.1 Sample preparation

Seed sludge and palm oil mill effluent (POME) were obtained from the palm oil mill at Seri Ulu Langat in Dengkil, Malaysia. During cultivation, intermittent feeding of POME as substrate was done in order to maintain the microbial population in the seed sludge.

## 2.2 Cultivation of mixed culture in UASB batch reactor

An up-flow anaerobic sludge blanket (UASB) reactor with an effective volume of 2.5 L as shown in Fig.1 (separate attachment) was used to cultivate mesophilic sludge. To start-up, 625 mL of seed sludge which represents 25% of the working volume is fed to the tank, while the remaining 75% consists of diluted POME. pH of the system was maintained in the range of 6.8-7.2 through the addition of 2 mol/L NaHCO<sub>3</sub> to ensure satisfactory methanogenic activity<sup>[6]</sup>. Treated effluent was collected by letting the mixture in the bioreactor to settle for 30 minutes. After which the top portion of the mixture was collected as supernatant and sent for qualitative and quantitative analysis. COD removal is used as criteria for increasing load in the feed to maintain the effectiveness of the system, especially when COD removal is higher than 80% or when there is less than 5% increase for 3 consecutive readings. The then matured mixed culture seed sludge was extracted from the batch reactor for drying procedure.

## 2.3 Drying methods

25 g of the mesophilic mixed culture sludge was extract from the bioreactor and used to perform drying experiment in three replicates. The sludge was dried until equilibrium moisture content (EMC) by using different drying methods as described in the following sections.

### 2.2.1 Heat pump drying

A laboratory scale heat pump dryer fabricated by I-Lab Sdn. Bhd., Selangor, Malaysia was used in this research. The heat pump dryer consists of a drying chamber of dimensions 0.8 m × 0.6 m × 0.6 m and a heat pump system. Mild temperature dehumidifier air produced by the heat pump system was used as a drying medium to dry the sludge in the chamber. The dryer operated at temperature of 22°C and relative humidity (RH) of 38.1%. In addition, the dryer is equipped with an auxiliary heater which can be switched on to give drying temperature of 32°C and RH of 29.5%. The average air velocity in the drying chamber was recorded at 2 m/s across the two drying conditions.

### 2.2.2 Hot air circulation oven drying

Hot air circulation oven (Memmert UFB500) was used to conduct drying of sludge at average temperature and relative humidity of 40.0°C, 50.0°C, 60.0°C, 70.0°C and 19.9%, 16.1%, 7.4%, 4.7%, respectively. The drying chamber has a dimension of 53 cm × 47 cm × 39 cm where air is circulated by an air turbine with measured average velocity of 1.9 m/s for all drying temperatures.

## 2.4 Drying rate and moisture diffusivity

The initial moisture content ( $M_0$ ), moisture content at a given drying time  $t$  ( $M_t$ ), equilibrium moisture content ( $M_{eq}$ ), moisture ratio ( $MR_t$ ) and drying rate ( $R$ ) of the mesophilic mixed culture sludge were calculated by equations (1) – (5) whereas the moisture diffusivity ( $D_{eff}$ ) of the samples was determined using Fick's second model (equation (6)).

$$M_0 = \frac{W_0 - W_d}{W_d} \quad (1); \quad M_t = \frac{W_t - W_d}{W_d} \quad (2); \quad M_{eq} = \frac{W_{eq} - W_d}{W_d} \quad (3); \quad MR_t = \frac{M_t - M_{eq}}{M_0 - M_{eq}} \quad (4)$$

$$R = \frac{W_d}{A_s} \left| \frac{F_{t+1} - F_t}{t_{i+1} - t_i} \right| \quad (5); \quad MR = \frac{8}{\pi^2} \left[ \sum_{n=0}^{99} \frac{1}{(2n+1)^2} \exp\left(\frac{-(2n+1)^2 \pi^2 D_{eff} t}{l^2}\right) \right] \quad (6)$$

Where  $W_0$ ,  $W_t$ ,  $W_d$ , and  $W_{eq}$ , refer to initial weight of the sample (kg), weight of the sample in the middle of drying process at time  $t$  (kg), bone dry weight of the sample (kg), and equilibrium weight of the sample (kg), respectively.  $A_s$  is denoted as the surface area of the samples ( $m^2$ ),  $F_t$  is the free moisture content of the sample at time  $t$  (kg  $H_2O$  / kg dry material).  $l$ ,  $t$  and  $n$  are the sample's thickness (m), drying time (s) and a positive integer, respectively.

## 2.5 Quality analysis

The quality of dried mixed culture mesophilic sludge was evaluated by assessing the viability of microorganisms after drying. To do that, the dried mixed culture was first rehydrated before it can be evaluated for cell survival, COD removal, and methane yield.

### 2.5.1 Rehydration of mixed culture

Rehydration was performed by adding distilled water in the amount equivalent to that lost during drying process and agitated in incubator shaker at 37°C and 250 rpm for 18 hours. The resultant rehydrated mixed cultures were then evaluated for cell survival by obtaining the most probable number (MPN) of microorganisms contained in the sample. The rehydrated sludge was also evaluated for its performance in treating POME through assessment of the COD removal and methane yield.

### 2.5.2 Cell survival

MPN enumeration was conducted to obtain the cell count of microorganisms following drying process. Culture medium was prepared by dissolving 30 grams of tryptic soy broth (TSB) in 1 L of distilled water. Next, serial dilutions of seed sludge were prepared by adding 1 mL of sample into 9 mL of sterile distilled water until a  $10^{12}$  times dilution is

obtained. Subsequently, 1 mL from each dilution number was then inoculated into vials containing TSB. This was done in triplicates for each dilution to enable comparison with 3-tubes most probable number (MPN) table. The vials were then incubated under anaerobic condition for 8 days at 55°C. To obtain the MPN of total anaerobes, each vial was first determined to be either positive if the mixture was cloudy or negative if the mixture was clear after incubation. The combination of positive and negative tubes was then compared against MPN table to obtain a corresponding MPN value<sup>[7]</sup>. In contrast, MPN for methanogens was obtained by detecting the presence of methane using biogas analyser (Binder Combimass Ga-m). Vials were marked as positive if methane is detected and negative otherwise. The combination of positive and negative tubes was compared against the same table as for total anaerobes. The cell survival of microbes was subsequently determined by equation (7).

$$\text{Log Reduction} = \log\left(\frac{\text{MPN}_{\text{before drying}}}{\text{MPN}_{\text{after drying}}}\right) \quad (7)$$

### 2.5.3 COD removal

A 250 mL Schott Duran Bottle was set-up as bioreactor where 50 mL of rehydrated mixed culture was used to treat 150 mL of POME after pH adjustment by adding 1 mol/L sodium bicarbonate. Supernatant was collected regularly for a period of 12 days from the bioreactor after allowing 30 minutes settling time. It was then analysed for COD level by following HACH Method 8000 which is USEPA approved for wastewater analyses (Standard Method 5220 D). The COD removal of the rehydrated sample was calculated using Equation (8).

$$\text{COD Removal} = \frac{(\text{COD}_{\text{initial}} - \text{COD}_{\text{final}})}{\text{COD}_{\text{initial}}} \times 100\% \quad (8)$$

### 2.5.4 Methane yield

Daily monitoring of bioreactor was conducted over 12 days period to obtain both biogas volume (mL) and methane composition (%). Biogas volume was measured by capturing the produced gas in an inverted measuring cylinder while its composition was obtained using biogas analyser Binder COMBIMASS® Ga-m.

## 3. Results and Discussion

### 3.1 Drying rate, effective moisture diffusivity, total drying time and EMC

Tables 1 shows that low temperature drying using heat pump took longer time compared to high temperature drying using hot air circulation oven drying as heat pump was operated at drying temperature that is equal to- or below ambient temperature and thus relies on low relative humidity as the main driving force. Generally, higher temperature of drying air enables greater transfer of heat from air to water molecules in the mixed culture. This gives

rise to higher rate of evaporation (i.e. drying rate) and hence shorter total drying time required for the sludge to achieve EMC. Air at higher temperature also has greater capacity to hold moisture and thus hotter air is able to remove more water molecules than colder air of the same flow rate. In terms of effective moisture diffusivity, the values of  $D_{\text{eff}}$  increased notably with increasing drying temperatures for both heat pump drying and hot air circulation oven drying. Lower relative humidity at high drying temperature promoted moisture concentration gradient between the surface of drying sample and its inner interstices, which stimulates the moisture diffusion from the interior of the sample to the surface and thus produced dried sludge with low EMC. Nevertheless, better survival of microorganism is achieved by drying at low temperature and relatively short drying time due to minimisation of heat and osmotic stresses<sup>[8]</sup>. Therefore, it is important to weigh over the importance of achieving high cell survivability over short drying time resulted from elevated drying temperature. Moreover, the performance of mixed culture in treating POME after subjected to drying process must also be considered.

*Table 1. Average drying rate, effective moisture diffusivity, total drying time and EMC of heat pump and hot air circulation oven dried mesophilic mixed culture*

Drying Method	Average Drying Rate (R) (g H <sub>2</sub> O / m <sup>2</sup> .s)	Average Effective Diffusivity ( $D_{\text{eff}}$ ) ( $\times 10^{-8} \text{m}^2 \text{s}^{-1}$ )	Total Drying Time (h)	EMC (g H <sub>2</sub> O/ g dry solid)
Heat pump (22°C)	4.67	0.85	26.6	0.148
Heat pump (32°C)	5.78	0.97	23.0	0.046
Oven (40°C)	8.57	3.39	7.5	0.034
Oven (50°C)	12.87	3.88	5.8	0.026
Oven (60°C)	19.41	4.25	4.5	0.017
Oven (70°C)	21.55	4.62	3.5	0.012

### 3.2 Cell survival, COD removal and methane yield

According to Table 2, the lowest log reduction for methanogens and anaerobes were obtained from 22°C-drying for heat pump drying with 1.4 & 2.4 and from 50°C for hot air circulation oven with 1.5 & 5.6, respectively. Generally, higher log reductions indicate that more cell deaths occur during the drying process. Higher cell survivability was found towards milder drying temperature was likely due to the nature of mesophilic mixed culture which thrives at 20-35°C combined with reduced thermal inactivation when drying was conducted at relatively lower temperatures<sup>[9]</sup>. As such, the mesophiles within mixed culture suffer from higher cell inactivation at higher temperature drying in a hot air circulation oven. As compared with mesophilic seed sludge, mesophilic mixed culture dried at the

various drying temperatures still gives comparable average COD removals in the range of 46.8% to 55.3%, with fairly similar trend with the preceding cell viability, where more favourable results were obtained with decreasing drying temperature. This is indicated in Table 3 where mixed culture dried at 22°C gave rise to higher COD removal as compared to other drying temperatures. In terms of methane yield, mesophilic mixed culture that was dried at 50°C in a hot air circulation oven produces highest yield at 37.6 mL CH<sub>4</sub>/g COD when compared with other drying temperatures. It is most likely that a balance between drying temperature and drying duration was reached at 50°C-drying, producing dried sludge with moisture content that favours the survival of methanogens, eventually resulting in second highest values for both N<sub>M</sub> (after HP 22°C) and N<sub>M</sub>/N<sub>A</sub> (after 60°C) as illustrated in Table 2. Optimum moisture content as well as drying time are both directly affected by drying temperature and could influence the cell viability in mixed culture after drying<sup>[4]</sup>.

**Table 2. Most probable number (MPN) and log reduction of mesophilic mixed culture following drying process**

Drying Technique	Most Probable Number (ml <sup>-1</sup> )			Log Reduction	
	Methano gens, N <sub>M</sub>	Anaerobes, N <sub>A</sub>	N <sub>M</sub> /N <sub>A</sub> (%)	Methanogens	Anaerobes
Mesophilic seed sludge	9.30·10 <sup>1</sup>	1.99·10 <sup>12</sup>	4.67·10 <sup>-9</sup>	n/a	n/a
Heat Pump (22°C)	0.36·10 <sup>1</sup>	7.50·10 <sup>9</sup>	4.80·10 <sup>-8</sup>	1.4	2.4
Heat Pump (32°C)	0.24·10 <sup>1</sup>	1.15·10 <sup>9</sup>	2.08·10 <sup>-7</sup>	1.6	3.2
Oven (40°C)	0.16·10 <sup>1</sup>	2.90·10 <sup>6</sup>	5.52·10 <sup>-5</sup>	1.8	5.8
Oven (50°C)	0.29·10 <sup>1</sup>	4.60·10 <sup>6</sup>	6.30·10 <sup>-5</sup>	1.5	5.6
Oven (60°C)	0.21·10 <sup>1</sup>	2.30·10 <sup>6</sup>	9.13·10 <sup>-5</sup>	1.6	5.9
Oven (70°C)	0.20·10 <sup>1</sup>	3.60·10 <sup>6</sup>	5.56·10 <sup>-5</sup>	1.7	5.7

**Table 3. COD removal and methane yield of mesophilic mixed culture before and after drying under heat pump and hot air circulation oven**

Drying Technique	COD Removal (%)	Methane Yield (mL CH <sub>4</sub> /g COD)
Mesophilic Seed Sludge	67.4 ± 9.8	44.1 ± 10.5
Heat Pump (22°C)	55.3 ± 8.9	17.9 ± 1.74
Heat Pump (32°C)	52.8 ± 5.6	14.1 ± 1.66
Oven (40°C)	52.9 ± 2.7	13.9 ± 1.55
Oven (50°C)	53.5 ± 3.4	37.6 ± 2.89
Oven (60°C)	50.2 ± 4.5	22.3 ± 3.61
Oven (70°C)	46.8 ± 7.0	37.2 ± 2.90

#### 4. Conclusion

Heat pump drying of mixed culture mesophilic sludge takes considerably longer time to reach EMC as compared to hot air circulation oven drying at elevated temperature. Nevertheless, in term of quality analysis, heat pump dried mesophilic mixed culture at mild temperature (22°C) gave rise to the best methanogenic survival, anaerobic survival, and COD removal among of all. The highest methane yield was produced by hot air circulation oven dried mesophilic mixed culture at 50°C. It might appear that either one of these two drying conditions could be considered as the most suitable drying condition for mixed culture mesophilic sludge depending on the desired outcome. However, hot air circulation oven drying at 50°C could be more practical in industrial setting as drying duration is shorter.

## 1. Introduction

Plastic films of petrochemical origin are currently used on a large scale in food packaging, and their use is contingent upon their mechanical and barrier properties. Although chemically stable, they are not biodegradable and cause environmental impact. One of the alternatives to this problem would be the development of edible and/or biodegradable films using raw materials from renewable sources.

The bioplastics industry is still in beginning, looking to identify and exploit market niches not only for the biodegradability, recycling and / or replacement of plastics of petrochemical origin by plastics from renewable sources, also concerned about the carbon cycle and sustainability. Bioplastics are defined as materials which, containing variable percentage biopolymers, can be molded by heat and pressure. They are potential alternatives to conventional thermoplastic polymers of petrochemical origin, such as polyolefins and polyesters<sup>[1]</sup>.

