Based on a work in <http://ocs.editorial.upv.es/index.php/IDS/IDS2018>

I am delighted and truly honoured to welcome you to IDS2018. As you know this is a landmark event representing completion of four decades since the establishment of this biennial series in 1978 at McGill University, Montreal, Canada.

I am happy to note that IDS2018, like its predecessor events, has attracted significant academic and industry interest in drying research and development from around the world. Exchange of ideas and dissemination of knowledge about both fundamental aspects and industrial applications have been the prime motivations for holding IDS events around the globe. As an interdisciplinary and multidisciplinary field which combines complex multi-phase transport phenomena with material science, drying is also highly energy-intensive and has controlling influence on the dried product quality in diverse industrial sectors. I believe that IDS and sister conferences devoted to drying have had a very significant impact on enhancements in drying technologies and innovation in dryer design. Much remains to be done of course.

I am sure the participants in IDS2018 will find the proceedings and networking opportunities rewarding and their stay in the wonderful historic city of Valencia memorable.

Finally, on behalf of all the attendees may I take this opportunity to thank and congratulate the Program Chair and his hardworking Organizing Committee supported by authors, reviewers and of course all the volunteers assisting with the smooth running of this complex event.

Arun S. Mujumdar

IDS Honorary Chairman

In this 40th anniversary of IDS it is a real honour to host at the Universitat Politècnica de València the celebration of IDS2018.

This is an event that, like in all other its predecessors, has attracted worldwide attention. Over 300 researchers from over 40 countries will present more than 450 papers at this event. As we can see IDS2018 promises to be a highly successful event. We are confident the founder of the IDS series Arun S. Mujumdar, would be very proud of it.

On this occasion we wanted to bring the event inside the University campus in order to get the students more actively involved in the organization and to make them aware of the importance and the impact of drying on many industries and different aspects of our life. This is a down to earth field that many times has been underestimated by our students and it's value needs to be recognized. Drying involves many aspects that may attract the interest of our students, from sustainability to product quality and the diversity of products. Valencia and the Mediterranean area have a long tradition of addressing the drying process; just remember the importance of dried fish on the Roman times that you still it find in our markets.

The quality of the contributions is very high and the discussion during the event will enhance fruitful exchanges among the participants. We hope that the academic environment will help to attain the goal of a friendly and fruitful interaction in the beautiful city of Valencia. We believe this event will fulfil your expectations.

On behalf of the Organizing Committee

Antonio Mulet

Chairman IDS2018

## **Organizing committee**

---

### **Co-Presidents:**

**Jose V. Garcia-Perez**

Universitat Politècnica de València, Spain

**Susana Simal**

## INDEX

---

### Key Notes

- Drying of mangoes applying pulsed UV light as pre-treatment 1  
*Thayane Rabelo Braga, Ebenezer Oliveira Silva, Sueli Rodrigues, Fabiano Andre Narciso Fernandes*
- Process intensification and process control in freeze-drying 9  
*Antonello A Barresi, Roberto Pisano*
- Supercritical CO<sub>2</sub> drying of food matrices 17  
*A. Zambon, T. M. Vizzotto, G. Morbiato, M. Toffoletto, G. Poloniato, S. Dall'Acqua, M. De Bernard, S. Spilimbergo*
- Ultrasound enhancement of osmotic dehydration and drying – Process kinetics and quality aspects 25  
*Grzegorz Musielak*
- Using Life Cycle Assessment methodology to minimize the environmental impact of dryers 33  
*Angélique Léonard, S. Gerbinet*
- Beyond freeze-drying of biologics: vacuum-foam drying and spray freeze-drying 41  
*A. Langford, B. Balthazor, B. Bhatnagar, S. Tchessalov, M.J. Hageman, A. Lukas, M. Plitzko, B. Luy, S. Ohtake*
- New technique of combined hot air and microwave drying to produce a new fiber ingredient from industrial by-products 49  
*Clara Talens, Marta Castro-Giráldez, Pedro J. Fito*
- Influence of drying on in vitro gastric digestion of beetroot: evaluation of the microstructure 57  
*Valeria Eim, Esperanza Dalmau, Juan A. Cárcel, Susana Simal*

Simultaneous wetting and drying; fluid bed granulation and tablet film coating <i>Ian C Kemp, Alex van Millingen, Houda Khaled, Lewis Iler</i>	65
Electrohydrodynamic (EHD) drying: fundamentals and applications <i>Alex I Martynenko, Tadeusz Kudra</i>	73
<b>Fundamentals, modeling and simulation – Oral Presentation</b>	<b>81</b>
Robust feedback control of continuously operated convective dryers for particulate materials <i>Carsten Seidel, Christoph Neugebauer, Robert Dürr, Andreas Bück</i>	83
Mathematical modeling of moisture evaporation in co-current foam spray drying <i>Maciej Jaskulski, Artur Lewandowski, Ireneusz Zbiciński</i>	91
A mathematical model of spray drying granulation process in formulation <i>Hiroyuki Kagami</i>	99
Mechanical and thermal segregation of milli-beads during contact heating in a rotary drum. DEM modeling and simulation <i>Aline Mesnier, Maroua Rouabah, Roman Peczalski, Séverine Vessot-Crastes, Pascal Vacus, Julien Andrieu</i>	107
The investigation of internal pressure development in convective drying of shrinking and non-shrinking materials using green and fired clay as an example <i>Anna Adamska, Zdzislaw Pakowski, Robert Adamski</i>	115
Multi-zone & multi-compartment model for dynamic simulation of horizontal fluidized bed granulator <i>Lisa Mielke, Andreas Bück, Evangelos Tsotsas</i>	123
Measuring REA-based drying kinetics through temperature-moisture content relationship <i>Xiao Dong Chen, Aditya Putranto</i>	131
Energy analysis and conservation opportunities in spray dryers <i>Sanjay Kumar Patel, Mukund Haribahu Bade</i>	139

The construction of thermodynamic expressions needed in the physicochemical mathematical model required for the rational quantitative evaluation of the freeze drying process of pharmaceutical solutions employing tertiary butyl alcohol as a co-solvent	147
<i>Jee-Ching Wang, Roberto Bruttini, Athanasios I Liapis</i>	
Implementation of p-controller in Computational Fluid Dynamics (CFD) simulation of a pilot scale outlet temperature controlled spray dryer	155
<i>Sepideh Afshar, Hasan Jubaer, Lloyd Metzger, Hasmukh Patel, Cordelia Selomulya, Meng Wai Woo</i>	
Application of multivariate image analysis to thermal images for in line monitoring of the freeze-drying process	163
<i>Domenico Colucci, José Manuel Prats-Montalban, Davide Fissore, Alberto Ferrer Riquelme</i>	
Feasibility of Vis/NIR spectroscopy and image analysis as basis of the development of smart-drying technologies	171
<i>Barbara Sturm, Roberto Moscetti, S.O.J. Crichton, Sharvari Raut, Michael Bantle, Riccardo Massantini</i>	
Modeling of atmospheric freeze-drying for sliced fruit	179
<i>Akane Horie, Takashi Kobayashi, Kyuya Nakagawa</i>	
Thermodynamic model of freeze-drying of poultry breast using infrared thermography	187
<i>Juan Angel Tomas-Egea, Marta Castro-Giraldez, Pedro J Fito</i>	
Rotary wheel atomizer study using computational fluid dynamics and full-scale testing	195
<i>Tórstein Vincent Joensen, Maximilian Kuhnenn, Frank Vinther, Mads Reck, Cameron Tropea</i>	
<b>Fundamentals, modeling and simulation – Poster Presentation</b>	<b>203</b>
Modeling of particle behavior in a wurster fluidized bed: Coupling CFD-DEM with Monte Carlo	205
<i>Zhaochen Jiang, Christian Rieck, Andreas Bück, Evangelos Tsotsas</i>	

CFD model-supported design of monodisperse co-current spray dryers <i>Maciej Jaskulski, Thi Thu Hang Tran, Evangelos Tsotsas</i>	213
Pore network model of primary freeze drying <i>Nicole Vorhauer, P. Först, H. Schuchmann, E. Tsotsas</i>	221
Moisture diffusion coefficient estimation in peas drying by means of a modified Hawladar and Uddin method <i>Carlos Martínez-Vera, Mario Vizcarra-Mendoza</i>	229
New model for the rehydration characteristics of white yam at different temperatures <i>Akinjide A. Akinola, S. N. Ezeorah, E. P. Nwoko</i>	237
A pore-scale study on the drying kinetics and mechanical behavior of particle aggregates <i>T. S. Pham, B. Chareyre, E. Tsotsas, A. Kharaghani</i>	245
Investigation of 3D particle flow in a flighted rotating drum <i>Lanyue Zhang, Fabian Weigler, Zhaochen Jiang, Vesselin Idakiev, Lothar Mörl, Jochen Mellmann, Evangelos Tsotsas</i>	253
Thermo-economic analysis of an efficient lignite-fired power system integrated with flue gas fan mill pre-drying <i>Xiaoqu Han, Jiahuan Wang, Ming Liu, Sotirios Karellas, Junjie Yan</i>	261
Drying behavior, diffusion modeling of cuminum cyminum L. undergoing microwave-assisted fluidized bed drying <i>Atefe Babaki, Gholamreza Askari, Zahra Emamdjomeh</i>	269
Model of the solutes transfer during osmotic dehydration of vegetal matrices: a proposal <i>Sahylin Muñoz-Becerá, Lilia Leticia Méndez-Lagunas, Juan Rodríguez-Ramírez, Sadoth Sandoval-Torres</i>	277
Three-dimensional measurement of internal structure in frozen food materials by cryogenic microtome spectral imaging system <i>Gabsoo Do, Sadanori Sase, Yeonghwan Bae, Tatsurou Maeda, Shigeaki Ueno, Tetsuya Araki</i>	283