Starch is a polysaccharide of plant origin, widely found in the international market, capable of forming films both by the casting technique and by the thermoplastic extrusion process. Films made with starch can also introduce additives into the packaging, such as natural antioxidant and antimicrobial agents.

The Brazilian pepper (*Schinus terebinthifolius Raddi*) is originally from Peru and is widely distributed throughout the Americas, including the Northeast, Southeast, South and Midwest of Brazil<sup>[2]</sup>. The fruit has healing properties attributed to the different volatile compounds that are distributed in its various organs, such as bark, leaves, flowers, fruits and seeds<sup>[3]</sup>. It is used in the food industries, as well as its essential oil in the development of pharmaceuticals and cosmetics<sup>[4]</sup>. The species has increasing pharmacological use, and is considered by popular medicine as an anti-inflammatory, antimicrobial and strong antioxidant agent<sup>[4,5,6]</sup>.

The process of extrusion allows the thermoplastification of a solid material by the application of heat and mechanical work, being the main process to obtain the bioplastics. It is a highly versatile process in which the extruder can behave as a heat exchanger due to the thermal changes occurring between the material to be extruded and the equipment<sup>[7]</sup>.

In this context, the objective of this work was to produce, through the thermoplastic extrusion process followed by blowing, manioc starch-based flexible films added with Brazilian pepper oil as an antioxidant and plasticizer agent, and verify if the bioactive compounds contained in the fresh pepper oil are present after the drying step of the thermoplastic extrusion process to obtain the biodegradable film. In parallel, we analyzed

the mechanical properties of the films to verify the effect of the pepper oil concentration on tensile strength, elongation and elasticity of the films.

## **2. Materials and Methods**

Materials: manioc starch, glycerol and brazilian pepper essential oil.

The films were produced by thermoplastic extrusion following buy blowing in single screw extruder. The range of temperature was 90 to 130oC and the velocity 35 rpm, the same conditions proposed by Fakhouri [8]. Three formulations were produced: i) manioc starch with glycerol (25%), ii) manioc starch, glycerol (25%) and brazilian pepper essential oil (2%) and iii) manioc starch, glycerol (25%) and brazilian pepper essential oil (3%).

Chemical characterization by Gas Chromatography : The analyzes were performed using a gas chromatograph equipped with a mass spectrometer detector (GCMS-QP2010 Ultra, Shimadzu, Kyoto, Japan). employing a fused silica DB-5 capillary column (J & W, 5% de phenyl-dimethylpolysiloxane) with 30 m in length x 0.25 mm i.d., 0.25 µm film thickness, under the following conditions: carrier gas helium (99.999% and flow rate 1.0 mL min-1); 1 µL injection volume, split ratio (1:20), with initial oven temperature of 50°C and heating from 50° to 280°C at 3°C min-1. The injector temperature, transfer line and detector temperatures were 250°C. The MS scan parameters included electron impact ionization voltage at 70 eV, a mass range of 45 to 600 m/z and a scan interval of 0.3 s. Temperature-programmed retention indices were calculated using a mixture of alkanes (C8-C30) as external references and compared with Adams[9]. The identifications were completed by comparing the mass spectra obtained in the NIST21 and WILEY229 databases and literature data [8].

Total flavonoids quantification by Spectrophotometry: The flavonoids content was determined in the acetonic extracts of extruded *S. terebinthifolius* using the colorimetric method involving the reaction with aluminum chloride by Chang [10] with adaptations for extrudates. Extracts were prepared with 100 g of sample added in 500 mL of acetone (50% w/v), and they were kept under constant agitation (150 rpm) for five hours. The sample was filtered, and the filtrate was considered the flavonoid extract for analysis.

The extract was reacted with aluminum chloride and the readings were performed in a spectrophotometer (Biochrom – Libra S60) adjusted at 415 nm. Quercetin solutions at nine concentrations (0.01 to 0.2 µg.µL-1) were reacted with sodium aluminum chloride in order to construct a standard curve. The results were expressed as milligrams of quercetin equivalent (QE mg.100g-1 sample) using the quercetin standard curve.

Elastic modulus, tensile strength and elongation at rupture will be determined using a texturometer (Universal testing machine Galdabini SUN 2500, TA-HDi Texture Analyser (Stable Microsystem, Surrey, England), the conditions were performed by ASTM methods<sup>[11]</sup>.

### 3. Results and Discussion

After analysis by gas chromatography-mass spectrometry, fourteen volatile compounds were found in the essential oil of *S. terebinthifolius* (Table 1). Among these compounds, we highlight the iso-sylvestrene (34.12%),  $\alpha$ -thujene (17.13%), myrcene (8.25%),  $\alpha$ -phellandrene (6.68%),  $\beta$ -longipinene (5.90%) and sylvestrene (5.87%). After the thermoplastic extrusion process at temperatures ranging from 90 to 130°, 5 volatile compounds were identified, knowingly:  $\alpha$ -pinene, sabinene,  $\beta$ -pinene, limonene and  $\alpha$ -copaene.

<sup>a</sup>Retention index calculated; <sup>b</sup>Retention index literature. The values of gas chromatography are expressed in % and the total flavonoids are expressed in mg.100g of quercetin equivalent.

Higher concentrations of pepper oil influenced the mechanical properties of the films, causing a significant increase in the elongation of the films and decrease of the tensile strength and elasticity (Figure 1).

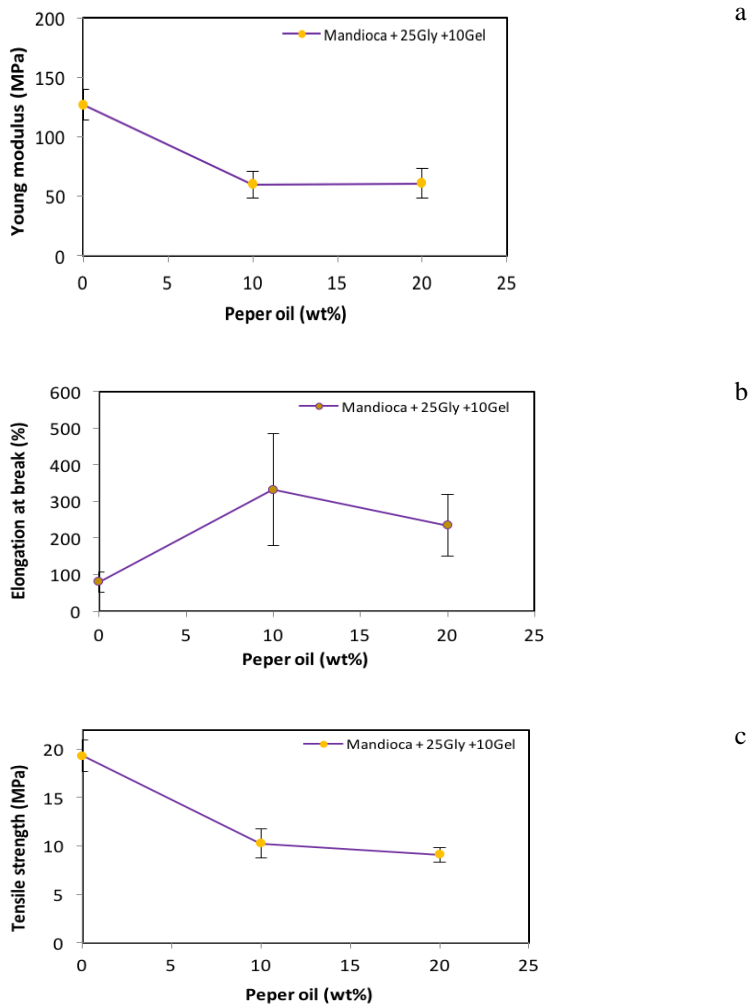

Figure 1. (a) Yong modulus (MPa), (b) Elogation at break (%) and (c) Tensile Strenght (MPa) of flexible films from starch and Brazilian pepper.

#### **4. Conclusions**

It was possible to obtain flexible films by manioc starch, glycerol and brazilian pepper essential oil by thermoplastic extrusion following buy blowing. After the thermoplastic extrusion process, five volatile compounds were identified, knowingly:  $\alpha$ -pinene, sabinene,  $\beta$ -pinene, limonene and  $\alpha$ -copaene in the flexible films. The brazilian pepper essential oil also influenced the mechanical properties of the films.

These results suggest that the temperatures used in the thermoplastic extrusion process, although high, kept some of the existing compounds in the Brazilian pepper essential oil adhered to the packages.

### **Abstract**

*We live in a world that usually use plastic bags either to go shopping or to pack the snack for a short trip. However, packaging makes life easier and serves as protection for products such as food. Bread is a common food product that needs packaging in order to be protected at storage and transportation. Therefore, with aim of reducing petroleum derived packaging consumption it was developed an edible film from potato starch to packaged bread and some quality characteristics like water content, firmness and weight loss were evaluated, showing that edible film can be used as a packaging*

**Keywords:** *biopolymers; edible coatings; packaging materials; starch; storage.*

---

## **1. Introduction**

Bread is the product obtained by the cooking dough at pan, showing elastic and homogeneous crumb, fine pores, thin and soft crust, produced from a mixture of flour, water, yeast and salt [n1]. This is a perishable product because of its high water activity so, its marketing period is short.

One of the shelf life limiting factors is the aging that occurs because of regress and favours to increase crumb firmness, giving a sensation of drying product by the ingestion [n2] this added to the necessary of decrease operational costs and expand the market let the bakers to require new technologies and the development of new methods of dough production [n3].

In this manner, the edible film technology has been implemented recently, there are applied indirectly to the product in the way of a thin layer that acts like a modified atmosphere, being a barrier for gas exchanges and loss of water vapor that can improve handling and the visual appearance of the protected food product [n4; n5].

On the other hand, the use of packaging to increase shelf life is not to recently, however several researches have studied the use of non-conventional packaging. Production of edible films from biopolymers is na alternative technology that has been highlighting because of its ability of increase the conservation time and allows higher handling and marketing flexibility of the product [n6]. Films can be obtained by different types of materials, being more used the polysaccharides, proteins and lipids [n5].

Starch is a polysaccharide that besides being the main source of carbohydrates for human nutrition, also has technological relevance for food, pharmaceutical, paper, textile, materials and oil drilling industries. According to the industry it can be used like a thickener, colloidal stabilizer, gelling agent, paste former and adhesive [n7]. Do to the above, its lower cost and high availability [n8], this polysaccharide stood out to be used at the productive chain. Starch can be obtained from plants and depending on each plant the reserves source of energy can be found in higher quantities at different regions of the plant like such as grains, roots, rhizomes, seeds and stems. The main commercial sources of this carbohydrate are corn, potato and cassava [n9].

In productive chain of bread the packaging is the last stage in which special care must be taken to guarantee longer shelf life. Success in Market depends on product intrinsic quality and packaging effectiveness to preserve and keep quality. Convectional procedure to packaging applied in bakery industry use atmospheric air and coverage materials approved for food. Several researches shown the effectiveness of the packing keeping bread quality characteristics, delaying loss of water content and fungi growth [n10, n 11].

## 2. Materials and Methods

### 2.1. Elaboration of filmogenic solution

To produce edible coatings was used methodology proposed by Fakhouri [n12]. Macromolecule used was commercial potato starch (3% for 100 mL of distilled water). The starch and water were deposited in glass beakers and homogenized. This solution was brought to the thermostatic bath (Quimis, Q334 M-14, SP, Brazil) heated to 80 ° C. After obtaining the filmogenic solution of potato starch the glycerol is added in a gentle manner to avoid blistering in sample. The film-forming solution was dispersed in petri dishes and dried in an air circulating oven (45 °C) for 6 hours. After drying, films were utilization for packing bread in sealing machine, and stored at room temperature by 3 days.

*Fig. 1 Production and application of edible packaging of starch potato*

It was used small breads (Bisnaguito, Pullman), with weight  $\cong$  23 g for unit, obtained local commerce from Campinas city, Brazil. Ingredients contained in small breads: wheat flour fortified with iron and folic acid, sugar, sunflower oil, invert sugar, salt, fatty acid monoglyceride emulsifier, sodium stearoyl-2-lactyl lactate, conservative calcium propionate.

## **2.2. Determination of Water content of bread**

Water content of bread was determined by oven drying at 105 °C until constant weight. Three slices obtained of bread center ( $10 \pm 1$  mm thickness) for each of two repetitions were used.

## **2.3. Firmness of bread**

Firmness was measured using the texture analyzer (TA.XT Plus, Stable Micro Systems Co. Ltd., UK) equipped with a 30 kg load cell and connected with a Warner Bratzler blade set with a speed of  $1 \text{ mm}\cdot\text{s}^{-1}$ . Three measurements were collected for each treatment and day (0 and 3). Firmness was measured as the maximum shear strength values and expressed as maximum force (N).

## **2.4. Weight loss of bread**

Weight loss of bread was determined by weighing the sample in initial day and three days after, in three repetitions were made.

## **2.5. Statistical analysis**

Data were submitted analysis of comparison of means by the Tukey test ( $p < 0.05$ ) through the statistical package Statistics 9.0.

## **3. Results and Discussion**

The changes in moisture content, firmness and weight loss of bread are shown at Table 1. The initial crumb moisture content of bread tended to decrease during storage, similar to the observed by Licciardello et al [n13] and others studies [n14, n15] in differently packed durum wheat bread samples. One of the objectives of a packaging system is to reduce water loss, and this can be achieved by materials with suitable barrier to water vapor. The observed results were therefore undesirable to low moisture content value of samples.

Texture is an important characteristic in consumer's perception of food and influences the purchasing decisions. Firming of bread is one of the quality factors in bread ageing and one of the most common parameters used to evaluate staling. A significant increase in firmness was observed for all samples during storage. This result agreed with the water content measures that evidenced likely of starch retrogradation in samples (Table 1), result too observed in other studies [n13, n14, n15].

The products packaged when compared to unpacked showed similar weight loss, however when texture values were observed, sample with packaging showed a lower value than sample without packaging. Indicating that the first one lost less mass than the second, which presented increase of firmness, probable dryness of product. The results showed that

the packaging did not adversely affect the product, since there was no significant difference between the treatments.

**Table 1. Moisture content, firmness and weight loss of bread**

Storage time (days)	Bread unP	Bread WP
<i>Moisture content (%)</i>		
0	26,54±0,15	26,54±0,15
3	16,94±0,65 <sup>a</sup>	16,44±0,08 <sup>a</sup>
<i>Firmness (N)</i>		
0	0,2±0,06	0,2±0,06
3	1,9±0,15 <sup>a</sup>	1,89±0,37 <sup>a</sup>
<i>Weight loss (g)</i>		
0	23,36±0,41	25,99±0,57
3	20,21±0,04 (3,15±0,45) <sup>a</sup>	22,65±0,31 (3,34±0,48) <sup>a</sup>

unP=unpacked; WP= with packing

Values are the average ± standard deviation (n=3). Demonstrated lower case letters that in the same parameter not different from each other (p < 0.05).

At the research led by Cioban et al. [n16] showed that the signs of bread degradation begin to appear after the third day in agreement with what was shown in this work, the smooth and rigid crust becomes wrinkled, elastic and soft, compressing core turns into brittle and becomes less compressing and rigid when stored.

## 5. Conclusions

Based on results analysis, when comparison product with and without packaging, bread characteristics in initial phase of storage exhibit allowing only slight changes, with respect weight loss, compared to packed product. However, in storage time the moisture content and firmness not extended the standard shelf life.

These packaging could be used to keep the product separation by form unitary as primary packaging, for product that would be consumed on same day. Resulting in the decrease of packaging consumption derivate of the petroleum used for same purpose and which has high degradation time. In this context, developing of packaging with potato starch can promote reduction environmental damage.

Another application for such packaging derived from renewable material would be in products which are desirable maintaining the breath, such as some fruits. But, with they were not significant differences between the treatments it is necessary to develop other

analysis with more days in different environments to better conclude the packing functionality.

### **Abstract**

*Commercial drying methods are limited either by high production costs or significant quality loss due to process-related stresses. The near-ubiquitous use of freeze-drying in the pharmaceutical industry makes it the standard to which other drying technologies are compared. However, the shortcomings of lyophilization warrant evaluation of new techniques and the benefits they offer, such as compatibility with continuous manufacturing. Novel drying technologies must also overcome barriers to commercial implementation including, but not limited to, scalability and integration into a GMP environment. There remain several opportunities for further research which direct focus and investment strategy for the next generation pharmaceutical drying technologies.*

**Keywords:** *pharmaceuticals; manufacturing technology; implementation; lyophilization; scalability*

## 1. Introduction

The dehydration of wet material can enable convenient storage options, decrease transportation costs, and improve the ease of sample handling. The specific mechanism of water removal plays a significant role in whether these benefits are achieved since the drying process impacts the material's physical and chemical properties. A combination of consumer demands for improved functional properties (e.g., rapid dissolution, longer shelf life) and manufacturers' concerns with the financial and operational aspects of a drying process are major drivers for implementing novel drying technologies in industrial applications (Fig. 1). In the food industry, J. A. Moses and coauthors rightly point out that "with technology and market-driven demands, new dryers will continually be developed." [1]

*Fig. 1 Drivers for novel drying technologies. Figure adapted from Moses et al. [1]*

It is critical for the pharmaceutical industry to have a similar mindset regarding drying technologies, especially since pharmaceuticals employ considerably fewer number of drying techniques during manufacture compared to foodstuffs. Additional drivers for the evaluation of new drying technologies include, but are not limited to, improved energy efficiency, reduced environmental impact (e.g., use of renewable energy sources), and compatibility with continuous manufacturing process. For these reasons, having a strategy for evaluating and implementing new manufacturing technologies is critical to meet the demands for reducing manufacturing costs and delivering next generation therapeutics.

## 2. Challenges and opportunities for new technology implementation

While we remain optimistic that the best scientific ideas will be appropriately nurtured, there are many obstacles to their growth, development, and future implementation. In simple terms, humans are often innately resistance to change. As we explore unknown areas, we move away from safety and comfort and into risk and potential frustration. Therefore, it is critical to keep an open mind when new technologies are being assessed. Management (in industry) should be wary to stifle an idea simply because it may not be

easily implemented or scalable. Pushing through the initial resistance associated with developing a new manufacturing technology may lead to long-term benefits. Consumers (i.e., HCP and patients) may need to be re-educated to utilize products with 'atypical' features since novel drying technologies may produce products possessing unique physical properties (e.g., density, color), which may differ from those being produced by currently-accepted technology.

A biopharmaceutical technology management strategy outlined by Thakur et al. describes a four-phased approach to improving capabilities which involves observation, alignment, decision, and action.[2] Observation requires detailed collection of information and data from both internal and external sources. A market assessment conducted by Janssen summarized seven key technology themes that may impact the manufacturing process.[2] These technology themes include; process innovation, single use/modularity, continuous, automation/robotics, data analysis, disruptive, and customer facing. Technology trends impacting all aspects of biopharmaceutical processing, including upstream and downstream bioprocessing, formulation and fill, and packaging/devices, can be easily sorted into these overarching themes.[2]

In some ways, regulators are playing a leading role in the conversation on the implementation of new manufacturing technologies. A statement released in September 2017 describes the FDA's commitment to pharmaceutical innovation, not only in regards to novel therapeutics, but also in the manufacturing technologies used to produce them. [3] CDER's Office of Pharmaceutical Quality created an Emerging Technology program to "promote the adoption of innovative approaches to pharmaceutical manufacturing... and [provide] a route for companies to engage with the FDA prior to regulatory submission".[3] In spite of these support structures in place, Munk [4] has summarized a number of challenges being encountered for implementation, including: 1) need for precedence, 2) need for a defined regulatory path, robust single-use technology, and robust process analytical technology (PAT) tools, 3) lack of comfort level and control tools, 4) lack of easy fit for continuous manufacture into existing infrastructure, facilities, and quality systems, 5) need for economic justification and adaptation of current quality or regulatory programs, and 6) need for unit operations to be fully developed for continuous processing.

While some of these concerns are specific to continuous manufacture, the core principles apply to the resistance shown and felt by the industry to accept the implementation of any new technology. There are further pharma-specific aspects for consideration. For legacy products, new technologies are not easily implemented; tremendous amounts of effort have been invested to fulfill the regulatory requirements of product approval and maintain the validated status. Often, the introduction of a new technology would represent a 'Major Change' that requires a very costly repetition of validation and requalification work, in addition to the risk that may be associated with the use of new technology.

Alternatively, a new technology may be introduced in conjunction with a new compound. This, however, narrows the range of potential users to introduce a new technology to the Rx-based industry. Furthermore, very significant risk is linked to the development of new compounds, which can fail in late development stages or even after market approval. To invest in a cGMP manufacturing site with a new technology that is not available in other sites of the company, or industry, for a new compound further increases the risk.

### **3. Challenges/limitations with lyophilization**

Lyophilization is the industry standard for drying of biopharmaceutical products and a significant fraction of pharmaceutical industry's knowledge is devoted specifically to freeze-drying.[5] Even though it is common-practice, there are several drawbacks to the lyophilization process, such as 1) high energy consumption, 2) long processing times, 3) significant production and maintenance cost, and 4) limited manufacturing and container closure flexibility.

The energy efficiency of a fully loaded production-scale lyophilizer was reported by Alina Alexeenko to be as low as 1.5 to 2%.[6] In general, drying processes are one of the most energy intensive unit operations.[7] The long drying process times during freeze-drying, which can vary from several hours to days, may also limit the number of batches that can be produced at manufacturing site. In some cases, the lyophilizer capacity may be the limiting factor to overall manufacturing production rate. This is one of the main reasons that significant effort is focused on optimizing the primary and secondary drying times during the freeze-drying cycle.[8] Since lyophilization is a batch process, it will also be challenging to adapt the technology into a continuous manufacturing process. From a container closure perspective, as previously mentioned, the primary packaging is limited to containers that are suitable for lyophilization (e.g. vial or bottles).

Despite these limitations, freeze-drying is a robust and scalable process that is widely applied in the pharmaceutical industry. In all likelihood, freeze-drying will remain the predominant method for drying pharmaceuticals; however, the drawbacks highlighted here demonstrate the potential benefit of evaluating next generation drying technologies that may overcome these challenges.

### **4. Potential solution to limitations associated with lyophilization**

In alignment with the technology management strategy, spray-freeze drying is a unique drying technology that is being evaluated for biopharmaceuticals due to the plethora of its offerings, which among them include manufacturing process innovation and new packaging options for customers [9-11]. Spray freeze-drying technology can be aimed at two major focus areas: product innovation and increased manufacturing flexibility. With respect to manufacturing flexibility, a major aspect is the production of homogeneous, free flowing and sterile microspheres as bulk that can be filled into vials, or any other container closure systems, at any time, with flexible (vial) dosing and batch quantities (e.g. even personalized medication). In contrast to conventional vial lyophilization, the general sequence of operation is reversed by having the lyophilization process prior to the filling process. With this technology, a long and rigid supply chain can be made flexible and cold chain logistics can be facilitated.

Since the product is already freeze-dried, the primary packaging does not need to be suitable for lyophilization; this allows for direct filling into syringes or any other application devices that would not be suitable for conventional shelf freeze-drying.

With respect to product innovation, the availability of free flowing bulk that can be dosed and filled allows to formulate combination products by compounding on the filling line. Furthermore, the availability of the increased product surface not only facilitates the drying due to increased heat and mass transfer, but also reduces reconstitution time. This specifically applies when high protein concentration products (up to 200 mg/ml) are processed. Spray freeze-drying is a good example of a technology that has successfully progressed through the technology management process and will continue to mature as more applications are investigated.

As described above, the introduction of new, disruptive technologies in pharmaceutical applications has its challenges, which has an impact on the overall product development timeline that needs to be taken into account (i.e., from first process development studies to cGMP operations). This can easily cover a period of 10+ years. This time span is a challenge even for an established technology provider, as the return on investment for the development does not occur prior to broader implementation in the industry, and the profitability is not in the range of new pharmaceutical compounds. The risks and challenges are greater for start-up companies that need to survive economically in that long development period.

Nevertheless, there are possibilities to balance these risks. It is advisable to team up with a major Big Pharma partner that, besides the economical strength and possible application, brings regulatory competence and IP strengths to the development process. At a certain level of maturation, it may be possible to look for additional companies, which could then form a User Group, or a consortium, in order to address the development needs that are associated with the implementation of a new technology as well as regulatory considerations. In regard to the latter, it may be preferable to solicit participation of regulatory bodies that can comment on their evaluation criteria, which will reduce the risk of surprises regarding the acceptability of the technology.

Alternatively, it may be possible to look for applications outside of pharma that do not carry the intrinsic risks and other time-consuming formal evaluation as in pharma applications. In these sectors, faster development and evaluation can be accomplished. Even with this approach, the challenge still remains to progress developments that are specific to the pharmaceutical application in parallel to reduce the time associated with implementation.

## 5. Conclusions

While the pharmaceutical industry continues to demonstrate its creativity associated with novel compounds in development (now venturing into the realms of gene and cell therapy, while a decade ago, it was solely focused on monoclonal antibodies), the processing technology has not kept its pace. This is not a reflection of the paucity of innovation associated with processing technology. Regulatory aspects, in which conventional testing or validation procedures and routines that are well accepted may no longer be applicable, pose another challenge that pharma companies face when considering the introduction of new processes. The introduction of a disruptive new technology is often only possible if a promising new compound strongly requires the benefits of that new technology, and if the

business case allows for the additional costs that are linked to its introduction. These concerns can broadly be classified as economic, logistical, technical, and psychological and all elements need to be overcome in order for successful implementation of a new technology.

### ***Abstract***

*The evaporation of water is a major energy consumer around the world where the evaporation of water from agricultural products, natural resources, processed foods and feeds, and petrochemical products is required for long term storage, subsequent processing or other desired attributes.*

*The control of product attributes associated with drying can also be challenging in terms of measurement and modelling which may lead to inefficiencies in the operation of a dryer.*

*This discussion below will address solutions to improve the thermal efficiency of dryers and to control the critical properties of the product being dried. In addition, the benefits of sharing information between the dryer supplier and the dryer operator will be discussed through the use of the Industrial Internet of Thing*

***Keywords:*** heat recover; design; control.

---

## **1. Heat Recovery for Conveyor Dryers**

In a well-balanced conveyor dryer, the energy associated with evaporation of water represents approximately 65% of the thermal energy input. The remaining energy is consumed by the hot exhaust air stream, the temperature increase in the product, and ambient losses to the environment. Much of this energy may be recovered by cooling the product after the drying step and using this air within the dryer, recovering the sensible and latent heat in the exhaust to pre-heat make-air, recovering energy for steam condensate, and improving the insulation of the dryer construction.

In order to reduce operating costs, energy conservation and heat recovery should be paramount to the configuration of any unit operation, specifically thermal drying. Numerous drying technologies benefit from energy recovery; however, the platform of this study focuses on reducing utility consumption in regards to conveyor drying. Gel drying applications are used as examples for recovering energy and recycling heat within the dryer. Drying the gel yields effluent streams with sufficient internal energy to justify modifying the process design of the dryer for heat recovery. Opportunities for heat recovery include cascading airflow, heat recovery from the exhaust air, and condensate flashing to maximize the energy from the steam supply.

Drying wet material requires a large amount of energy/mass transfer to obtain the desired final moisture content of the product. The physical properties of the gel have an inlet moisture typically around 50-60% wwb, while the desired outlet moisture range is 3-5% wwb. Depending upon the nature of the gel, the product is first tested in a laboratory dryer to establish optimal drying conditions for air temperature, velocity, and bed depth. Many cellulous or protein derived gel polymers are sensitive to air temperature, unlike refined gel polymers from petroleum based reactions. The latter is considered for the purpose of this analysis. Dryer components (fans, heat source, etc.) are designed for high process air temperatures (T range 165-180°C) and flow rates through the stacked bed of product (V range of 1.6-2 m/s) in order to facilitate a high rate of evaporation. A typical gel conveyor dryer configuration can be seen in Figure 1.

Buhler Aeroglide has a proprietary heat and mass balance spreadsheet, in which the process is broken down to identify areas where energy can either be reduced or reused. Figure 2 shows an approximate energy consumption profile for a conveyor dryer, without heat recovery, producing dried gel at five tons per hour. As seen in the bar chart, water evaporation requires the most amount of energy due to the phase change. The second largest contribution to the thermal load is from heating a supply of cool dry make-up air in exchange for hot wet exhaust air. For this example, the most beneficial savings can be achieved by recovering the thermal energy used to evaporate the water and heat the make-up air. These dryers also have a cooling zone; therefore, heat from the product can be recovered by

recycling air from the cooling exhaust. Improving the dryer design to limit ambient heat losses will also improve the energy efficiency.

**Figure 1 - Gel dryer configuration**

**Figure 2 - Gel energy breakdown**

For dryers without heat recovery, over six mega-watts of energy is required to produce five tons per hour of dried gel. These values do not include the electrical load to operate the mechanical equipment (conveyors, fans, etc.). Gel drying applications are ideal for heat recovery because the production and evaporation rates are substantial for systems producing more than four tons per hour. Thermally processing gel incurs high energy consumption and utility costs. As mentioned previously, the gel enters the dryer with an average moisture content between 50-60% wwb and exits at 3-5%. Operating expenses, for a dryer demanding 6 MW of thermal energy for evaporation, are considerable.