Dynamic optimization of the transmission efficiency between the solid state microwave sources and the microwave applicator <i>Simon Zuber, Marcel Joss, S. Tresch, M. Kleingries</i>	291
Discrete modeling of ion transport and crystallization in layered porous media during drying <i>Arman Rahimi, T. Metzger, A. Kharaghani, E. Tsotsas</i>	299
Dependency of continuum model parameters on the spatially correlated pore structure studied by pore-network drying simulations <i>Xiang Lu, Abdolreza Kharaghani, Evangelos Tsotsas</i>	307
Use of a multi-vial mathematical model to design freeze-drying cycles for pharmaceuticals at known risk of failure <i>Bernadette Scutellà, Ioan Cristian Trelea, Erwan Bourlés, Fernanda Fonseca, Stephanie Passot</i>	315
Comparison between the finite differences, finite volume and finite element methods for the modelling of convective drying of fruit slices <i>Adriana María Castro, Edgar Yesid Mayorga, Fabian Leonardo Moreno</i>	323
The role of boundary conditions on the dynamics of green coffee beans in a rotated dryer <i>M.V.C. Machado, I.A. Resende, R.M. Lima, R.J. Brandão, M.R. Pivello, S.M. Nascimento, C.R. Duarte, M.A.S. Barrozo</i>	331
Lattice Boltzmann modeling and simulation of isothermal drying of capillary porous media <i>Githin Tom Zachariah, Debashis Panda, Vikranth Kumar Surasani</i>	339
Drying kinetics of cellulose nanofibers suspensions <i>Belal Al Zaitone</i>	347
Convective air drying of brown seaweed <i>Bifurcaria bifurcata</i> in thin layer configuration <i>Santiago Arufe-Vilas, Jorge Sineiro, Francisco Chenlo, Ramón Moreira</i>	355
Hybrid solar-gas-electric dryer optimization with genetic algorithms <i>H. El Ferouali, M. Gharafi, A. Zoukit, S. Doubabi, Naji Abdenouri</i>	363

Multivariable modeling of an innovative hybrid solar-gas dryer <i>A. Zoukit, H. Elferouali, I. Salhi, S. Doubabi, Naji Abdenouri</i>	371
Identification of moisture transport mechanism in gypsum during convective drying <i>Robert Adamski, A. Adamska, Z. Pakowski</i>	379
Modeling of kinetics of drying process of polycapramide granules considering its sorption properties <i>Maria Konstantinovna Kosheleva, Olga Roaldovna Dorniyak, Marina Sergeevna Maklusova</i>	387
Computational fluid dynamics simulation of spray dryers: transient or steady state simulation? <i>S. Afshar, H. Jubaer, B. Chen, J. Xiao, X. D. Chen, M. W. Woo</i>	395
Semi empirical models for drying of agricultural products by used structured artificial neural network <i>Kornél Bessenyei, Zoltán Kurják, János Beke</i>	403
Image Segmentation and 3D reconstruction for improved prediction of the sublimation rate during freeze drying <i>Luigi C Capozzi, Andrea Arsiccio, Amelia C Sparavigna, Roberto Pisano, Antonello A Barresi</i>	411
Mathematical relationship between glass transition temperature and water activity of cellular and non-cellular food systems <i>Thanh Khuong Nguyen, Seddik khalloufi, Cristina Ratti</i>	419
Modeling sorption isotherms and isosteric heat of sorption of roasted coffee beans <i>Gentil Andres Collazos-Escobar, Nelson Gutiérrez-Guzmán, Henry Alexander Vaquiro-Herrera, Erika Tatiana Cortes-Macias</i>	427
Modelling the water sorption isotherms of <i>Warionia Saharæ</i> and determination of sorption heats and drying kinetics <i>Fedol Amel, A. Cheriti</i>	435

Hybrid cylinder dryer for the drying of sheet-form materials with hot air <i>Sung Il Kim, Sang Hyun Oh, Won Pyo Chun, Ki Ho Park, Byoung Hyuk Yu</i>	443
Thermodynamic properties and moisture sorption isotherms of two pharmaceutical compounds <i>A. Zammouri, M. Ben Zid, N. Kechaou, N. Boudhrioua Mihoubi</i>	449
Comparison between bubbling and turbulent regime for the simulation of batch pharmaceutical powders fluidized bed drying <i>A. Zammouri, N. Boudhrioua Mihoubi, N. Kechaou</i>	457
Modeling and simulation of intermittent drying of high moisture foods <i>Ana Paula Filippin, Érika Fernanda Rezendes Tada, João Claudio Thomeo, Maria Aparecida Mauro</i>	465
The aggregation rate constant of the discrete population balance model in hot melt fluidized bed coating process <i>W. Xin, Y. Yan, X. Qing, W. Long</i>	473
Study of the hot air drying process of chicken breast by non-invasive techniques <i>Juan Angel Tomas-Egea, Marta Castro-Giraldez, R.J. Colom,, Pedro J Fito</i>	481
Flat plate solar air heater with helical integrated fins for drying processes <i>Maytham A. Al-Neama, Istvan Farkas</i>	489
Drying of sugarcane bagasse in a partially filled horizontal drum <i>Érika Fernanda Rezendes Tada, Andreas Bück, Fernanda Perpétua Casciatori, João Cláudio Thoméo</i>	497
Moisture content modeling and effective moisture diffusivity determination during convective solar drying of blackberry ( <i>rubus spp</i> ) and basil ( <i>Ocimum basilicum L.</i> ) <i>Anabel López-Ortiz, Octavio García-Valladares, Isaac Pilatowsky-Figueroa, Juan Rodriguez-Ramírez</i>	505
Drying characteristics and mathematical modelling of the drying kinetics of oyster mushroom ( <i>Pleurotus ostreatus</i> ) <i>A. A. Satimehin, M. O. Oluwamukomi, V. N. Enujiugha, M. Bello</i>	513

Thermodynamic model of Ca(II)-alginate beads drying by spectrophotometry <i>Patricio R. Santagapita, Marta Castro-Giraldez, Maria Victoria Traffano-Schiffo, Pedro J Fito</i>	521
Development and use of three-dimensional image analysis algorithms to evaluate puffing of banana slices undergone combined hot air and microwave drying <i>A. Satiengkijumpai, M. Jinorose, S. Devahastin</i>	529
On the importance of heat and mass transfer coupling during characterization of hygroscopic insulation materials <i>Patrick Perre, Arnaud Challansonnex</i>	537
A physical interpretation of the use of fractional operators for modelling the drying process <i>Patrick Perre, Ian Turner</i>	545
Theoretical and experimental investigation of temperature and moisture distributions and changes in nutritional quality during Intermittent Microwave Convective Drying <i>Imran Khan, Nghia Duc Pham, Azharul Karim</i>	553
<b>Drying Products – Oral Presentation</b>	<b>561</b>
Effects of different drying conditions on curcumin concentration in turmeric <i>Qixin Li, Robert H Driscoll, George Srzednicki</i>	563
Electrically enhanced drying of white champignons <i>Ivanna Bashkir, Tadeusz Kudra, Alex Martynenko</i>	571
Influence of drying conditions on process properties and parameter identification for continuous fluidized bed spray agglomeration <i>Gerd Strenzke, Ievgen Golovin, Maximilian Wegner, Stefan Palis, Andreas Bück, Achim Kienle, Evangelos Tsotsas</i>	579
Encapsulation of krill oil by spray drying <i>S. Takashige, A. Hermawan Dwi, A. Sultana, H. Shiga, S. Adachi, H. Yoshii</i>	587
Thin layer drying behaviour of fermented cocoa ( <i>Theobroma cacao</i> L.) beans <i>Saheeda Mujaffar, Aveena Ramroop, Darin Sukha</i>	595

Microencapsulation of pumpkin seed oil by spray dryer under various process conditions and determination of the optimal point by RSM <i>Mansoureh Geranpour, Zahra Emam-Djomeh, Gholamhassan Asadi</i>	603
Nano spray drying of pharmaceuticals <i>Cordin Arpagaus</i>	611
Evolution of “Chili” Tunisian landrace durum wheat sprouts properties after drying <i>Sarra Jribi, Hela Gliguem, Andras Nagy, Nagy Gabor Zsolt, Lilla Szalóki-Dorkó, Zoltan Naër, Ildiko Bata-Vidács, Sarra Marzougui, Zsuzsanna Cserhalmi, Hajer Debbabi</i>	619
Cellulosic fibre drying: fundamental understanding and process modeling <i>Sabyasachi Mondal, Puja Agarwala, Suvankar Dutta, Vishvas Naik-Nimbalkar, Pratik Pande, Sunil Dhumal</i>	627
Study and optimization of freeze-drying cycles of a model probiotic strain <i>Pierre Verlhac, Séverine Vessot-Crastes, Ghania Degobert, Claudia Cogné, Julien Andrieu, Laurent Beney, Patrick Gervais</i>	635
Enhancing antioxidant property of instant coffee by microencapsulation via spray drying <i>Desi Sakawulan, Richard Archer, Chaleeda Borompichaichartkul</i>	643
Ambient temperature drying of therapeutic protein solution with use of microwave <i>Takaharu Tsuruta, Takuma Ogawa, Ryosuke Abe, Hirofumi Tanigawa</i>	651
Immobilization of <i>Candida rugosa</i> lipase on eco-friendly supports by spouted-bed technology: Use in the synthesis of isoamyl caprylate <i>Tales Alexandre Costa-Silva, Ana Karine Furtado Carvalho, Claudia Regina Fernandes Souza, Larissa de Freitas, Heizir F Castro, Wanderley Pereira Oliveira</i>	659
Recent developments in functional bakery products and the impact of baking on active ingredients <i>Lu Zhang, Remko M. Boom, Xiao Dong Chen, Maarten A.I. Schutyser</i>	667

The effect of drying on the mechanical properties and structure of biodegradable films <i>Gabriela Silveira da Rosa, Sai Vanga, Yvan Gariepy, Vijaya Raghavan</i>	675
Investigation of influence of pre-treatment and low-temperature on drying kinetics, sorption properties, shrinkage and color of brown seaweeds ( <i>Saccharina Latissima</i> ) <i>Ignat Tolstorebrov, Trygve Magne Eikevik, Inna Petrova, Yulia Shokina, Michael Bantle</i>	683
Stabilization of encapsulated probiotics from the bacterium <i>Lactobacillus casei</i> by different drying techniques <i>Elsa Maritza Acosta-Piantini, M. Carmen Villaran, Jose Ignacio Lombrana</i>	691
Coupling of microwave radiations to convective drying for improving fruit quality <i>N. Bahloul, M. A. Balti, M. S. Guellouze, N. Kechaou</i>	699
Ohmic heating/vacuum impregnation treatments on osmodehydrated apples enriched in polyphenols from concentrated pomegranate juice <i>J. Moreno, P. Zúñiga, M. E. Guerra, K. Mella</i>	707
Valorization of the tomato to obtain a powder rich in antioxidant constituents <i>Djamel Mennouche, Abdelghani Boubekri, Bachir Bouchekima, Slimane Boughali, Rebiha Moumeni, Djihad Boutadjine</i>	715
Effect of solar radiation on cooking/drying process of grapes using solar oven <i>Jannika Bailey, Marta Castro-Giráldez, Alfredo Esteves, Pedro J Fito</i>	723
Microstructural characterization of apple tissue during drying using X-Ray microtomography <i>M. M. Rahman, M. M. Billah, M.I.H. Khan, A. Karim</i>	731
<b>Drying Products – Poster Presentation</b>	<b>739</b>
Solar drying of strawberry coated with nopal mucilage: It's effect on phenolic compounds <i>M.J. León,, A. López-Ortiz, F.I. Pilatowsky, L.L.L. Méndez</i>	741

Optimization of the spray drying process for the obtaining of coconut powder (Cocos nucifera L.) fortified with functionally active compounds <i>J. C. Lucas-Aguirre, G. Giraldo, R. M. Cortes</i>	749
Effect of phospholipid composition on the structure and physicochemical stability of proliposomes incorporating curcumin and cholecalciferol <i>Matheus Andrade Chaves, Samantha Cristina Pinho</i>	757
Physical properties of commercial infant milk formula products <i>Eoin G Murphy, Nicolas E Regost, Yrjo H Roos, Mark A Fenelon</i>	765
Relaxation of ceramic tile stresses generated by fast drying: a kinetic model <i>J. L. Amorós, V. Cantavella, E. Blasco</i>	773
Fixed-bed drying of grains: analysis of the structural properties of packed-beds of non-spherical particles <i>Heitor O Nogueira Altino, Maria do Carmo Ferreira</i>	781
Effects of ozone pretreatment on drying kinetics and quality of Granny Smith Apple dried in a fluidized bed dryer <i>Thatyane Vidal Fonteles, Ronnyely Braz Reis do Nascimento, Sueli Rodrigues, Fabiano Andre Narciso Fernandes</i>	789
Effects of assistance of high frequency dielectric and infrared heating on vacuum freeze drying characteristics of food model <i>Atsushi Hashimoto, Ken-ichiro Suehara, Takaharu Kameoka, Kazuhiko Kawamura</i>	795
Estimation of the apparent glass transition temperature of spray-dried emulsified powders and yeast powders by their flavor release behavior under temperature ramping conditions <i>A. Sultana, J. L. Zhu, H. Yoshii</i>	803
Hot air drying combined vacuum-filling nitrogen drying of apple slices: Drying characteristics and nutrients <i>Xiaoli Huang, T. Li, S.N. Li, Z.H. Wu, J. Xue</i>	811

Bioavailability of freeze-dried and spray-dried grapefruit juice vitamin C <i>María del Mar Camacho, Marta Igual, Juan José Martínez-Lahuerta, Nuria Martínez-Navarrete</i>	819
Economic feasibility of freeze-drying to obtain powdered fruit <i>María del Mar Camacho, Miguel Ángel Casanova, Loreto Fenollosa, Javier Ribal, Juan José Martínez-Lahuerta, Nuria Martínez-Navarrete</i>	827
Influence of freeze-drying conditions on orange powder flowability <i>Mariana Usganda, Andrea Silva, Luis Egas, María del Mar Camacho, Nuria Martínez-Navarrete</i>	835
Impact of shelf temperature on freeze-drying process and porosity development <i>L. A. Egas-Astudillo, A. Silva, M. Uscanga, N. Martínez-Navarrete, M. M. Camacho</i>	843
Effect of saccharide additives on dehydration–drying kinetics and quality properties of dried kiwi fruit products <i>Shigeaki Ueno, Rei Iijima, Mari Harada, Hsiuming Liu, Reiko Shimada, Ken Fukami</i>	851
Drying of wastes of almond shells in conical spouted beds <i>Maria J San Jose, Sonia Alvarez, Raquel Lopez</i>	857
Effect of air drying temperature on phytochemical properties of brown seaweed <i>Bifurcaria bifurcata</i> <i>Santiago Vilas Arufe, Jorge Sineiro, Francisco Chenlo, Ramón Moreira</i>	865
Effect of spray drying conditions on antioxidants activity, flavonoids and total phenolic compounds of stevia <i>rebaudiana</i> <i>Irene Chaparro-Hernández, Juan Rodríguez-Ramírez, Lilia L. Méndez-Lagunas, Luis Gerardo Barriada-Bernal</i>	873
Effects of drying conditions on the content of glycosides and antioxidants of packed bed of stevia leaves <i>Juan Rodríguez-Ramírez, Beatriz Noyola-Altamirano, Luis Gerardo Barriada-Bernal, Lilia L. Méndez-Lagunas</i>	879