The operating costs associated with the dryer can be reduced based on the energy recovery options. However, there were parameters that were constant throughout the simulations. The quality of the air entering the dryer was defined at ambient conditions (TDB=20°C) and sea level. Also, the general dryer configuration and process parameters were standardized while

modeling the energy options. The defined process operating conditions and assumed rheological properties are in noted in Table 1. As mentioned, the overall configuration of the dryer in regards to airflow direction, drying/cooling area, and general arrangement were consistent. In terms of design, the conveyor dryer is a single pass, single plenum machine. Each simulation had six drying zones with an extended cooling zone. The direction of airflow in the first three zones were upflow, proceeded by downflow air in the later sections of the dryer.

**Table 1 - Dryer process parameters**

Parameter	Value
Production Rate (kg/hr)	5.000
Inlet Moisture (% wwb)	60
Outlet Moisture (% wwb)	5
Wet Density (kg/m <sup>3</sup> )	460
Product Depth (mm)	100
Retention Time (min)	30
Air Temperature (°C)	160
Air Velocity (m/s)	1,65

**Figure 3 - (a) Buhler aeroglide cascading air flow, (b) Flash steam system (c) Air to heat exchanger**

The simulations share many design features in common; however, the energy recovery features were unique to each. This study focused primarily on cascading airflow, air-to-air heat recovery from exhaust to make-up, and condensate flashing to preheat make-up air. Figures 3a, 3b (Spirax Sarco Inc., “Design of Fluid Systems - Hook-Ups” 2012. pg. 97), and 3c (Munters Corporation, “Counterflow Plate Type Air-to-Air Heat Exchangers” 2013) provide illustrations of the equipment.

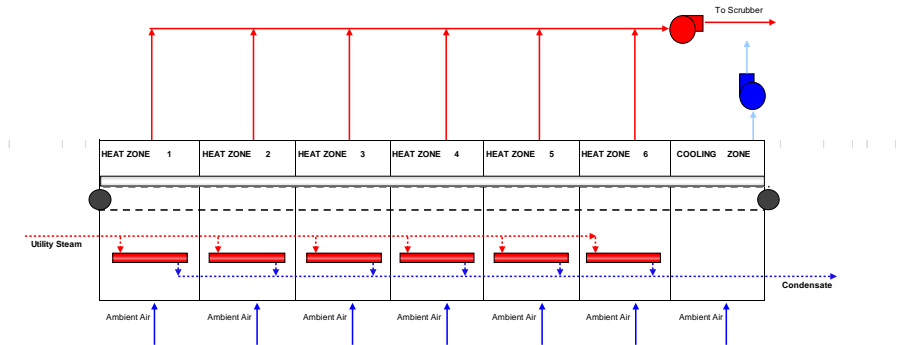

## 2.1 Base Design

The first scenario that was modeled had no heat recovery in addition to the recirculated air. The results of the energy and mass balance for Case 1 can be seen in Table 2. The dryer’s

exhaust and makeup air flow were set to provide absolute humidity levels in the exhaust of  $0.15 \text{ kg}_{\text{H}_2\text{O}}/\text{kg}_{\text{D.A.}}$ .

**Table 2 - Case 1: Results**

<b>Dryer Performance</b>	<b>Value</b>
Energy Usage (kW)	6.045
Steam Usage (kg/hr)	11.442
Spec. Energy Consumption ( $\text{kJ}/\text{kg}_{\text{Evp}}$ )	3.166
Spec. Steam Consumption ( $\text{kg}_{\text{Steam}}/\text{kg}_{\text{Evp}}$ )	1,66
Spec. Moisture Extraction Rate ( $\text{kg}_{\text{Evp}}/\text{kWh}$ )	1,14

**BUHLER**

**Figure 4 - Case 1: Process flow diagram**

Case 1 represents the most energy intensive and least cost effective option from an operating perspective. This scenario is a reference point for the following simulations and it is identical to the energy breakdown shown in Figure 2. Table 2 shows the specific energy and steam consumption along with the specific moisture extraction rate. These values are frequently used to compare similar drying applications but at varying sizes and production rates. They will be used as a baseline for the following energy Cases.

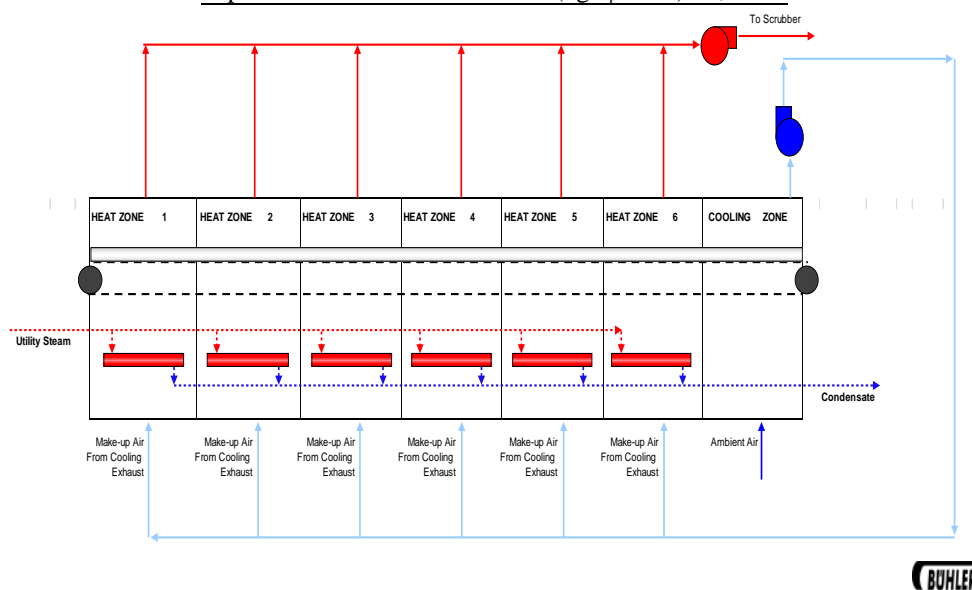

### 1.2 Cooler exhaust air used as dryer make-up air

The second scenario focused on heat recovery from the cooling exhaust. In this design, the air being exhausted from the cooling section was ducted to the makeup air dampers entering each heat zone. The makeup air to each zone was no longer at ambient conditions; rather, it was preheated ( $T_{\text{DB}}=30^\circ\text{C}$ ). The cooling exhaust air flow rate was set based on the required makeup air mass flow rate. Similarly to Case 1, it was assumed that the quality of the air entering the cooler was at ambient conditions ( $T_{\text{DB}}=20^\circ\text{C}$ ) and sea level.

Table 3 shows the calculated energy and mass balance results for Case 2. When compared to Case 1, there was a 2% savings in energy usage. As expected, the specific energy and steam consumption are less because the same amount of water was evaporated using less energy. Similarly, the specific moisture extraction rate increased because it is inversely proportional.

**Table 3 - Case 2: Cooling exhaust make-up air results**

Dryer Performance	Value
Energy Usage (kW)	5.908
Steam Usage (kg/hr)	11.183
Energy Savings (%)	2%
Spec. Energy Consumption (kJ/kg <sub>Evap</sub> )	3.094
Spec. Steam Consumption (kg <sub>Steam</sub> /kg <sub>Evap</sub> )	1,63
Spec. Moisture Extraction Rate (kg <sub>Evap</sub> /kWh)	1,16

**Figure 5 - Case 2: Process flow diagram**

### 1.3 Cascading airflow

Cascading airflow was simulated in Case 3. Similarly to Case 2, the cooling exhaust is utilized as make-up air; however, it only enters the dryer in heat zones 1, 2, and 6. The make-up air is introduced in zone 6. The exhaust from zone 6 internally “cascades” as the make-up air to zone 5. This design is continued to zone 3, where it is finally exhausted from the dryer. The cascading design conserves energy by reusing relatively dry preheated air.

**Table 4 - Case 3: Cascading air flow results**

Dryer Performance	Value
Energy Usage (kW)	5.803

Steam Usage (kg/hr)	10.983
Energy Savings (%)	4%
Spec. Energy Consumption (kJ/kg <sub>EvP</sub> )	3.039
Spec. Steam Consumption (kg <sub>Steam</sub> /kg <sub>EvP</sub> )	1,60
Spec. Moisture Extraction Rate (kg <sub>EvP</sub> /kWh)	1,18

Depending upon the drying characteristics of the product and the configuration of the dryer, some applications permit cascading airflow through all the heat zones. A prime example of cascading airflow would be a rubber dryer. Consequently for gel drying, there is a high evaporation load in the first two heat zones in addition to the change in airflow direction from zones 2 to 3. Therefore, it is mechanically and thermodynamically impractical to cascade airflow from zone 6 to zone 1 for gel drying applications.

Table 4 depicts the results of the energy analysis for cascading airflow. In comparison to Case 1, there is a 4% reduction in energy consumption.

#### 1.4 Flash steam

*Table 5 - Case 4: Flash steam result*

<b>Dryer Performance</b>	<b>Value</b>
Energy Usage (kW)	5.456
Steam Usage (kg/hr)	10.328
Energy Savings (%)	10%
Spec. Energy Consumption (kJ/kg <sub>EvP</sub> )	2.857
Spec. Steam Consumption (kg <sub>Steam</sub> /kg <sub>EvP</sub> )	1,50
Spec. Moisture Extraction Rate (kg <sub>EvP</sub> /kWh)	1,26

Flash steam is generated when high pressure condensate, from the internal steam coils, is released to low pressure. The excess latent heat allows some of the condensate to re-evaporate into steam (Spirax Sarco Inc., “Design of Fluid Systems – Steam Utilization” 2012). The design for the flash steam systems requires that the low pressure flash steam be a minimum of 520 kPa below the high pressure condensate.

In the drying simulation, the low pressure flash steam is utilized via an external steam coil. The exhaust air from the cooling section is ducted to the low pressure steam coil. After the air is preheated by the flash steam, it is then distributed to each heat zone.

In the simulator, the condensate was leaving the dryer at 1765 kPa and the flash tank was operating at 690 kPa. Based on the energy balance, the dryer produced condensate at a rate of 10,330 kg/hr. The flash steam system was able to recover nearly 500 kW of power from the high pressure condensate in the form of lower pressure steam. Table 5 lists the values from the flash steam energy balance. The flash steam modifications yielded energy savings of 10% when compared to the base case scenario.

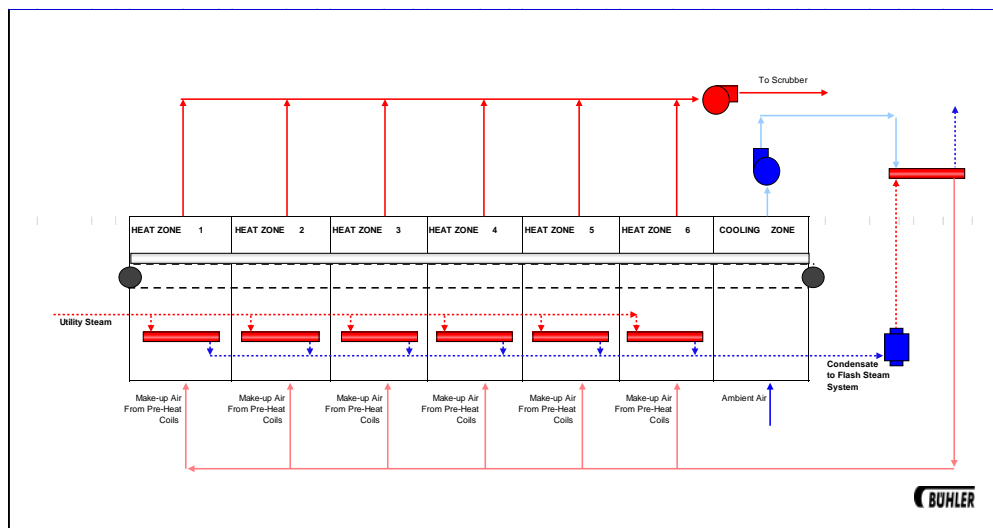

Figure 6 - Case 4: Process flow diagram

## 1.5 Air-to-air heat exchanger

The air-to-air heat exchanger recovers heat from the exhaust streams that would have otherwise been released to the environment. Once again, the make-up air is supplied from the cooling exhaust/transfer fan. An illustration of the dryer configuration can be seen Figure 8.

A counter-current parallel plate and frame heat exchanger is used to reduce pressure drop and achieve improved approach temperatures between the hot exhaust air and cooler make-up air. Pressure drop becomes a concern while sizing transfer and exhaust fans. Typically, the pressure drop across the heat exchanger is between 620-750 Pa; thus, significantly increasing the fans' motor sizing. There are also design considerations in regards to the approach temperatures of the make-up air. For petroleum based gel polymers, the efficiency of the heat exchanger is limited by the formation of condensation in the exhaust stream. The humid exhaust air contains gel particulate, which will foul the heat exchanger if water condenses along the heat transfer surface area. Therefore, the exhaust temperature must maintain at least an 11°C buffer above the dew point temperature. ( $T_{EX} \geq T_{DEW} + 11^{\circ}C$ ). This exhaust temperature set point is used as a design parameter for the heat exchanger.

Figure 7 - Case 5: Process flow diagram

Table 6 - Case 5: Heat exchanger results

Dryer Performance	Value
Energy Usage (kW)	5.396
Steam Usage (kg/hr)	10.213
Energy Savings (%)	11%
Spec. Energy Consumption (kJ/kg <sub>Evp</sub> )	2.826
Spec. Steam Consumption (kg <sub>Steam</sub> /kg <sub>Evp</sub> )	1,49
Spec. Moisture Extraction Rate (kg <sub>Evp</sub> /kWh)	1,27

Despite these design considerations, counter-current air-to-air heat exchangers improve the energy efficiency of system. Table 6 shows the benefits of recovering energy from the exhaust air stream to preheat the make-up air. There were 11% energy savings; however, case studies show potential energy savings up to 16% (Mujumdar A. “Handbook of Industrial Drying” CRC Press. November 2006).

### 1.6 Combined energy conservation measures

Table 7 - Case 6: Combined energy conservation results

Dryer Performance	Value
Energy Usage (kW)	4.917
Steam Usage (kg/hr)	9.306
Energy Savings (%)	19%
Spec. Energy Consumption (kJ/kg <sub>Evp</sub> )	2.575
Spec. Steam Consumption (kg <sub>Steam</sub> /kg <sub>Evp</sub> )	1,35
Spec. Moisture Extraction Rate (kg <sub>Evp</sub> /kWh)	1,40

Case 6 combined the energy features described in Cases 2-5. First, the exhaust air from the cooling section was passed through an air-to-air heat exchanger. Hot exhaust air from zones

1, 2, and 3 ran counter-current to the preheated make-up air. The second feature involved further heating the make-up air using flash steam coils. Then, the hot make-up air was ducted to zones 1, 2, and 6. Finally, the air was cascaded from zone 6 to 3, where it was exhausted from the dryer.

Figure 8 - Case 6: Process flow diagram

The combined energy savings from the heat recovery features was 19% when compared to Case 1. The specific steam consumption was determined to be 1.35 kg<sub>Steam</sub>/kg<sub>EvP</sub>.