Effect of ultrasound on drying kinetics of El Henna leaves ( <i>Lawsonia inermis</i> ) <i>Said Bennaceur, Lyes Bennamoun, Antonio Mulet, Belkacem Draoui, Juan A. Cárcel</i>	887
Spray drying of lipid nanosystems (SLN and NLC) loaded with <i>Syzygium aromaticum</i> essential oil <i>Debora Morais Rosa, Wanderley Pereira Oliveira</i>	895
Effect of rehydration on texture properties of Mexican plum ( <i>Spondias purpurea</i> L.) dehydrated by tray drying and freeze drying <i>Paulina Guillen-Velazquez, Cinthia Muñoz-López, Denis Cantu-Lozano, Guadalupe Luna-Solano</i>	903
Evaluation of the physicochemical properties of dehydrated artisanal cheese during storage <i>Carlos Jair Calis-Pérez, Alfredo Domínguez-Niño, Galo Rafael Urrea-García, Guadalupe Luna-Solano</i>	911
The infrared radiation and vacuum assisted drying kinetics of flue-cured tobacco leaf and its drying quality analysis <i>Wenkui Zhu, Gaofei Guo, Chaoxian Liu, Liangyuan Cheng, Le Wang</i>	919
Moisture sorption isotherms and isosteric heat sorption of habanero pepper ( <i>Capsicum chinense</i> ) dehydrated powder <i>Mario Luna-Flores, Mariana Gisela Peña-Juarez, Angélica Mara Bello-Ramirez, Javier Telis-Romero, Guadalupe Luna-Solano</i>	927
Observation of microstructure change during freeze-drying by in-situ X-ray Computed Tomography <i>Kyuya Nakagawa, Shinri Tamiya, Shu Sakamoto, Gabsoo Do, Shinji Kono, Takaaki Ochiai</i>	935
A green coffee based product and its comparasion to commercial products regarding the antioxidant capacity <i>F. C. A. Souza, E. F. Souza, S. M. Pontes, W. F. Leal Junior, O. Freitas-Silva, R. I. Nogueira</i>	943
Nutritional potential of dehydrated residues from rice milk production <i>Luan Ramos Silva, A. C. A. B. Casari, J. I. Velasco, F. M. Fakhouri</i>	951

Healthy apple snack developed using microwaves <i>Dinar Fartdinov, Josep Comaposada, Israel Muñoz, Nieco De Wit, Pere Gou, Maria Dolors Guàrdia</i>	957
Solar convective drying kinetics and sorption isotherms of Citrus aurantium flowers <i>Hicham El Ferouali, Ahmed Zoukit, Said Doubabi, Naji Abdenouri</i>	965
Organic apples (cv. Elstar) quality evaluation during hot-air drying using Vis/NIR hyperspectral imaging <i>Luna Shrestha, Roberto Moschetti, Stuart Crichton, Oliver Hensel, Barbara Sturm</i>	973
Physicochemical parameters and consumer acceptance in espresso and american coffee pods <i>Lina Ximena Parrado, Andrés Felipe Bahamon, Nelson Gutierrez</i>	981
Physicochemical characterization of mesquite flours <i>S. Sandoval Torres, L. Reyes López, L. Méndez Lagunas, J. Rodríguez Ramírez, G. Barriada Bernal</i>	989
Thermal stability of amorphous sugar matrix, dried from methanol, as an amorphous solid dispersion carrier <i>K. Imamura, K. Takeda, K. Yamamoto, H. Imanaka, N. Ishida</i>	997
Effect of tray dryer's independent variables (drying temperature and air velocity) on the quality of olive pomace and system's energy efficiency <i>Ulaş Baysan, Mehmet Koç, A. Güngör, Figen Kaymak-Ertekin</i>	1005
Identification of key factors determining the surface oil concentration of encapsulated lipid particles produced by spray drying <i>Annika Linke, Tobias Balke, Reinhard Kohlus</i>	1013
Technological and nutritional aspects of gluten-free pasta based on chickpea flour and tiger nut flour <i>M. E. Martín-Esparza, G. B. Bressi, A. Raga, A. Albors</i>	1021
Experimental investigation of drying of malt bagasse <i>B. D. Zorzi, K. Machry, P. Krolow, C. M. Moura, E. G. Oliveira, G. S. Rosa</i>	1029

Vitamin C content of freeze dried pequi ( <i>Caryocar brasiliense</i> Camb.) pulp <i>C. T. Soares, F. G. Nogueira, A. A. Santana, R. A. Oliveira</i>	1035
Effect of spray drying on volatile compounds of acerola pulp <i>P. M. Nogueira, M. T. Leite Neta, H. C. S. Araújo, M. S. Jesus, S. Shanmugam, N. Narain</i>	1043
Aroma retention during drying of caja-umbu fruit pulp <i>Anderson Santos Fontes, Maria Terezinha Santos Leite-Neta, Patricia Nogueira Matos, Hannah Caroline Santos Araújo, Monica Silva Jesus, G. Rajkumar, Narendra Narain</i>	1051
Blackberry pulp microencapsulation with arrowroot starch and gum arabic mixture by spray drying and freeze drying <i>Gislaine Ferreira Nogueira, Farayde Matta Fakhouri, Rafael Augustus de Oliveira</i>	1059
Drying conditions and analysis of physicochemical characteristics of <i>Capsicum pubescens</i> <i>Consuelo Sánchez-García, Óscar Andrés Del Ángel-Coronel, Ingrid Paniagua-Martínez, Guadalupe Luna-Solano, Alejandra Ramírez-Martínez</i>	1067
Functional properties of dried tarragon affected by drying method <i>Banu Koç, Nazan Çağlar, Gamze Atar</i>	1075
Effect of the solar dehydration on the antioxidant capacity and the content of flavonoids of the blackberry pulp ( <i>rubus</i> spp) <i>Azucena Silva-Norman, Anabel López-Ortiz, Isaac Pilatowsky-Figueroa, Octavio García-Valladares</i>	1083
Long-term maintenance of dried acellular matrices <i>Alessandro Zambon, Giovanni Giobbe, Massimo Vetralla, Filippo Michelino, Luca Ubani, Maria Pantano, Nicola Pugno, Paolo De Coppi, Nicola Elvassore, Sara Spilimbergo</i>	1091
Spray dried proliposomes of <i>Rosmarinus officinalis</i> polyphenols: a quality by design approach <i>Victor Oloruntoba Bankole, Claudia Regina F. Souza, Wanderley Pereira Oliveira</i>	1099

The drying and rehydration process of chayote ( <i>Sechium edule</i> ) <i>Alejandra Álvarez-Morales, Guadalupe Luna-Solano, Alejandra Ramírez-Martínez</i>	1107
Drying parameters influence on 'Ameclya' <i>Opuntia ficus</i> prickly pear oil quality <i>L. Hassini, H. Desmorieux</i>	1115
Generation of high drug loading amorphous solid dispersions by Spray Drying <i>Bhianca Lins de Azevedo Costa, Martial Sauceau, Romain Sescousse, Maria Ines Re</i>	1123
Effect of particle size of blueberry pomace powder on its properties <i>Laura Calabuig-Jiménez, Cristina Barrera, Lucia Seguí, Noelia Betoret</i>	1131
Changes in antioxidant and probiotic properties of a freeze-dried apple snack during storage <i>Cristina Burca, Lucia Seguí, Noelia Betoret, Cristina Barrera</i>	1139
Preliminary study of superheated steam spray drying: A case study with maltodextrin <i>Maelada Fuengfoo, Sakamon Devahastin, Chalida Niumnuy, Somchart Soponronnarit</i>	1147
Influence of drying temperature and ultrasound application in some quality properties of apple skin <i>Matheus P. Martins, Edgar J. Cortés, Susana Simal, Antonio Mulet, Nieves Pérez-Muelas, Juan A. Cárcel</i>	1155
Radio frequency-vacuum drying of kiwifruits: kinetics, uniformity and product quality <i>Shaojin Wang, Xu Zhou</i>	1163
Characteristics of oven-dried Jerusalem artichoke powder and its applications in phosphate-free emulsified chicken meatballs <i>Burcu Öztürk, Meltem Serdaroglu</i>	1171

Quality changes of sucuks produced with turkey meat and olive oil during fermentation and ripening <i>Aslı Zungur-Bastioğlu, Meltem Serdaroglu, Burcu Öztürk, Berker Nacak</i>	1179
Impacts of air drying and DIC pretreatments on textural properties of frozen/thawed apple fruits <i>L. Ben Haj Said, S. Bellaga, K. Allaf</i>	1187
Partial drying of apple fruits to improve freeze/thaw quality during long term frozen storage <i>L. Ben Haj Said, S. Bellaga, K. Allaf</i>	1195
Combined effects of sodium carbonate pretreatment and hybrid drying methods on the nutritional and antioxidant properties of dried Goji berries <i>Huihui Song, Jinfeng Bi, Qinqin Chen, Mo Zhou, Xinye Wu, Jianxin Song</i>	1203
<b>Drying Process – Oral Presentation</b>	<b>1211</b>
Experimental analysis of particle breakage and powder morphology in foam spray drying <i>Artur Lewandowski, Maciej Jaskulski, Ireneusz Zbiciński</i>	1213
Spray drying of high viscous food concentrates: Investigations on the applicability of an Air-Core-Liquid-Ring (ACLR) nozzle for liquid atomization <i>Marc Oliver Wittner, Heike Petra Karbstein, Volker Gaukel</i>	1221
Heat recovery from biomass drying in energy systems <i>J. Havlik, T. Dlouhý</i>	1229
Capillary disconnect during drying in model porous media at different wettability <i>Ayorinde K Rufai, John P Crawshaw</i>	1237
Ultrasound assisted low temperature drying of food materials <i>H. T. Sabarez, S. Keuhbauch, K. Knoerzer</i>	1245
Microwave assisted fluidized bed drying of celery <i>Amanat Kaur, Yvan Gariépy, Valérie Orsat, Vijaya Raghavan</i>	1251

The consumption of exergy for lignite drying with different technologies: a comparative theoretical study <i>Ming Liu, Shan Wang, Rongtang Liu, Xiaoqu Han, Junjie Yan</i>	1261
CT-scanning of the drying process of <i>Eucalyptus nitens</i> <i>José Couceiro, Lars Hansson, Ahec Ambrož, Dick Sandberg</i>	1269
Effects of different drying methods on the physicochemical properties of powders obtained from high-oleic palm oil nanoemulsions <i>M. Hernández-Carrión, M. Moyano-Molano, L. Ricaurte, F.L. Moreno, Maria Ximena Quintanilla-Carvajal</i>	1277
Multifluid macroscopic approach to drying in papermaking <i>Francisco J. Durán-Olivencia, Milad Farzad, Burt S. Tilley, Jamal S. Yagoobi</i>	1285
Freeze dried quince ( <i>Cydonia oblonga</i> ) puree with the addition of different amounts of maltodextrin: physical and powder properties <i>Özle Ünlüeroğlugil, Hira Yüksel, Gülşah Çalışkan Koç, Safiye Nur Dirim</i>	1293
Drying the corn in a farm heat pump dryer with fluidized bed <i>S. P. Rudobashta, G. A. Zueva, V.M. Dmitriev, E.A. Muravleva</i>	1301
Ultrasonic atomizing-assisted spray drying: Effect on the quality of skimmed milk powders <i>Yuchuan Wang, Ying Cui, Bo Wang, Min Zhang</i>	1309
Agitated thin-film drying of spinach juice <i>Jun Qiu, R. M. Boom, M.A.I. Schutyser</i>	1317
Influence of the low temperature drying process on optical alternations of organic apple slices <i>M. Bantle, C.A. Kopp, I.C. Claussen, I. Tolstorebrov</i>	1325

### **Abstract**

*High intensity pulsed UV Light is a non-thermal treatment used in sanitization of fruits and vegetables. In this work, we have applied high intensity pulsed UV light as a pretreatment for convective air-drying evaluating the benefits of the pretreatment to the drying process and to the nutritional quality of the dried product. Mangoes were subjected to pulses of UV light. The pretreated samples were further dried in a convective oven-drier until 90% of the initial water content has been removed. Drying kinetics, water apparent diffusivity, vitamin B, vitamin C content and total carotenoids content were analyzed. Pulsed UV light showed to be an interesting pretreatment for mangoes given the higher nutritional content of the dried product.*

## 1. Introduction

New food product development should focus on retaining as much of the naturally occurring vitamin content as possible, on increasing the availability of vitamins, and on reducing the appearance of undesirable breakdown products. Factors that play a role in the degradation of vitamins during food processing include temperature, air, light, moisture content, water activity, pH and enzymes related to the food spoilage [1]. Air-drying reduces the moisture content of the product decreasing the effect of one of the primary factors, the water activity, that determines the rate of vitamin deterioration by several biochemical reactions [1]. However, air-drying may increase vitamin loss by increasing the food exposition to high temperature for a long period of time.

Pulsed ultraviolet (UV) light processing of foods is a nonthermal technology used to enhance the quality and safety of foods. Its uses range from sanitization of foods (primary use) to extension of shelf life of fruits and vegetables, and enhancement of phytochemical content in fruits [2,3]. UV treatment is currently in use by the industry especially in sanitization of fruit and vegetables. Several studies reported that UV light also contributed towards the enhancement of the nutritional quality of food products, enhancing vitamin content, total carotenoids content, antioxidant capacity and other phytochemical properties [3–5].

Despite the importance of quality parameters in dried foods, most published studies are limited to determining the drying rate and some diffusional aspects and only few studies have focused on evaluating the changes on product quality after drying. In this work, pulsed UV light was applied as a pretreatment prior to air-drying for the drying of mangoes. The influence of the pretreatment and the drying process on vitamins B1, B3, B5, B6 and C, total carotenoids as well as its influence on the effective water diffusivity were evaluated.

## 2. Materials and Methods

### 2.1 Preparation of samples

Mangoes (*Mangifera indica* L. var. Tommy Athikins) were bought from the local market (Fortaleza, Brazil). Only fruits with same maturity stage were used. Cubic samples (side 10 mm) were obtained using a household tool from the mango flesh. The moisture content was determined by oven drying at 110°C until constant weight (24h).

### 2.2. Pulsed UV light pre-treatment

The pre-treatment was carried out in a pulsed UV light equipment (SteriBeam model Xe Matric A, Germany) equipped with a xenon flash lamp (19 cm). The samples (12 g ± 1 g) were placed inside the treatment chamber of the equipment (20 cm wide × 14 cm deep × 12 cm high) and subjected to UV light pulses. The samples were subjected to 10, 20, 30, 40 and 50 pulses of UV light. Each pulse corresponded to a fluence (energetic density) of 0.36 J/cm<sup>2</sup> and were delivered in 250 μs. All experiments were carried out in triplicate.

## 2.3 Air drying

Drying kinetics were carried out in a conventional convective oven-drier. Air-drying experiments with mango samples were carried out at 0.5 m/s (air velocity) and 60 °C (temperature). The drying experiments were conducted in triplicates and completed when the samples lost 90% of the initial weight. For each experiment,  $25 \pm 1$  g cubes of mangoes were distributed over a custom sample holder inside the drying chamber.

The air-drying kinetics of mangoes was modeled assuming diffusion-controlled mass transfer. Only the falling-rate period (diffusion-controlled mass transfer period) was considered because the constant-rate period (heat transfer-controlled mass transfer period) was not observed. The model considered the solution of Fick's second law for cubic shaped samples (Equation 1) [6].

$$W(t) = W_{eq} + (W_{crit} - W_{eq}) \left[ \sum_{n=0}^{\infty} \frac{8}{(2n+1)^2 \pi^2} \exp\left(-\frac{D(2n+1)^2 \pi^2 t}{4a^2}\right) \right]^3 \quad (1)$$

## 2.4 Determination of vitamins

To determine the vitamins of the B complex, 1 g of fruit was homogenized with 6 mL of distilled water for 2 min using a cell homogenizer (Ultraturrax IKA model T25). The vitamins were extracted by adding sulfuric acid 0.25 M (1 mL) to the sample, which was heated for 30 min in a water bath (70 °C). After cooling in an ice bath, the pH was adjusted to 4.5 using a 0.5 M sodium hydroxide solution. The sample was centrifuged at  $8400 \times g$  for 10 min. The supernatant was collected and analyzed spectrophotometrically at 215 (Vitamin B5), 254 (Vitamin B1), 265 (Vitamin B3) and 716 (Vitamin B6) nm using water as blank. All analyses were carried out in triplicate and results were expressed as the vitamin gain/loss using the fresh fruit as reference.

## 2.5 Determination of total carotenoid content

The carotenoids were extracted milling 1 g of mango sample with 6 mL of distilled water in a cell homogenizer (Ultraturrax IKA model T25). Hexane (5 mL) was added and the mixture was vigorously stirred in a vortex for 1 min. The supernatant (hexane phase) containing the lipid fraction was collected and analyzed spectrophotometrically at 452 nm to determine the total carotenoids content, using hexane as blank. All analyses were carried out in triplicate.

# 3. Results and Discussion

## 3.1. Pulsed UV light pretreatment

Mangoes presented an initial moisture content of  $84.2 \pm 0.4$  g water/100 g fresh fruit (wet basis). The moisture content of the samples decreased during the UV light pretreatment,

reducing the initial moisture content by 4.3 to 15.9%. Figure 1 presents the water loss observed as a function of the energetic density that was applied.

*Fig. 1 Water loss during the pulsed UV light pretreatment as a function of the UV dosage applied to the samples.*

Overall, pulsed UV light pretreatment contributed to an initial reduction of the moisture content of the samples.

### 3.2. Air-drying experiments

Figure 2 presents the experimental drying kinetics of mangoes obtained with and without application of pulsed UV light. Drying kinetics of mangoes presented the typical behavior observed for other fruits [7]. Only the falling rate period was observed during the drying process. Drying was carried out until 95% of the initial moisture was removed, corresponding to a final moisture content of  $0.08 \pm 0.01$  g water/g dry matter.

The water apparent diffusivities in mangoes were calculated using Equation 1. The results are presented in Table 1. The diffusion model used in this work was adequate for describing the drying kinetics of mangoes cubes under the different experimental conditions, presenting  $R^2$  values between 0.986 to 0.995.