## 2.7 Energy Savings Results

The energy savings were calculated using a mass and energy balance at the design conditions. A nominal throughput of five tons per hour was selected as the production rate for the gel dryer. Operating parameters were consistent with the industry’s standard. The theoretical savings are summarized in Table 8.

The heat recovery options were compared separately to the base case scenario, which had no energy saving features. Each energy case was not added incrementally to the same simulation. Since each energy saving option was evaluated and optimized independently, there are overlapping savings between each option. Therefore, the “Combined” savings are not cumulative and will not equal the sum of the individual options.

**Table 8 - Energy conservatioin measure results summary**

Dryer Production Rate 5000 kg/hr	Steam Usage (kg/hr)	Energy Usage (kW)	Spec. Steam Consumption (kgSteam/kgEvp)	Spec. Energy Consumption (kJ/kgEvp)	Spec. Moisture Extraction Rate (kgEvp/kWh)	Energy Saving (%)
Base Case	11.442	6.045	1,66	3.166	1,14	-
Cooling Exhaust MUA	11.183	5.908	1,63	3.094	1,16	2%
Cascading	10.983	5.803	1,60	3.039	1,18	4%
Flash Steam	10.328	5.456	1,50	2.857	1,26	10%
Heat Exchanger	10.213	5.396	1,49	2.826	1,27	11%
Combined	9.306	4.917	1,35	2.575	1,40	19%

## 2. Product Quality Control

During drying, the control of product quality attributes is critical to successful production. Parameters such as moisture content, color, and specifically for nut roasting the reduction in pathogens should be measured and controlled within the process. Methods for modelling and/or measuring these key product quality parameters will be discussed as well as how the dryer process parameters may be manipulated to maintain the values within the users' specifications.

### 3.1 Increased dryer yield

Even small percentage gains can mean significant increases in yield and profitability over time. A product moisture control will automate the dryer operation to optimize performance, bringing more product closer to target moisture. This increases overall yield by preventing over drying. It also eliminates the risks associated with under drying. Continuous monitoring, constant control uses suitable sensor technology for the specific product to be dried. Typically larger extruded products, the moisture content can be determined via their dielectric properties using microwave or capacitive sensors. While fine materials or surface drying applications near infrared based sensors are successful. These types of sensors coupled with controls that use algorithms built on decades of technical drying experience allow dryer manufacturers to provide benefits to their customers. The resulting

comprehensive closed loop system delivers full time automated control of the dryer. The moisture content at the dryer's output is sampled continuously and the necessary adjustments to the dryer are made immediately, eliminating the need for manual sampling and the associated time gaps between sampling, testing, and making dryer adjustments. This fully automated method significantly increases the frequency of sampling and moves more of the product closer to the target moisture content. Consistent, reliable dryer management improves energy efficiency by making the correct dryer control decisions quickly and reliably. Moisture content targets can be input by operator or by recipe control, and the dryer will automatically establish and maintain the optimal drying environment for the remaining production run. This eliminates the wasted energy and product that can result from manually attempting to reach a moisture target.

### **3.2 Ensuring safe thermally processed food.**

In the USA alone, the annual cost of foodborne outbreaks caused by harmful bacteria, is \$17B USD. Each recall can cost a single company up to \$30M USD per incident. The number of recalls have doubled over the last 10 years. As a consequence of these incidents, there are new legal requirements (FSMA - Food Safety Modernization Act) in the USA that put much more pressure on food manufacturers in the form of increased government oversight and greater customer scrutiny. One recall due to food safety failings can be disastrous to a company or a brand.

Beyond the financial considerations, there are far greater consequences from food safety incidents. The Centers for Disease Control and Prevention (CDC) estimates that each year roughly 1 in 6 Americans (or 48 million people) get sick, 128,000 are hospitalized, and 3,000 die of foodborne diseases. As part of the food supply chain, we all bear a moral obligation to ensure we are producing the safest food possible for consumption by the public.

#### *3.2.1 Regulatory requirements*

In 2011, the Food Safety Modernization Act became law. It is the most sweeping reform of US food safety laws in more than 70 years. With it came many new legal requirements for food processors. Among these new requirements is the need to guard against bacterial hazards in the food production process. Processors must now:

- Analyze potential hazards in the food being processed
- Put preventive controls in place
- Validate the process to show the controls work
- Record process data to show the controls are met
- Be able to recall data quickly upon request

For many foods where bacteria presence is known or expected, a kill step is the typical control. This step separates unsafe raw material from a safe-to-eat consumer product. The

kill step is usually a high temperature process, meaning processors can use existing processes originally designed for operations such as roasting of nuts, as a kill step for bacteria. Gaining insights to a process to ensure that it is capable of delivering the required kill, and then monitoring and recording processing conditions, is currently done using tedious methods that are time consuming, costly, manual, and vulnerable to human errors and adulteration. Many times there are also conflicts between food safety and quality needs.

### 3.2.2 Ensuring the Kill Step

With enhanced processing monitoring, food manufacturers can now take full advantage of their dryer manufacturer's food safety expertise and food technology knowledge to meet these new challenges. A system that can provide a continuous real time view into the thermal process, enables operators to react faster to process changes, reducing product losses and increasing production time, while its digital data recording, storage, and reporting capabilities help to reduce the vulnerabilities associated with manual and paper-based methods.

## 3. Sharing Success – A Partnership between Dryer Users and Dryer Manufacturers

Having this process instrumentation and controls isolated at the plant level does not benefit the corporation as a whole. Utilizing the Industrial IoT and data analytics allows this information to be shared throughout the plant, multiple corporate facilities and the process equipment vendor. Some of the benefits of this partnership are listed below.

1. It will be possible for the drying process to be monitored in real-time from any location. This will allow the management to respond to unexpected upsets, eliminate wasted idle time, and reduce inventory ready to ship to customers. Data from multiple sites will allow comparison of plant efficiencies and methodologies to improve each production line.
2. Connected dryers can be monitored and managed remotely. The dryer operator does not need to directly in front of a control panel in order to adjust the process. Smart sensors and algorithms can be used to better understand what is happening within the drying process which can improve the final product, conserve energy costs and improve overall profitability.
3. The dryer information from multiple sites can be monitored and modelled to form a predictive maintenance algorithm. This will allow dryer operators to reduce downtime and achieve a greater return on their capital investment.
4. Information may be used to study cause and effects that may result in material not meeting specifications. Data affecting quality can be sent to the right people in real time so that they may make informed decisions and work to identify problems, find the root cause and implement solutions. This data can then be used to confirm the solution.
5. This information can help the management team make decisions in a competitive environment in real time by seeing what is happening on their plant floors throughout

the company. This will allow them to better manage overall operating costs and efficiencies.

## **6. Conclusions**

A partnership between an equipment supplier and the user of the equipment can have many benefits as described above that can lead to the optimal use of energy (minimize energy input into the drying step) to lower operating costs. Communications and data sharing through the Internet of Things will allow the partnership to succeed through multiple plant locations to result in the optimal use of resources, plant process lines and increased production quality.

## Determination of the moisture content of white and yellow corn from ohaji in imo state of nigeria using the dry-weight technique

Offurum, J. C.<sup>a\*</sup>; Morgan, C.M.<sup>a</sup>

<sup>a</sup> Department of Chemical Engineering, Imo State Polytechnic, Umuagwo-Ohaji

\*E-mail of the corresponding author: [jullyengine@yahoo.com](mailto:jullyengine@yahoo.com)

---

### **Abstract**

*The water content determination of two maize species (Yellow corn- and White corn-), located at Ohaji in Imo State of Nigeria was considered in this study. This was motivated by the regular reported cases of the seed post-harvest spoilages. Modified High Constant Temperature Oven method, as prescribed by the International Seed Testing Association was employed, at a temperature of 132oC. The procedure for each sampling was replicated accordingly, and the mean value was identified as the actual result. The moisture content for Sample A (white corn) was found to be 31.6%, while that of Sample B (yellow corn) was found to be 21.5%, which shows that the yellow corn would always have longer storage value than the white corn. As any change in the seed moisture has a way of affecting its storage life, it is advisable not to store the white corn longer than it could be applied to the yellow corn*

**Keywords:** *Determination, Moisture Content, White Corn, Yellow Corn, Dry-weight Basis.*

---

## **1. Introduction**

Moisture content of a seed can be described as the percentage quantity of water in the seed at a given time (1). The moisture content can be expressed on either weight basis (percentage of the weight of the fresh seed) or on dry-weight basis (percentage of the dry-weight of the seed). The seed moisture content is among the factors that determine whether or not the seed can be stored safely without loss of germination and vigour (2). In most cases, higher moisture content encourages higher heat content of the seed, which regularly prepares the seed for bacterial growth. As seeds of a given crop would usually have high moisture content at maturity, they become (more or less) naturally unsafe for storage without reducing their inherent percentage moisture content through applicable drying technique. The essence of drying is to reduce the excess moisture of the seeds that has the capacity of exposing them to microbial contamination and spoilage (3).

When a seed/grain dries, it releases its moisture into the drying air, and consequently, loses weight upon which the moisture content assessment depends. The range of systems available for drying seeds varies, from thin-layer under the sun (or simple maize crib), through oven-drying, to extensive mechanized systems (such as use of continuous-flow dryers). But the choice of any of these systems depends on a number of factors, such as rate of harvest, volume of seeds (to be dried), available storage facilities, as well as flexibility (4, 5). As a very important cereal plant that is widely grown in Nigeria for both human food and livestock feed, maize is used in the industrial production of alcohol, starch and oil (6). It is economically not important to store maize seeds that are above 23% moisture content in a grain bin, as the kernels may freeze together and, subsequently, deform or stick together (7). Post-harvest management of maize seeds demands critical attention towards providing a good aerated (cool) condition for keeping the corn, as wet corn will deteriorate very easily. The use of maximum (but optimum) drying temperature during corn drying encourages drying efficiency and lowers the total required drying energy. On the other hand, decreasing the drying temperature in the lower portion (especially for a multistage dryer) could reduce the susceptibility to heat damage.

However, as much as the seeds could be preserved when dried (at appropriate drying conditions), they could also be damaged when dried too rapidly (over-dried), and any change in the moisture content of the seed affects the storage life of the seed. These, thus, necessitated the present study, which centers on the moisture content determination of two maize species- Sorghum and Var. Rugosa (white and yellow corns) from Ohaji, in Imo State of Nigeria.

## 2. Materials and Methods

The two maize samples used in this study were collected from a Late-planting farm (upon maturity) at Awarra-Ohaji, which is located at the Western part of Owerri, the Imo State capital in Nigeria. The method of moisture content determination adopted in this work is the modified high-constant temperature oven method, prescribed by the International Seed Testing Association (ISTA) (8)

### 2.1. Pre-drying

Exactly 1.0000g of each of the seed samples was weighed into a dish using analytical weighing balance, to obtain the weight,  $W_1$ . The dish (of seed) was left in a warm dry place over-night. After 24hours, the sample was taken and re-weighed to obtain the weight,  $W_2$ . The percentage moisture content for the pre-drying stage,  $S_1$  was evaluated using Eq. 1.

$$S_1 = \frac{W_1 - W_2}{W_1} \times \frac{100}{1} \quad (1)$$

Where  $W_1$  = Weight of dish and fresh seed

$W_2$  = Weight of dish and pre-dried seed

### 2.2. Grinding

Each of the pre-dried seed samples was grinded to about 1mm size distribution, and then placed in a clean dry dish separately

### 2.3. Drying

The ground form of each of samples was weighed into a clean dry dish using analytical weighing balance, to obtain the initial weight,  $W_3$ . The dish was the carefully placed in a thermostat oven set at 132°C. When the oven temperature reached the set point, the switched went off automatically, and the oven operation was maintained for a holding time 4hours (at that temperature). At the elapse of the time, the dish was removed and placed inside a (covered) desicator, to cool for 40munites (at room temperature). The sample was then removed and re-weighed, to obtain the final weight,  $W_4$ . The moisture content of the normal drying,  $S_2$  was evaluated using Eq. 2.

$$S_2 = \frac{W_3 - W_4}{W_3} \times \frac{100}{1} \quad (2)$$

Where  $W_3$  = Weight of dish and ground seed

$W_4$  = Weight of dish and dried seed.

The final moisture content,  $M$  was obtained using Eq. 3

$$M (\%) = (S_1 + S_2) - \frac{S_1 \times S_2}{100} \quad (3)$$

Where  $S_1$  = Percentage moisture content from Pre-drying

$S_2$  = Percentage moisture content from Drying

This procedure was, however, replicated for each of the seed samples (giving rise to  $R_1$  and  $R_2$  data for each Sample), and the average moisture content,  $M_{avg}$ , was evaluated using Eq. 4.

$$M_{avg} = \frac{S_1 + S_2}{2} \quad (4)$$

### 3. Result and Discussion

The results of the dry-weight measurements for **Samples A** and **B** are presented in *Tables 1* and *2* respectively, while those of the moisture contents are presented in *Table 3*.

*Table 1: Dry-weight Analysis of Sample A (White Corn)*

Dish Number	Weight of Dish, g	Weight of (Dish and Fresh Feed), g	Weight of (Dish and Dry Feed), g
<b>Pre-drying Stage</b>			
1	20.3500	34.3313	32.4419
2	20.4424	34.4224	33.0248
<b>Drying Stage</b>			
3	10.8611	14.5201	13.7928
4	10.9130	14.6046	14.3521

*Table 2: Dry-weight Analysis of Sample B (Yellow Corn)*

Dish Number	Weight of Dish, g	Weight of (Dish and Fresh Feed), g	Weight of (Dish and Dry Feed), g
<b>Pre-drying Stage</b>			
1	22.0025	36.6240	33.9925
2	22.9034	36.7071	35.0059
<b>Drying Stage</b>			
3	11.1424	15.5036	15.3016
4	11.8013	16.0411	15.8512

**Table 3: Moisture Content Analysis of the Samples**

Moisture Content (%)	A			B		
	S <sub>1</sub> (%)	S <sub>2</sub> (%)	M (%)	S <sub>1</sub> (%)	S <sub>2</sub> (%)	M (%)
<b>R<sub>1</sub></b>	13.5	19.9	30.7	18.0	5.5	22.5
<b>R<sub>2</sub></b>	31.5	1.4	32.5	12.3	9.4	20.5
<b>Average “M”</b>	<b>M<sub>avg.</sub> (%)</b>		<b>31.6</b>	<b>M<sub>avg.</sub>(%)</b>		<b>21.5</b>

The results of the moisture content (M), in Table 3, show that there is no significant difference between the replications (R1 and R2). In other words, the differences between the R-values, for both samples, fall within the limits of +2, indicating absolute homogeneity and acceptability of the data (9, 10, 11). The moisture content of Sample A (31.7%) was observed to be greater than 23%, and as such should not be stored in poly bags or grain bins, as this may cause the kernels to freeze and bind together, unlike Sample B that can be reliably stored in a grain bin (7). Alternatively, storage of shelled corns of higher moisture contents (> 25%) should be in silos or silo bags (7)

#### 4. Conclusions

The white corn has higher moisture content than the yellow corn. During post-harvest management of the grains, white corns should be stored in silos or silo bags, while the yellow corns could be stored in poly bags or grain bins. Generally, the seeds of the white maize should not be stored for longer periods as could be applicable to those of the yellow maize (under natural drying conditions), because of the high moisture content of the former; this will create enabling room for optimum exploitation of their storage values

## 6. Appendix 1

R<sub>1</sub>

$$S_1 = \frac{34.3313 - 32.4419}{34.3313 - 20.3500} \times \frac{100}{1} = \frac{1.8894}{13.9813} \times \frac{100}{1} = 13.5\%$$

$$S_2 = \frac{14.5201 - 13.7928}{14.5201 - 10.8611} \times \frac{100}{1} = \frac{0.7273}{3.6590} \times \frac{100}{1} = 19.9\%$$

$$M = (13.5 + 19.9) - \frac{(13.5 \times 19.9)}{100} = 33.4 - 2.67 = 30.7\%$$

R<sub>2</sub>

$$S_1 = \frac{34.4224 - 30.0248}{34.4224 - 20.4424} \times \frac{100}{1} = \frac{4.3976}{13.9800} \times \frac{100}{1} = 31.5\%$$

$$S_2 = \frac{14.6046 - 14.5521}{14.6046 - 10.9130} \times \frac{100}{1} = \frac{0.0525}{3.6916} \times \frac{100}{1} = 1.4\%$$

$$M = (31.5 + 1.4) - \frac{(31.5 \times 1.4)}{100} = 32.9 - 0.441 = 32.5\%$$

$$M_{avg.} = \frac{30.7 + 32.5}{2} = 31.6\%$$

### A. Moisture Content Computation for Sample B

(R<sub>1</sub>)

$$S_1 = \frac{36.6240 - 33.9925}{36.6240 - 22.0025} \times \frac{100}{1} = \frac{2.6315}{14.6215} \times \frac{100}{1} = 18.0\%$$

$$S_2 = \frac{15.5036 - 15.3016}{15.5036 - 11.8013} \times \frac{100}{1} = \frac{0.2020}{3.7023} \times \frac{100}{1} = 5.5\%$$

$$M = (18.0 + 5.5) - \frac{(18.0 \times 5.5)}{100} = 23.5 - 0.99 = 22.5\%$$

(R<sub>2</sub>)

$$S_1 = \frac{36.7071 - 35.0059}{36.7081 - 22.9034} \times \frac{100}{1} = \frac{1.7012}{13.8037} \times \frac{100}{1} = 12.3\%$$

$$S_2 = \frac{16.0411 - 15.8512}{16.0411 - 11.1424} \times \frac{100}{1} = \frac{0.4599}{4.8987} \times \frac{100}{1} = 9.4\%$$

$$M = (12.3 + 9.4) - \frac{(12.3 \times 9.4)}{100} = 21.7 - 1.2 = 20.5\%$$

$$M_{avg.} = \frac{22.5 + 20.5}{2} = 21.5\%$$

## Energy analysis of an ultrasound-assisted atmospheric freeze-drying process for food

### **Abstract**

*The atmospheric freeze-drying process can be significantly accelerated using power ultrasound. This paper aims to investigate the impact of power ultrasound on the energy consumed by the process. Apple, carrot and eggplant were chosen as representative products with different textures and water content. A mathematical model of the whole plant required to carry out the atmospheric ultrasound-assisted freeze-drying process was developed. Model parameters were tuned according to the results obtained in a pilot-scale unit. Life Cycle Assessment (LCA) was used to gain an insight on the environmental impact of the process. The results showed that the use of ultrasound reduces the total energy consumption of the whole process, while the LCA analysis highlighted the cooling system as the most critical stage for all the impact categories.*

**Keywords:** *atmospheric freeze-drying; ultrasound; process modeling; LCA.*

## 1. Introduction

During the atmospheric freeze-drying process water is removed from a frozen product thanks to the difference between the water partial pressure in the ice and in the drying chamber [1]. To guarantee this driving force, a stream of dry air is used as carrying agent for moisture [2]. This provides some specific advantages with respect to the traditional batch vacuum freeze-drying, among others, a continuous processing and a reduction of total energy consumption [3]. Besides, the advantages of low temperature drying, in terms of product quality, are also obtained in this case [4]. The limiting step of the atmospheric freeze-drying process is the low drying rate that can be achieved, and thus several methods have been proposed to accelerate it. In this sense, power ultrasound appears to be particularly successful to increase drying kinetics [5]-[7], without affecting product quality [8], mainly because of the moderate thermal effect with respect to other techniques, e.g. microwaves.

However, a rigorous investigation on the impact of power ultrasound on the energy consumed by the process is still missing; this paper aims to gain an insight on this issue.

## 2. Materials and Methods

The research included the following steps: products with different porosity were chosen and the kinetics of the ultrasonically assisted dehydration were obtained from literature; the actual energy consumption of a laboratory dryer with ultrasound application was measured and a model of an industrial scale drier was developed. Finally a life cycle assessment (LCA) was carried out to calculate the potential environmental impacts of the process.

### 2.1. Raw materials

Three different products were considered in this study, namely apple (*Malus domestica* cv. Granny Smith), carrot (*Daucus carota* L.) and eggplant (*Solanum melongena* L.), whose experimental drying kinetics have been published elsewhere [5]-[8]. These products are characterized by a very different internal structure, which explains their different porosity (0.423 for the eggplant, 0.233 for the apple and 0.031 for the carrot) [9]. From the literature, the moisture effective diffusion coefficients at different drying conditions were obtained:

- air velocity: 1, 2 and 4 m s<sup>-1</sup>;
- air temperature: -10, 0, 10 and 20°C
- ultrasonic power applied: 0, 10.3, 20.5 kW/m<sup>3</sup>.

## **2.2 Lab-scale dryer**

The experimental drying kinetics of these products were determined in a lab-scale dryer [5] which consists of a cylindrical chamber where food samples are placed. The chamber acts as the ultrasound radiator, which is directly connected to a piezoelectric transducer. The required air flow rate is obtained through a fan. The air at the exit of the chamber is recycled, and the temperature of the air is thus decreased by means of a heat exchanger, using a glycol–water solution (45% v/v) at  $-19^{\circ}\text{C}$ . The cold air is subsequently heated at the desired drying temperature in contact with an electric resistance. The air stream is then forced to pass through a desiccant material, which is periodically changed and regenerated. The electric energy consumed by the different elements of the systems (fan, ultrasonic generator and heating resistance) was experimentally measured with a power quality analyzer (Fluke 435, Fluke Corporation Holland) at the different drying conditions considered.

## **2.3 Industrial-scale dryer**

In order to assess the effect of the operating conditions on the energy consumption of the real freeze drying process, an industrial-scale process was designed and simulated. A sketch of the industrial-scale dryer is shown in Fig. 1.

In the system, the frozen product is placed onto the shelves of the drying chamber. Dry cold air flows continuously, heating the product (as ice sublimation is endothermic) and removing the moisture. The outlet air is then filtered and cooled in such a way that the moisture is partially removed. This system also encompasses a desiccant wheel, which removes the moisture from the air, and a heating system which increases the temperature of the air stream used to regenerate the desiccant material/wheel. Before entering the drying chamber, a heating system is used to bring the process air to the required temperature. Moreover, air-handling systems are used to move both the stream of air to the drying chamber and that used for the regeneration.

The plant was designed to process 100 kg of fresh product, with a shelf size of 2 m x 1 m and a shelf-to-shelf distance of 0.1 m.

## **2.4 Mathematical modeling**

A mathematical model was used to calculate the energy consumption of the different systems of the lab-scale dryer. Model parameters were tuned based on the results obtained in the lab-scale unit, thus allowing the use of the model to simulate the whole industrial dehydration process. The air stream was considered to be incompressible, due to the low pressure drop. The pressure drop in the various pieces of the equipment was calculated according to their

geometry. A temperature drop of 2°C was considered in the drying chamber due to the exchange with the external environment, independently of the operating conditions (as measured experimentally). Regarding the cooling unit, the outlet air temperature was determined modeling the heat exchange in the unit according to its specific geometry. The drying kinetics of the investigated products was modelled according to the data available in the literature [5]-[7].

As to the modelling of the industrial-scale apparatus, the model of the drying chamber was the same reported by Colucci et al. [7], while data about the energy required by the desiccant system were taken from the catalogue of the manufacturer [10]. The energy consumed by the ultrasound system was calculated using the correlation obtained in the lab-scale system, while the pressure drops, and the heat exchanged, were calculated taking into account the specific geometry of the system.

Fig. 1: Sketch of the industrial unit.

## 2.5 Life Cycle Assessment

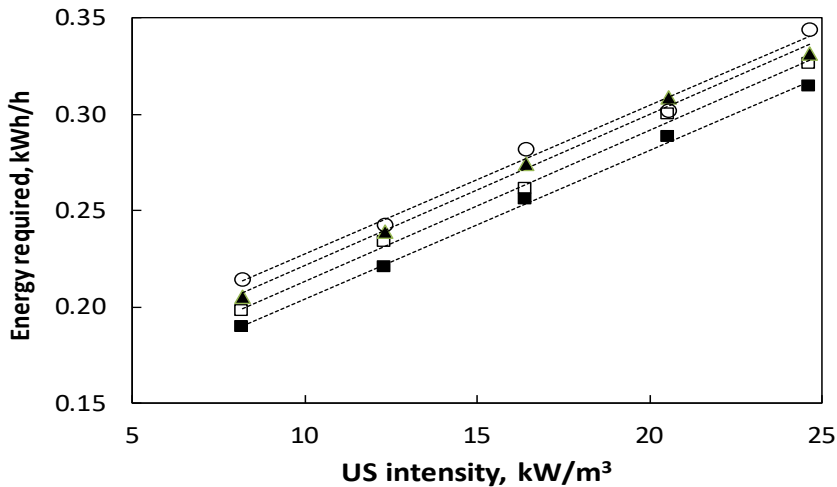

To calculate the environmental impact of the simulated industrial-scale process of the different products, a Life Cycle Assessment (LCA) [11] was carried out. The functional unit to which all the process inputs and outputs were related was 1 kg of processed product. Gate

to gate system boundaries were set. Capital goods manufacturing were not included. Process inventory data were obtained from the mathematical simulation of the industrial plant whereas background data (production of electricity, ethylene glycol, R-404) were obtained from Ecoinvent 3.1 database. ReCiPe 1.08 with a hierarchical approach was used to calculate the environmental impacts.

### 3. Results

In the first part of the study, the values of the actual energy consumption in the different units of the lab-scale dryer were compared to the calculated ones. Thus, the adequacy of the proposed equations used was proved/tested, and the missing parameters that best fit the experimental results were estimated. The fan and resistance efficiencies were calculated, obtaining values of 0.298 and 0.95 respectively. Using these parameters, the error between the measured experimentally energy consumption, and the calculated one ranged from 0.25% to 6.25%, depending on the operating conditions considered.

The effect of the air velocity on the energy consumed by ultrasonic generation system was negligible regardless of the product. On the contrary, the higher the air temperature and ultrasound intensity applied, the greater the energy consumed by the system (Fig. 2).

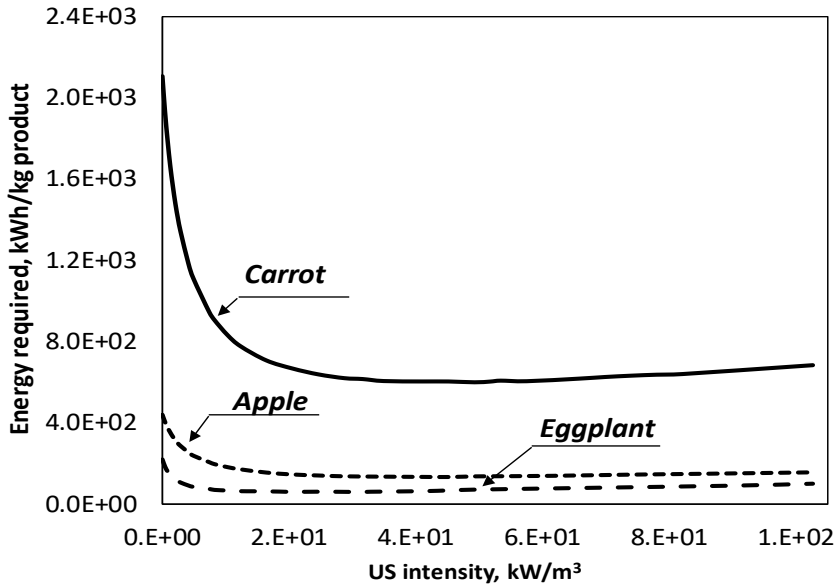

**Fig. 2:** Influence of the ultrasound (US) intensity and of the operating temperature (■:  $-10^{\circ}\text{C}$ , □:  $0^{\circ}\text{C}$ , ▲:  $10^{\circ}\text{C}$ , ○ =  $20^{\circ}\text{C}$ ) on the energy required by ultrasound generating system. Dotted line shows the linear relationship calculated by Eq. 1.

A linear equation was proposed to relate these parameters:

$$P_{US} = 10^{-3} I_{US} + 2 \cdot 10^{-5} T_{air}^{1.571} \quad (1)$$

where  $P_{US}$  is the power required by the ultrasound generating system (kW),  $I_{US}$  is the ultrasound intensity and  $T_{air}$  is the air temperature. This equation was used in the simulation of the industrial scale unit, to calculate the total energy consumed (Fig. 3).

**Fig. 3: Influence of the type of product and of the ultrasound (US) intensity on the total energy required by the process.**

Relevant differences in the energy consumption were observed for the products considered in the study due to the differences in the water diffusivity, since the higher the water diffusivity the shorter the time needed to dry the product. That means that in the case of ultrasonically assisted drying, although the use of ultrasound increased the energy consumption per hour ( $\text{kWh} \cdot \text{h}^{-1}$ ), the total energy consumption of the whole process (kWh) was lower, since the total operation time is reduced. In particular, about 70% energy reduction was obtained in those drying experiments with an ultrasonic power of  $10.3 \text{ kW/m}^3$ , regardless of the product processed. An optimal value of ultrasound intensity corresponding to the minimum energy required was observed, as shown in Fig. 2. When ultrasound is applied, the drying time is reduced as well as the total energy consumption. However, when the ultrasound power is above a certain threshold, the increase of the energy consumption per hour of process does not compensate the drying time reduction.

The LCA results showed that the use of ultrasound allowed all the impact indicators to be reduced compared to a conventional atmospheric freeze-drying process (Fig. 4). Besides, the LCA results highlighted the cooling system as the most critical stage for all the impact categories studied. This is mainly due to the use of ethylene glycol and R-404 in the refrigeration cycle. Nevertheless, when dehydrating low porosity products, the energy consumption of the air dryer increased, and this stage becomes the most critical from an environmental point of view.