Despite the initial reduction in moisture content attained during the pretreatment, the pulsed UV light pretreatment did not reduce the air-drying time. In fact, the samples took between 2 and 16% more time to dry than the untreated sample. It must be stated that the required air-drying time to reduce 80% of the initial moisture content was statistically similar among the sample not subject to pretreatment and the samples pretreated with a total energetic density above  $10.8 \text{ J/cm}^2$ .

Figure 2. Moisture content (in dry basis) as a function of drying time for the samples with and without pulsed UV light pretreatment.

Table 1. Water apparent diffusivity of mangoes subjected to pulsed UV light pretreatment.

Total energetic density applied (J/cm <sup>2</sup> )	Number of UV light pulses (#)	Apparent diffusivity (10 <sup>7</sup> m <sup>2</sup> /min)	R <sup>2</sup>
0.0	0	4.37 ± 0.38 <sup>a</sup>	0.995
3.6	10	3.90 ± 0.03 <sup>b</sup>	0.986
7.2	20	3.76 ± 0.09 <sup>b</sup>	0.986
10.8	30	4.26 ± 0.12 <sup>a</sup>	0.987
14.4	40	3.92 ± 0.27 <sup>a</sup>	0.988
18.0	50	4.10 ± 0.01 <sup>a</sup>	0.991

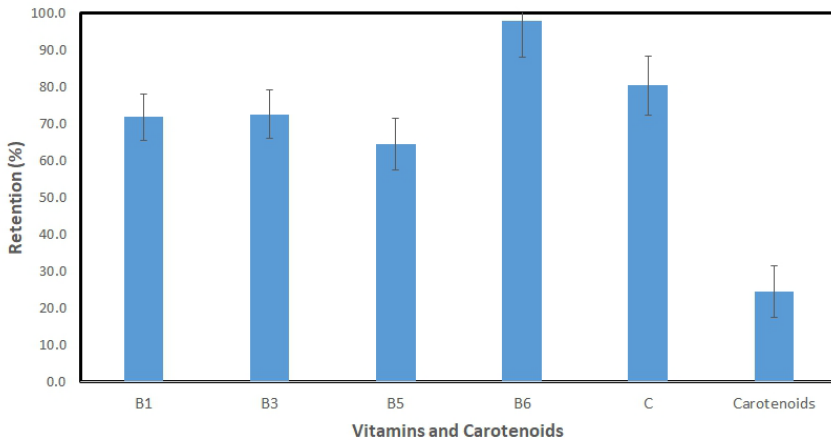

As such, if the main objective of the pretreatment is to reduce the air-drying time, the pulsed UV light pretreatment would not be a proper technology to achieve this goal.

### 3.3. Vitamins and carotenoids content

The drying process decreased the content of vitamins and total carotenoids in mangoes. The retention of vitamins and total carotenoids depended on the vitamin, the use or not of pulsed UV light pretreatment and the intensity of the pretreatment.

Figure 3 presents the retention of vitamins and total carotenoids for non-pretreated mangoes subjected to air-drying. Total carotenoids content presented the lowest retention ratio (24.6

%), while vitamin B6 presented the highest retention ratio (97.7 %). The changes observed in Figure 3 represents the effect of heating in the vitamins and total carotenoid content.

**Figure 3. Retention of vitamins and carotenoids in mangoes after air-drying without UV pretreatment.**

The pulsed UV light pretreatment showed a positive effect on vitamins B1, B3 and B5 when up to 7.2 J/cm<sup>2</sup> were applied to the samples. Under such conditions, the dried product would present between 10.0 to 28.8 % more vitamins B1, B3 and B5 than the untreated dried product. Above the 7.2 J/cm<sup>2</sup> level, the effect of the pretreatment is statistical non-significant (at a 95% confidence level), due to a probable degradation of these vitamins by UV light.

Vitamin B1 (thiamin) is the most thermolabile among the B vitamins, so degradation due to thermal effect was expected [8] and was confirmed by the experimental data. The effect of pulsed UV light seemed to be mainly positive and a trend of higher retention of vitamin was observed. The high energy of the pulsed light treatment may have broken the bound of the phosphorylated vitamin, changing it to its free and bioavailable form, thus resulting in a slightly higher content of this vitamin in the treated dried product.

The retention of vitamins B3 and B5 followed a similar trend. As with vitamin B1, the energy delivered by pulsed UV light might have broken the bound between the vitamin and its bounds, releasing an amount of vitamin that otherwise would be unavailable. This is plausible because vitamins, nucleotides and coenzymes absorbs UV energy and could use this energy to break the chemical bond between vitamins and nucleotides, and vitamins and coenzymes. The energy absorbed from pulsed UV light causes physical damages to membranes and other structures due to the release of chemical and physical bonds in these structures [9]. Thus, the same energy that is responsible for bond breaking damage in microorganisms can be responsible for the bond breaking reactions that release the bonded vitamins and transform it in free and bioavailable vitamins.

The pulsed UV light pretreatment had a significant negative effect on vitamin B6. The retention of vitamin B6 that was at 97.7 % for the dried untreated mango, dropped to retentions levels between 48 to 61 %. This vitamin is considered light-sensitive. As such, both UV light and visible light released by the pulses have degraded this vitamin resulting in a significant reduction in its content when the UV pretreatment was applied.

The UV pretreatment did not change significantly the amount of vitamin C in the dried product. The pretreatment was only statistically different (at a 95% level of confidence) when a fluence of 12 J/cm<sup>2</sup> was applied. Under this condition, the amount of vitamin C was 28.6 % higher than the untreated sample. Vitamin C is considered a light sensitive vitamin that present high UV light absorbance in the germicidal range (215 to 260 nm) but does not absorb significant light above 300 nm. The equipment used in our experiments releases light in a spectrum between 310 and 400 nm, thus it has not affected the vitamin C content of the mangoes samples.

The UV pretreatment increased the total carotenoids when a fluence up to 12 J/cm<sup>2</sup> was applied. Overexposure to high intensity UV light tended to degrade the carotenoids. The increase in the total carotenoid content can be attributed to an alteration of the carotenoid-binding protein with a consequent increase in availability of free carotenoids, which has been reported previously for mango juice subjected to UV light treatment [10].

#### **4. Conclusions**

Pulsed UV light decreased the initial moisture content of the mangoes samples but did not increase the effective water diffusion of mangoes nor reduced its drying time. The application of pulsed UV light increased the availability of vitamins B1, B3, and B5, vitamin C and carotenoids in the dried product. The light sensible vitamin B6 degraded significantly when compared to the untreated dried mango samples. Overexposure to pulsed UV light (dosages greater than 15 J/cm<sup>2</sup>) degraded all vitamins and carotenoids, thus the UV dosage must be carefully optimized. Pulsed UV light can be a potential pretreatment for drying fruits given its simplicity, rapid application and because it confers better nutritional quality to dried mangoes.

### **Abstract**

*Widespread use of advanced process control allows reduction of costs, by reducing drying time and energy consumption. The “control of the freezing stage” (by forced nucleation) also appears to be beneficial to process intensification, as it can impact the product structure and modify the product resistance to mass transfer. An alternative way to increase the drying rate is the use of organic solvents as they can lead to larger solvent crystals, hence lower product resistance to vapor flow.*

*Atmospheric freeze-drying may be a good alternative to vacuum freeze-drying, as a way of increasing process efficiency. A further improvement can be obtained by combining atmospheric or vacuum freeze-drying with new technologies.*

*A further step towards process intensification is given by continuous plants, as this allows a dramatic increase in throughput and product quality uniformity.*

**Keywords:** *freeze-drying; process intensification; controlled nucleation; continuous process.*

## **1. Introduction**

The freeze-drying process is widely used in pharmaceuticals manufacturing, as well as for drying foodstuffs, as high-quality products can be obtained due to the low operating temperatures. Anyway it is quite an expensive process, and this fact limits applications in food and probiotic industry. Reduction of costs, by reducing drying time and energy consumption, and a better uniformity in end-product quality can be reached by means of process optimization and widespread use of advanced process control, but there is a big potential for process intensification by process modifications.

According to Stankiewicz and Moulijn [1], process intensification can be obtained by modifying equipment, to optimize critical parameters (e.g., heat transfer and mass transfer), or by process intensifying methods, changing the process or using alternative energy sources. Proposed control approaches, and in particular advanced process control, will be first discussed in this review. Other possibilities for process intensification will be then discussed, focusing in particular on controlled nucleation and process modifications in production of pharmaceuticals.

## **2. Process optimization and widespread use of advanced process control**

Improvement of the process control has been recognized as a development need for the pharmaceutical industry over the last thirty years, but relatively few changes occurred at the production scale. It must be evidenced that today even the most advanced industrial freeze-dryers have no robust process control. An open-loop control approach is generally adopted, but rarely the cycle has been really optimized, and cycle transfer between different pieces of equipment or scale up is generally challenging [2-5].