**Fig. 4:** Climate change impact, as kg-equivalents of CO<sub>2</sub>, for the atmospheric freeze-drying of 1 kg of eggplant. Red bar shows data for non-ultrasonic assisted drying and blue bar for ultrasonically assisted freeze drying (20.5 kW/m<sup>3</sup>)

#### 4. Conclusions

The use of power ultrasound in an atmospheric freeze-drying process allows to both speed-up the process, and to save energy compared to the conventional process. About 70% of the total energy required by the process can be saved using ultrasound and the main impact parameters considered in a LCA can be reduced of about 40 to 50%. Considering the values of kWh per kg of product processed, the process appears particularly attractive for those high porosity products, whose structure allows a high diffusivity of water vapor in the dried layer to be obtained.

## 1. Introduction

Food preservation aims at preventing the growth of bacteria, fungi and other microorganisms as well as retarding oxidation of fats to reduce rancidity, thus allowing it to be stored for longer periods. Water is the main food component involved in food spoilage reactions, thus the decrease of water activity by dehydration is one of the oldest and well-known preserving strategies<sup>[1]</sup>. Drying reduces weight and volume so foods can be carried easily and can be storage in low space needs. Besides this, any preservation method should ensure that the quality, edibility and the nutritive value of the food remain as intact as possible. For this purpose, different dehydration methods can be used depending on the type of product. Dehydration techniques can be divided in two main groups according to whether the water is eliminated in the liquid phase, as in the case of osmotic dehydration, or if the water is removed by surface evaporation<sup>[2]</sup>. In the case of osmotic methods, sugar or salt are used in syrup or brine form to dehydrate fruits, meat or fish products, while in evaporation methods, an air flow is needed to remove the water from the food surface; this is the case of bed dryers, fluidized bed dryers, shelf dryers, spray drying, etc.

It is well known that microwaves can assist most of food drying processes; but despite its benefits, microwave energy has not yet been exploited to its potential in the industrial applications. Some of the reasons are because available microwave technology (tubes and valves) cannot offer a homogeneous heating, causing hot/cold spots depending on product geometry and distribution in the chamber or tunnel<sup>[3]</sup>. Particularly in drying processes, when available water decreases, the efficiency of the process will decrease. If the microwave power is not adjusted at this point of the drying process, the electromagnetic field strength increases, and thermal runaway, arcing, or plasma formation can be created. Currently, the solid-state microwave heating (S<sup>2</sup>MH) technology is considered one of the most promising options to avoid the ancient problems preserving the known advantages<sup>[4]</sup>. The new S<sup>2</sup>MH features include frequency and phase variability and control, low input-voltage requirements, compactness and rigidity, reliability, and better compatibility with other electronic possibilities (Internet-of-Things). The first notable advantage is the S<sup>2</sup>MH system ability to assess feedback from forward and reflected signal<sup>[4]</sup>. This allows the application to easily measure and track the energy levels being put into the load, which can avoid the mentioned final drying problems, together with many others related to monitoring needs. On the other hand, almost all energy consumption and CO<sub>2</sub> generation in drying processes correspond to air heating stage. To tackle this problem, Advanced Materials for Microwaves based Heating (AM<sup>2</sup>H) have been developed for transducing electromagnetic energy into heat, which is transferred to air by using high contact surface ceramic structures. The aim of this work is to review Microwaves Assisted Drying Processes and to present the advantages offered by two

innovative microwave technologies: Solid-State Microwave Heating (S<sup>2</sup>MH) technology and Advanced Materials for Microwaves based Heating (AM<sup>2</sup>H).

## 2. Microwave-assisted drying in Food Technology. Advantages and drawbacks

Microwave drying is a process based on the volumetric heating that involves heat generation and mass transfer. The heat is generated within the product because of dipolar induction and orientation when the electromagnetic field is alternated. During the process, electromagnetic energy is transformed into heat, and the corresponding vapor is then spread through internal pressure gradient; water is evaporated and transported toward the surface. However, microwaves alone cannot fully complete a drying process, so combined techniques are highly recommended, such as forced-air or vacuum-drying, in order to complete the drying and further improve the process efficiency<sup>[5]</sup>. Air and vacuum act then as carriers of evaporated moisture and contribute to a more homogeneous and faster drying. Utilization of microwaves combined to conventional drying processes have shown beneficial effects, mainly energy savings, reduced processing time and operational costs without mitigating the food quality<sup>[6]</sup>. During **Microwaves-assisted air-drying**, microwaves can be applied either at the beginning, when the drying rate begins to fall, or at the end of the process of falling rate <sup>[7]</sup>. Microwave-assisted air-drying acts as follows: on the one hand, the airflow favors the removal of outside moisture of the product, while the volumetric heating of the microwaves leads to an intensive moisture evaporation and transportation toward the food surface. This combined process has been extensively proven to reduce drying time, and thus, energy requirements, while improving product quality <sup>[7-9]</sup>. Thus, reductions of 55–85% of drying time were reported when microwaves assisted hot-air drying of apple and strawberry slices<sup>[8]</sup>, and of osmotic pre-treated cherry tomatoes<sup>[9]</sup>, compared to analogous air-dried products. Berteli and Marsaioli<sup>[10]</sup> observed a reduction of drying time by a factor of 10 times during pasta drying compared to conventional air drying. They also highlighted a decrease of 90% of the space required for drying when microwaves are applied. With regards to **Intermittent microwave-convective drying** (IMCD), which consists of microwave application at pulsed rates, has been widely used because of it results in more homogenous moisture and temperature distributions together with an enhanced quality of the dried foods<sup>[11]</sup>. For instance, Soysal et al.<sup>[12]</sup> reported a processing time reduction of 4.7-17.3 and better sensory qualities of oregano under IMCD conditions. **Microwave-assisted vacuum drying** has been widely studied in the recent years due to the advantages derived from combining the volumetric heat absorption provided by microwaves with an increase of drying kinetics at reduced pressure <sup>[6]</sup>. The absence of air prevents oxidation and thus, the color, flavor and texture are minimally affected. As vacuum drying requires less temperature, high vitamin contents are retained compared to convective drying. Some attempts have been also performed to evaluate the impact of microwaves during freeze-drying. In this sense, Duan et al.<sup>[13]</sup> reported an additional decrease of energy consuming and freeze-drying time when microwaves power is

used to supply the heat of sublimation. Some studies have also paid attention to the **Microwave-assisted infrared drying**. Considering that the main limitation of infrared drying is the low penetrating power, microwave energy has been applied together to compensate this weakness. Notable time savings (from 55 to 98 %) were obtained in banana, kiwifruit, raspberry, green pepper and egg plants subjected to different conditions of microwave and infrared energies combinations<sup>[6]</sup>.

Apart from the reduction of drying rates, the application of microwaves presents a positive impact on rehydration capacity of dried products and, in volume and bioactive compounds retention<sup>[14]</sup>.

Despite of the remarkable benefits of microwave application in food drying, its implementation in the food industry remains still not common, even if some formerly successful applications has been listed<sup>[15]</sup> such as in pasta drying, snack drying and, in the finish drying of potato chips, biscuits and crackers. The major limitation for their industrial employment seems to be the loss of efficiency of the microwave process as long as dehydration of the food progresses. The reduction of available water causes an increase of the electromagnetic field strength (because of load mismatch) and the consequent lower microwaves absorption during drying, being necessary an adaptation of microwaves power at this point of the drying process, that is not easy. This adaptation would be also dependent on the dielectric properties, size and geometry of the product, and on the presence of other materials that also absorb the microwaves, and therefore modifies the local field strength<sup>[14]</sup>. Other additional problems that could appear are thermal runaway, arcing, or plasma generation because of a drastic increase of the electromagnetic field strength causing damages in both the equipment and the product. The homogenous distribution of microwaves power in the drying chamber remains also a challenge to be solved due to the undesirable occurrence of hot and cold spots in the product, causing reflections that can lead to overheating in central areas, edges or corners<sup>[3,16]</sup>. Some manufacturers tried to solve this lack of homogeneity by the incorporation of mode stirrers or a turntable (as in household microwave ovens), although appropriate homogeneity has not been achieved. In addition, the design of microwaves-assisted dryers to reach an optimal heat distribution is unique for a binomial process-product; thus, reducing the versatility of the drying process to be extended to other food products.

### **3. Solid-State Microwave Heating technology (S<sup>2</sup>MH)**

The solid-state technology allows producing microwaves with power enough to generate heat inside dielectric materials, using solid state transistors to amplify a specific signal instead of valves (which are power oscillators). At the beginning of this century, the laterally-diffused metal-oxide semiconductor (LDMOS) technology became mature and cost-effective, in particular for the market segment of cellular communication base-stations<sup>[4]</sup>. The first

relevant use of a LDMOS amplifier for microwave heating purposes (~10cc samples) was presented in 2006 at IMPI-40 by Schwartz et al.<sup>[17]</sup>. Solid-State RF Amplifiers (LDMOS) efficiency has improved in recent years to performance levels compared to magnetron-based conventional microwave systems: from 50% efficiency and 180W in 2014 to 68.5% efficiency and 250W in 2017<sup>[18]</sup>.

There are several differences in the design and performance between S<sup>2</sup>MH and magnetron systems. Mainly, while valves systems generate powered waves in a given spectrum (inside a bandwidth from ISM), the systems based on LDMOS have more degrees of freedom, being able to vary frequency (inside a bandwidth and among them) and the power (in amplitude and phase) in real time. In addition, LDMOS are littler, more durable (4 vs. 20 years) and permit better compatibility with electronic circuitry (Internet-of-Things). Among these advantages, the most important it the capacity of the S<sup>2</sup>MH system to evaluate the feedback from forward and reflected power levels (amplitude, phase), what favors the measurement and control of the energy levels present in the system. This feature could solve the load mismatching along the process, one of the main problems in drying applications. Moreover, the feedback system will detect and manage the problems of thermal runaway along the drying process, a big limitation of microwave-assisted drying. Different authors have developed new techniques to improve efficiency, with the aim of maximizing microwave absorption, by developing algorithms controlling frequency and phase<sup>[19]</sup>. Concretely, it has been developed a feedback scheme capable of associate the scatter parameters related to the dielectric properties to the load temperature changes in food. Furthermore, the system integrates the measurements of cavity power delivery into an oven. Detailed ‘fingerprints’ of the load can be sensed in this way, which provide feedback from the changing dielectric and structural properties of the food as heating proceeds<sup>[19]</sup>. In addition, the capability of the S<sup>2</sup>MH to modify frequency bandwidth (among the permitted in ISM), and thus, the penetration depth, could minimize the problems of size and geometry refereed in magnetron based systems<sup>[3,16]</sup>. Recently, Tang et al.<sup>[20]</sup> have proposed a novel method (using a solid-state amplifier) to improve heating uniformity by selecting optimal frequencies. From the industrial point of view, only in microwave ovens capable to modify the frequency range will extend the variability of products (different sizes). Apart from the signal measurement and control, S<sup>2</sup>MH modules offer excellent reliability (reduced “Mean Time Between Failures”), security (lower voltage), scalability, and design freedom (regarding form factor and system integration), which will allow a better industrial implementation<sup>[4]</sup>.

#### **4. Advanced ceramic materials to absorb microwave energy quickly and efficiently**

Advanced Materials for Microwaves based Heating (AM<sup>2</sup>H) have been recently developed by adding a ceramic matrix composite<sup>[21]</sup>. AM<sup>2</sup>H can be performed adding high loss factor materials (SiC, zirconia) into low loss factor ceramic matrix (Al<sub>2</sub>O<sub>3</sub>, cordierite). These

materials behave as localized susceptors into ceramic matrix and work as high energy source (due to microwave energy absorption). Beyond the materials applications, Microbiotech have patented a heating system (named MBT-01) that uses AM<sup>2</sup>H as heat emission elements which are heated by means of microwave radiation distributed by planar technology<sup>[22]</sup>. The first stage was to optimize AM<sup>2</sup>H to be used as heat emitter by achieving the non-reciprocal behavior that would lead to energy efficiency. The MBT-01, is the result of the research on the combination of different ceramic matrix with microwave susceptors integrated in it<sup>[23]</sup>. Once optimized, MBT-01 has been integrated in novel planar devices able to transduce wave energy (2.45 GHz) to heat with an efficiency better than 99%, both in microstrip (resonant) and stripline (wideband) variations<sup>[23]</sup>. Fig. 1 shows a transducer, and some thermographic images obtained along a heating of an integrated cell, applying 30W at 2.45 GHz per cell.

**Fig. 1. Picture of stripline radiators (A) and, (B) Thermographies of a heating cycle, applying 30 W microwave power at 2.45 GHz per cell, on the right<sup>[24]</sup>.**

The ability to increase 10°C the ambient temperature with a 300 W prototype has been tested in controlled conditions; the high thermal inertia of the ceramic material to be heated with microwaves allow to save about 60% of energy as compared to current electric ceramic heaters. Savings in CO<sub>2</sub> emissions with respect to electrical systems are about 70% (analysis performed with the energy certification program Ce3X). Fig. 2 shows the temperature variation of the surface, where the non-reciprocal behavior can be appreciated (heating rate (0.75 ± 0.03 °C/s) vs. cooling rate (0.05 ± 0.02 °C/s)<sup>[25]</sup>.

**Fig. 2. Temperature variation of the surface of a 300 W prototype<sup>[26]</sup>.**

The capacity of AM<sup>2</sup>H to heat fluids was also tested, obtaining high-energy efficiency using on-off cycles (efficiencies about 69.8% in water heating)<sup>[26]</sup>.

## 5. Conclusions and future prospects

Microwave energy improves efficiency and quality of food drying processes; but the common use technology (tubes and valves) cannot offer a homogeneous heating, causing hot/cold spots depending on product geometry and distribution in the chamber or tunnel. S<sup>2</sup>MH technology is considered one of the most promising options to avoid the ancient problems preserving the known advantages. Additionally, S<sup>2</sup>MH offers several advantages over tubes and valves because admits more flexibility in energy application and control, has low input-voltage requirements, compactness, rigidity, reliability, durability and compatibility with other electronic possibilities. S<sup>2</sup>MH allows the application to easily measure and track the energy levels being put into the load, which can avoid the mentioned final drying problems, as well as others related to monitoring needs. Moreover, the use of optimized AM<sup>2</sup>H (quick and high-efficiency) can heat air and fluids. Future works will lead to AM<sup>2</sup>H based microwave devices with optimized tridimensional structures to improve air heating.