Effective monitoring and control systems are required to manage the process in such a way that product quality is not jeopardized at the end of the process. Besides, as the duration of the freeze-drying process is an important concern, the control systems should be able to optimize in-line the operating conditions, namely the pressure in the drying chamber and the heating power, i.e. the temperature of the heating source. In the following different the methods proposed will be analyzed.

A first group of methods is based on the measurement of product temperature obtained through a thermocouple (or another temperature sensor); they optimize only the temperature of the heating element. In this case it is possible to use just the temperature measurement, with a fuzzy logic-based algorithm. Alternatively, a mathematical model can be coupled to the experimental measurements, thus obtaining a soft-sensor; this can be used

to calculate the optimal control actions using, for example, a PI algorithm, or calculating in line the design space of the process [6-8].

The second group of methods is based on the pressure rise test [9]; this is a technique for the in-line process identification that allows estimating both the state of the product (temperature and residual amount of ice) and the values of some model parameters. By this way a mathematical model can be used to optimize the process using, for example, a classic proportional algorithm, or an advanced Model Predictive Control algorithm [10,11]. Control logics based on measurement of heat or sublimation flux will be also discussed.

Control procedures are available also for the secondary drying step. The key feature of the method is the coupling of the measurement of the desorption rate, obtained by means of the PRT or other devices, with a mathematical model of the process [12].

### 3. Control of the freezing stage

Freezing plays a fundamental role in the freeze-drying process, as it determines product morphology and, therefore, drying performances and drug stability [13]. Therefore, it has become essential to increase the knowledge and control over this process. A brief overview of the tools which allow control of the impact of freezing on product morphology, and, consequently, on drying efficiency and product quality will be presented.

During freezing, the stochastic nature of nucleation is regarded as a demerit, because it is directly linked to vial-to-vial variability in terms of product morphology, drying behavior and, ultimately, product stability. Hence, lots of attention was given to the control of the temperature at which nucleation occurs, trying at least to make it as uniform as possible over a batch of vials. In fact, it is not actually possible to really “control the nucleation” even if this term is often used for simplicity; as said before, what is possible to do, is to force nucleation to take place at a given temperature and control the batch temperature holding it until nucleation is completed. The higher the nucleation temperature, the larger the ice crystal size, and thus the lower the cake resistance. In recent years, almost all the principal freeze-dryers manufacturers developed their proprietary technology to induce ice crystallization and to reduce the time span for completing the freezing in all the vials of the batch. Many patents were deposited, and different technical solutions were made commercially available, especially at the pilot-scale; even if many difficulties still limit somehow the application to large production scales of some methods, controlled ice nucleation starts moving also into manufacturing [14,15].

Ultrasound nucleation has been the object of an extensive research, but the passage from lab to commercial scale faced strong difficulties. The main problems were related to the difficulty to efficiently propagate the ultrasonic waves, and to scale the process, as the

optimum ultrasonic frequency depends on the set up. Actually commercially available equipment adopts either a variant of the ice fog, or the depressurization method, or the vacuum induced nucleation. The ice fog concept is probably the first method proposed to control nucleation (as it is known since 1990), but only recently the technical developments made it really suitable for practical applications.

The easiest and cheapest way to control nucleation is surely the vacuum induced surface freezing, VISF (also known as vacuum induced nucleation, VIN), as this technology requires no hardware, any equipment can be easily retrofitted, and there are limited sterility concerns (related to sterilization of large valves required for rapid depressurization) [16]. It is important to evidence that notwithstanding the concern for possible product denaturation, in particular with the depressurization and the VIN method (for the possible presence of small bubbles), all the discussed controlled nucleation technologies gave particularly good results; in fact, as a consequence of the larger ice crystals (and thus of their reduced solid surface), an improved stability even for very sensitive products was observed.

Thus the described methods are effective approaches to process intensification, but to guarantee the required final quality and uniformity of the batch, they must be coupled with methods that assure the temperature uniformity of all the vials. In all cases, the depressurization rate is the element that may limit the applicability to large units, as it poses constraints to the geometric characteristics of the apparatus and of the depressurization circuit.

#### **4. Process modifications**

The use of a strictly organic or organic/water system is beneficial to both product quality and process optimization. Potential advantages and disadvantages of use of organic solvents and cosolvents (mixed with water, that up to now has been the most common solvent used) in freeze-drying are widely discussed by Teagarden and Baker [17]. The main advantage in addition to the increase in solubility of the product, is the increase in rate of sublimation and hence decrease of drying time. However, before a specific solvent is used in the manufacture of a parenteral product, lyophilization professionals have to carefully weigh advantages and disadvantages.

The use of organic liquids, either as solvent or co-solvent, produces larger ice crystals and, thus, increases the average diameter of the pores created during ice sublimation. As a result, the product resistance to vapor flow decreases and, if product temperature does not change, the rate of sublimation increases, as said above. In addition to the reduction in product resistance, most of the cosolvents used in freeze-drying applications increase the rate of sublimation because they have a higher vapor pressure than water and, hence, they increase the driving force for mass transfer. In addition, a further reduction in energy consumption

results from the fact that the sublimation enthalpy of organic solvents is smaller than that of water ice. Unfortunately, organic solvents are rarely used in the manufacture of a lyophilized pharmaceutical product, mainly because of safety concerns. Specifically, attention has to be paid to how the organic solvents can be safely handled, e.g., preventing fires or explosions during their manipulation or avoiding contamination of the vacuum pump oil, which can decrease the pump efficiency and, hence, impede adequate control of pressure inside the equipment. Furthermore, in the case of mixture of solvents, monitoring the state of progress of drying might be very complex, because the various solvents can show significantly different rates of sublimation. Therefore, it is necessary to track the separation of the individual solvents, e.g., using sensors that are sensitive to only specific solvents and completely insensitive to others [18].

In food processing, vacuum freeze-drying produces dried products that retain almost all their original characteristics, e.g. color, flavor, and taste. The high specific surface area generally allows an easy and fast rehydration. The drawback is represented by the cost of the operation: fixed costs can be high due to vacuum requirement, and the energy cost can be significantly higher with respect to other drying processes (the specific moisture extraction rate in a vacuum freeze-drying process is in the range of 0.4 kg of water per kWh). In order to reduce the cost and the energy consumption of the process, thus improving its sustainability, the atmospheric freeze-drying (drying with cold air or nitrogen at normal pressure) has been proposed [19,20]: in this case it is possible to achieve a specific moisture extraction rate ranging from 1.5 to 4.6 kg of water per kWh. For example it has been claimed that up to 35% of energy savings could be achieved when using atmospheric freeze-drying instead of vacuum freeze-drying for potato slices.

Most of the literature deals with atmospheric freeze-drying in fluidized bed dryers and in spray freeze-dryers. When the atmospheric freeze-drying is carried out in a fluidized bed it can take advantage of the high values of the heat and mass transfer coefficients; the product has to be frozen and granulated before drying. A drawback of the process is represented by the size reduction caused by mechanical cracking. As an alternative it is possible to carry out the process in a tunnel dryer, even if the heat and mass transfer is not so good.

A detailed comparison of vacuum and atmospheric freeze-drying has not been carried yet, and work is currently ongoing also in the labs at Politecnico di Torino. Surely drawbacks related to the limitation in process temperature, to avoid ice melting, and the necessity to recirculate and dry large volumes of gas at low temperature must be taken into account. In particular, atmospheric freeze-drying produces higher quality products (in comparison to traditional drying) but still entails long drying times. Energy consumption can be reduced by new technologies which use alternative forms and sources of energy for processing. These technologies can be applied to either enhance heat transfer between product and heat source, such as microwave, radiofrequency and infrared radiation, or simply intensify the rate of dehydration without increasing the amount of heat supplied to the product, e.g. by

using high intensity sonic and ultrasonic waves.

Spray freeze-drying seems to be a valuable alternative to produce a free-flowing powder, with high surface area, porous end product, and good instant characteristics, with enhanced solubility and a uniform and ultrafine particle size. Spray freeze-drying into liquids, gases (e.g. a refrigerated air stream), and into gases over a fluidized bed have been reported in the literature. This technology has also a good potential for continuous processes. Spray freeze-drying allows the massive production of pharmaceuticals for dry powder inhalation, and a more precise control of particle size compared to spray drying. Furthermore, the rapid cooling rates promote the formation of glassy water that is beneficial in preventing the aggregation of proteins during the cryo-concentration phase.

## **5. Continuous plants**

Recently, many pharmaceutical manufacturers are trying to convert their processes in favor of continuous production. To achieve this objective, it is necessary to integrate those production steps, that are performed sequentially in a conventional batch configuration, in a continuous process, leading to more compact units with a higher degree of automation and fewer manual interventions. This is particularly true for the lyophilization of pharmaceuticals and biopharmaceuticals in unit-doses which, although it is a robust and well-established technology, still remains inefficient and expensive. For example, the drying behavior within a batch, as well as from batch to batch, is still a problem of deep concern, despite the elaborate equipment design and the sophisticated control systems recently introduced.