### **Abstract**

*The knowledge of water vapour diffusion in biomaterials is very important in several fields of application (drying, building materials, food packaging...). The process of vapour water transfer in biomaterials is usually described by Fick's law of diffusion. Nevertheless, sometimes the experimental data of transient experiments in biosourced materials do not respect the standard Fickian model.*

*The precise determination and formulation of this non-Fickian behaviour is therefore an important topic. This work presents a new methodology to quantify the non-Fickian diffusion. Based on memory functions and imbedded in a comprehensive heat and mass transfer computational model, the method is robust and prone to be applied to different biomaterials. Examples of application are proposed in the case of biofilms and lignocellulosic materials.*

**Keywords:** Biofilm; Low Density Fiberboard; Modeling; Non-Fickian diffusion; Wood

## 1. Introduction

A detailed understanding of water vapour transfer in biomaterials is very important in several fields of application (drying, building materials, food packaging...). Regarding the drying process, the value of mass diffusivity, as well as its variations with moisture content, governs the second drying period, which is the most important in terms of drying time, energy consumption and product quality. As they are exposed to cyclic changes in relative humidity of the air, inducing cyclic changes in moisture content and bound water transfer, biomaterials used in building are always in transient regime. Finally, in the case of biofilms used as barrier in food packaging, the transfer properties are among the most important physical properties to ensure a good end-use.

Nevertheless, experimental data of water vapour uptake of some biomaterials showed that did not follow the standard Fickian model. In these works, a phenomenon of slowing down the process of mass transfer at the final stage, often called non-Fickian behaviour was observed [1, 2]. In polymer science, this phenomenon is attributed to molecular relaxation, either at a local scale or at a global scale, in relation with stress relaxation [3, 4, 5]. The precise determination of this non-Fickian behaviour showed to be a difficult task since the physical phenomena causing this non-Fickian behaviour is different depending on the biomaterial structure and physical properties.

This work presents a new methodology to quantify the non-Fickian diffusion very robust and prone to be applied to different biomaterials. Examples of application of this methodology on porous [6] and amorphous polymer [7] will be presented. The final part of this paper is devoted to abnormal behaviours, due to dual-scale effects, observed at short times in the case of low density fiberboards (LDF) [8].

## 2. Materials and Methods

### 2.1 Materials

Vapour sorption experiments were applied on two types of biomaterials: porous material (wood, thermal-treated wood, Low density Fiberboard) and amorphous polymer (biofilms).

Sorption tests have been performed on native and thermally modified European beech (*Fagus sylvatica* L.). Thermally modified wood samples were submitted to a temperature level of 220°C during 60 min [6]. The oven dry density of unmodified and thermally modified wood was 680 and 655 kg/m<sup>3</sup>, respectively. The interested reader can refer to the reference [6] for a detailed description of the experiments.

Concerning biofilms, neat PLA (Polylactide) films were prepared using the casting method described in [9]. Biofilms were 60 - 80  $\mu\text{m}$  thick, with a standard deviation of 20 %. They were stored over  $\text{P}_2\text{O}_5$  at room temperature prior to sorption tests.

Prior to the sorption tests, the LDF samples was stabilised to an equilibrium moisture content close to 12%. The disk-shaped samples, with a diameter of 72 mm, were cut from the equilibrated material from 20-mm thick panels. An epoxy resin was applied to the lateral face of the sample to block the surface porosity. Because of the propensity of fibreboard samples to absorb the epoxy resin, the resin was first applied to a thin strip of aluminium, which was then applied around the sample.

## 2.2 Sorption tests

### 2.2.1 Sorption tests applied on wood samples

The samples were firstly stored in containers with controlled air temperature of 20°C and relative humidity of ca. 35% during 6 months, wich allowed obtaining their uniform initial bound water content. Then the samples were transferred to the set-up with controlled air parameters, i.e. temperature of 23.5°C, relative humidity of 75.5% and the forced air flow of 0.8 m/s. The final bound water content of each sample was determined by the gravimetric method after the sorption experiment. More details about the vapour mass sorption results can be found in [6].

### 2.2.2 Sorption tests applied on biofilms

Water vapour sorption was performed by using dynamic vapour sorption with a DVS intrinsic apparatus (Surface Measurement Systems, London, UK). A support pan was specially designed to allow the entire film surface to be available for the vapour exchange. Approximately 20 mg of sample was placed in the sample pan. The samples were first equilibrated at 0% RH over 360 min. The amount of dry matter was determined at the end of this plateau. Then, the RH was increased to 30% and maintained at this level for 1440 min. Finally, the RH was increased to 90% and maintained at this level for 2880 min. Preliminary tests confirmed that the duration of each RH plateau was sufficient to attain the equilibrium condition (the rate of change of mass per unit time ( $\text{dm}/\text{dt}$ ) was less than 0.0005%/min). The data were saved every 20 s. More details about the methodology are available in [9].

### 2.2.3 Sorption tests applied on LDF

LDF samples were tested according to a new method proposd in [8]. The principle of this method is to impose a sudden change in RH on one side of the sample to create a transient

diffusive flux through the sample. The RH measured on the back face of the sample provides the information from which the mass diffusion coefficient is determined by inverse analysis. To that purpose, a specific device was conceived and built to obtain quasi 1-D transfers along the sample thickness. This requires the back face chamber, where the RH is measured, to be perfectly airtight and as small as possible [8].

### 3. Mathematical model to determine the Non-Fickian diffusion

Several effects taking place at the local, microscopic scale, have important effects at the macroscopic scale. In this section, we will treat two major effects encountered in bio-based building materials :

- molecular relaxation : due to the mobility of macromolecules, new sorption sites appear due to the reorganization of molecules after change of bound water content. For ligno-cellulosic materials, this is particularly observable at high levels of relative humidity or for thermally modified products [8, 10],
- dual scale effects : due to the long characteristic time of diffusion in the secondary cell wall, the local equilibrium sometimes fails. At the macroscopic level, this induces a delay between the change of air characteristics and the moisture content of the product, even at the very fine microscopic scale.

#### 3.1 Molecular relaxation

This phenomenon can be approached using a relaxation function, defined by a sudden change of RH surrounding the product at the microscopic scale, from  $RH_{ini}$  to  $RH_{fin}$ , assuming the cell wall to be at equilibrium at  $t = 0$  ( $X_{ini} = X_{eq}(RH_{ini})$ ). In this case, the evolution of the local moisture content is simply the signature of molecular relaxation:

$$X(t) - X_{ini} = \Delta X_{eq} \times \varphi(t) \tag{1}$$

where  $\Delta X_{eq}$  is defined by the sorption isotherm values  $\Delta X_{eq} = X_{eq}(RH_{fin}) - X_{eq}(RH_{ini})$  and  $\varphi$  a monotonic function which respects  $\lim_{t \rightarrow \infty} \varphi(t) = 1$ .

In a more general case, the value of  $RH$  varies continuously in time, so that a convolution product is required :

$$X(t) - X_{ini} = \int_0^t \varphi(t-\tau) \frac{\partial X_{eq}}{\partial \tau} d\tau \tag{2}$$

It is obvious from equation (1) that if  $\varphi$  is the casual function (the Heaviside function, see Fig. 1), any memory effect vanishes.

**Fig. 1.** Some possible shapes of the relaxation function.

### 3.2 Dual scale effects

Similar effects can arise from dual scale phenomena : depending on the characteristic time for the moisture field to equilibrate at the microscopic scale, a delay might exist between the equilibrium moisture content and the actual moisture content. This is known as the failure of the local thermodynamic equilibrium. For the sake of example, we can refer to mass diffusion in a cylindrical fiber of radius  $a$ . By neglecting the resistance to mass transfer in the gaseous phase of the porous medium, the equilibrium moisture content  $X_{eq}$  can be used as Dirichlet boundary conditions at the solid phase surface. In the case of a perfect cylindrical shape for example, the corresponding analytical solution reads [11]:

$$X(r,t) - X_{ini} = \Delta X_{eq} \times \left( 1 - \frac{2}{a} \sum_{n=1}^{\infty} \frac{\exp(-D\alpha_n^2 t) J_0(r\alpha_n)}{\alpha_n J_1(a\alpha_n)} \right) \quad (3)$$

Where the values of  $\alpha_n$  are the positive roots of

$$J_0(a\alpha_n) = 0 \quad (4)$$

Where  $J_0(x)$  and  $J_1$  are the Bessel functions of the first kind of order zero and one. The integration of equation (3) over the cylindre volume allows the average moisture content  $\bar{X}$  to be obtained :

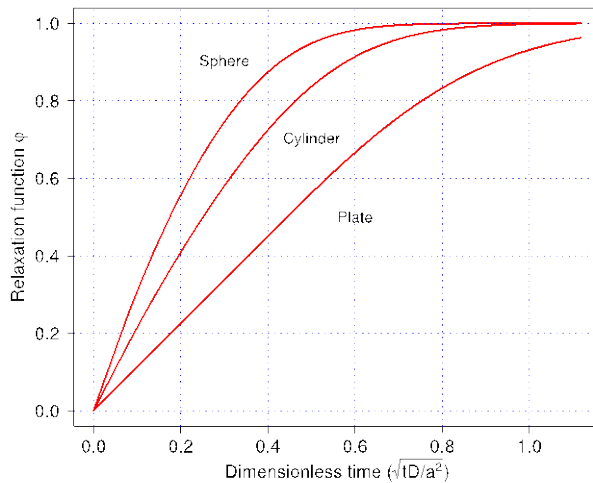

$$\bar{X}(t) - X_{ini} = \Delta X_{eq} \times \left( 1 - \sum_{n=1}^{\infty} \frac{4}{a^2 \alpha_n^2} \exp(-D\alpha_n^2 t) \right) \quad (5)$$

This equation is very similar to the equation obtained in the case of molecular relaxation (2). A function  $\varphi$  can be therefore be deduced from equation (5):

$$\varphi(t) = 1 - \sum_{n=1}^{\infty} \frac{4}{a^2 \alpha_n^2} \exp(-D\alpha_n^2 t) \quad (6)$$

### 3.2 Computational solution

The previous sections tells us that equation (2) is a general expression allowing the non-Fickian behaviour to be accounted for in the macroscopic formulation. The kernel function  $\varphi$  is therefore the signature of the product behaviour and its history can be expressed as the form of a convolution product that account for the time evolution of the conditions undergone by the product. This formulation was embedded in the coupled heat and mass transfer code *TransPore*, a custom computational model currently used in our team as comprehensive physical engine to perform inverse analysis [8, 12].

**Fig. 2. Dimensionless change of moisture content. Result obtained for different shapes using the first 500 terms of the respective analytical solutions [11].**

## 4. Results

The water vapour uptake of the biomaterials studied can be observed in Figs 3 and 4. Each figure contains experimental results and predicted bound water content changes as a function of the square root of time simulated by the formulation presented in the previous section.

Fig. 3 gives a clear vision of transient water vapour transfer in native wood (left) and thermally treated wood (right). The parameter identification allows the sorption behaviour to be represented as a combination of Fickian and non-Fickian behaviour. The red line stands for the full model whereas the blue line was obtained by cancelling the relaxation function (its value was set constant at  $\varphi(t) = \varphi(0), \forall t$ ). The effect of thermal treatment on the wood/water relations is obvious in the plots : significant reduction of the sorption isotherm [13] and considerable increase of the non-Fickian part. Olek et al. [6] attributed this non-Fickian behaviour to the chemical changes in wood components (hemicellulose, cellulose and lignine) caused by thermal treatment.

*Fig. 3. Sorption tests and theoretical analysis for native (left) and thermally treated beech wood (right). Note the impressive increase of the non-Fickian behavior in treated wood (after Olek et al. [6])*

*Fig. 4. Sorption tests and theoretical analysis for PLA. (after Almeida et al. [7]).*

Table 1 list the diffusion parameters identified by the model: Diffusion coefficient, following the Fickian diffusion law ( $D_0$ ), total amount of bound water molecules allowed by relaxation and reorganization of already sorbed water at infinite time ( $\varphi(0)$ ) and time constant of relaxation ( $\tau$ ). According to these parameters, thermal modification alters the diffusion behavior of wood in two characteristics: (a) significant reduction of diffusivity, (b) dramatic increase of the non-Fickian part [6]. For PLA, the determined diffusion coefficient ( $D_0=5.7 \times 10^{-12} \text{ m}^2 \cdot \text{s}^{-1}$ ) is in the range of published data [5, 14]. Works in progress depicts also a large increase of the non-Fickian proportion when the PLA film is charged with nanostructures.

**Table 1. Fickian and non-Fickian Diffusion parameters determined by the model**

<b>Biomaterial</b>	<b><math>D_0</math> (<math>\text{m}^2 \cdot \text{s}^{-1}</math>)</b>	<b><math>\varphi(0)</math></b>	<b><math>\tau</math> (s)</b>
Unmodified wood <sup>a</sup>	$0.58 \cdot 10^{-10}$	0.065	$5.35 \cdot 10^5$
Thermally treated wood <sup>a</sup>	$0.38 \cdot 10^{-10}$	0.47	$7.65 \cdot 10^5$
PLA <sup>b</sup>	$0.057 \cdot 10^{-10}$	0.18	$0.67 \cdot 10^5$

<sup>a</sup> data from Olek *et al.* [6]; <sup>b</sup>Almeida *et al.* [7].

The final part of this paper is devoted to transient diffusion in LDF ( $160 \text{ kg} \cdot \text{m}^{-3}$ ). This kind of materials, used for insulation in construction, presents an open porosity that allows a rapid diffusion at the macroscopic level. Therefore, in spite of the huge contrast between the macroscopic dimension (thickness in buildings) and the microscopic solid phase (the order of one or some natural fibers) the characteristic time diffusion of the micro- and macro-scale overlaps. This induces a non-local equilibrium and alter the macroscopic behavior. In this case of open porosity, the macroscopic mass transfer is expressed as follows :

$$q_v = -\rho_g f D_v \nabla \omega_v \tag{7}$$

Where  $D_v$  is the diffusivity of water vapour in air and  $f$ , the product parameter, represents the dimensionless coefficient of resistance ( $0 < f < 1$ ). In order to focus on the dual-scale effect and to avoid the relaxation effect, we focus here on the first hours of diffusion (Fig. 5). When using the usual macroscopic formulation, yet accounting rigorously for the coupling between heat and mass transfer, an unrealistic value of  $f$  (2.5) is needed for the model to fit the experimental data. This was already discussed in [8]. Using a relevant value of  $f = 0.5$ , as predicted by homogenisation from the real 3D morphology [15], the model predict a too low dynamic of RH increase at the back face. Finally, the use of a simple

$\phi$  function, whose parameters were determined by identification, the dynamic of RH evolution can be captured with the same value of  $f(0.5)$ . Additional works are in progress in our team to further test this new approach. It seems in particular that this new formulation allows both the MC and the RH at the back face to be simulated with the same set of parameters.

*Fig. 5. The back-face method with LDF: experimental RH value at the back face of the sample and computed evolution obtained with various assumptions (data after Perré et al. [8]).*

## 5. Conclusion

This paper presents a general approach to account, at the macroscopic level, for various situations of non-Fickian diffusion in biosourced products. This model is applied to experimental data of water vapour uptake of biomaterials presenting completely different physico-chemical structure (porous biomaterials with different morphologies and biopolymer films). The proposed model is able to describe the diffusion behavior of such biomaterials and differences obtained are discussed. It is proved that the non-Fickian diffusion must be taken into account for such materials in order to insure its proper transformation and good end-use.