It must be noted that continuous freeze-drying find currently application mainly for soluble coffee production. Many patents have been deposited for food technology applications, but realizations are still very limited. In the pharmaceutical industry there are much more severe constrains, and just a relatively few patents have been deposited. In particular, so far, only two technologies have been proposed for the production of end-to-use lyophilized products in a continuous way [21,22]. In both technologies, processing time and equipment size is dramatically reduced, up to 10 times, and all manual interventions and breaks have been minimized reducing the risk of product contamination. Furthermore, in-line control can easily be implemented, and scale-up simply consists of adding parallel modules. Despite their numerous advantages, the application of these technologies to real cases in industry still requires time. The above proposed technologies are still in development, and their capability to work under GMP conditions, meeting all the stringent requirements of a pharmaceutical production, has not been completely demonstrated yet. Nevertheless, these solutions are concrete steps toward continuous manufacturing of lyophilized pharmaceuticals, similarly to what food industry did years ago.

## 6. Conclusions

Different approaches to process intensification, coupled with improved process control for freeze-drying have been discussed. In the last years, many progress have been carried out in process monitoring and control, including the control of the freezing step. Current research should favor the transition towards a more robust design of freeze-drying cycles, based on deep knowledge of phenomena involved rather than on empirical observations. This would be extremely beneficial, especially for the pharmaceutical industry, where particular emphasis is placed on product homogeneity and process control. Process modifications, like atmospheric freeze drying and spray-freeze drying are interesting alternatives whose real potentiality are currently under investigation. The most ambitious goal is certainly the realization of a continuous process at the industrial scale for pharmaceuticals.

The intensification of the process and the reduction of the processing costs, on the other way, may open new possibilities of wider application of freeze drying in processing of valuable foods and in particular of probiotics, for which the market is requiring higher qualitative standards.

### **Abstract**

*This work explore the use of supercritical CO<sub>2</sub> drying as alternative technique for the obtainment of pasteurized and high quality dried product. Several tests were conducted on animal, vegetable and fruit matrixes in order to investigate the effectiveness of SC-CO<sub>2</sub> drying process at different process conditions. Design of experiment was performed to find the optimal process conditions for vegetable and fruit matrices, using the final water activity of the products as key indicator for the drying efficiency. The inactivation of naturally present microorganisms and inoculated pathogens demonstrated the capability of SC-CO<sub>2</sub> drying process to assure a safe product. Moreover, retention of nutrients was compared with conventional drying methods. Results suggest that supercritical drying is a promising alternative technology for food drying.*

**Keywords:** *supercritical drying; carbon dioxide; food drying; microbial inactivation*

---

## 1. Introduction

Fresh food products, in particular ripped fruits and vegetables, are rich sources of nutrients with an important role in human health [1]. However, fresh products are seasonal and an optimal cold chain is needed to prolong their limited shelf life.

An alternative is represented by food dehydration, which is one of the oldest and widely used processes for the long-term maintenance of food products. By reducing the amount of moisture, the microbial and enzymatic activities are inhibited, promoting the extension of the product's shelf-life [2,3]. Conventional hot air-drying is one of the most commonly used dehydration process in food industry. Nevertheless the overall quality of the final product is often reduced by the combination of high temperatures and the presence of oxygen which promotes physical, structural, chemical and nutritional changes [4,5]. Higher retention of those compounds can be achieved using freeze-drying technology [6], however it is an expensive and very slow process, making it suitable only for high value foods [3,7].

Recently the use of carbon dioxide at supercritical conditions (Sc-CO<sub>2</sub>) has been investigated as alternative drying food process, specifically for carrots [8], basil [9], mango and persimmon [10] and coriander [11], demonstrating to be a promising process for the retention of the original structure and the preservation of the most valuable compounds.

Within Sc-CO<sub>2</sub> drying the vapour-liquid interface can be avoided meaning that the water is removed as a liquid dissolved in the supercritical fluid. The result is a minor capillary stress for the product, which allows a better preservation of the original structure. Moreover, the critical point, and consequently the critical temperature (31.1°C), is low, which allows to operate at lower temperatures than conventional air drying, helping the prevention of the heat sensitive degradation's reactions and thus giving a final product with higher quality [8,9]. Sc-CO<sub>2</sub> have been largely investigated as alternative food pasteurization at low temperature [12] because it is able to inactivate microorganisms and enzymes.

The present work explore the use of Sc-CO<sub>2</sub> for drying and simultaneous pasteurization of foodstuff. The influence of process parameters (temperature, pressure, flow rate and treatment time) on the final water activity were studied within a Box Behnken Design method. Overall the results demonstate the possibility to obtain a high quality product microbiologically safe.

## 2. Materials and Methods

### 2.1 Sample preparation

Different types of food products were daily bought in the local market in Padua (Italy): red bell peppers (*Capsicum annuum*, L.), coriander (*Coriandrum sativum*), strawberry (*Fragaria ananassa*), apple (*Golden delicious*) and chicken breast fillet. The vegetables were cut into slices while coriander leaves were removed from the stem. The chicken breast fillet was cut into small cubes with a weigh of approximately 1g.

## 2.2 Sc-CO<sub>2</sub> drying apparatus and procedure

The high pressure carbon dioxide apparatus consists of a sapphire high pressure visualization cell (Separex S.A.S., Champigneulle, France) with an internal volume of 50 mL designed to withstand up to 400 bar and 100 °C. The plant includes a CO<sub>2</sub> tank, kept at room temperature, a chiller reservoir (M418-BC MPM Instruments, Milan, Italy), a HPLC pump (307 Gilson, Milan, Italy), and a thermostatic water bath (ME-Julabo, Seelbach, Germany) to keep the vessel at the desired temperature. Further details of the reactor and drying procedure are reported elsewhere [11,13]. Experiments were carried out between 40/60°C and 100/140 bar up to 16 hours of drying for red peppers, while 40°C and 100 bar were chosen for the other food products.

## 2.3 Experimental design

The Box Behnken Design was used to study the effect of supercritical CO<sub>2</sub> drying process parameters on the final water activity of treated red peppers. To quantify the relationship between the controlled input and the accomplished responses, a second order regression model was used. All the calculations were done using Minitab®.

## 2.4 Physical and chemical analysis

Water activity was measured (Hygropalm Rotronic, Bassersdorf, Switzerland) at the end of the process. Samples were weighted before ( $W_{start}$ ) and after ( $W_{end}$ ) the treatment and the weight loss in terms of percentage  $\Delta W$  was calculated as  $(W_{start} - W_{end})/W_{start}$ . Chemical characterization was performed for flavonoids as previously described [11]. For all the HPLC analysis an Agilent 1260 system equipped with Diode array (126 series) and Ion trap Mass spectrometer (Varian/Agilent MS500) were used. For vitamin C 200 mg of grinded powder plant material were extracted three times for 10 minutes in an ultrasound bath with 8 ml of solution composed of water with 1% (v/v) formic acid. Zorbax SB C3 4.6x 150mm (DTO Servizi, Spinea, Italy) was used for the stationary phase. Isocratic conditions of elution used two solutions: solution A was acetonitrile while solution B was water 1% formic acid. For the quantification, standard solutions of ascorbic acid (Sigma Aldrich, Milano, Italy) were used to build up a calibration curve in the range 3-120 µg/mL.

## 2.5 Microbial analysis

Mesophilic bacteria, mesophilic bacterial spores and yeasts and molds were counted before and after the treatments by means of the standard plate count technique, as previously described [11]. Briefly, mesophilic bacteria and spores were cultured using total plate count agar (Microbial Diagnostici, Catania, Italy) at 30°C within pour plate, while yeasts and molds were cultured with DRBC agar (Bitec S.r.l., Grosseto, Italy) supplemented with chloramphenicol at 22°C within spread plate. For the enumeration of mesophilic spores, the first dilution tubes were inserted in a thermostatic bath at 80°C for 10 min before plating. The incubation time for mesophilic bacteria and spores was 72 h, while 72-120 h for yeast and

molds. The enumeration was referred to the weight of initial fresh product and expressed in CFU/g. Reductions are expressed as  $\log(N_0/N)$  where  $N_0$  was the number of initial microorganisms in the untreated sample and  $N$  the number of viable microorganisms after the treatment, in CFU/g of fresh product. The limit of quantification was set to 200 CFU/g for the mesophilic bacteria and mesophilic bacterial spores, 2000 CFU/g for yeast and molds while the limit of detection was  $< 10$  CFU/g  $< 100$  CFU/g respectively. Experiments with inoculated pathogens (*E.coli*, *Salmonella* and *Listeria monocytogenes*) were performed on coriander, apple slices and strawberry slices following the protocol by Bordeaux et al [14]. Results were analyzed with one-way analysis of variance to compare effects of the different treatments with significance at  $\alpha = 0.05$ .

### 3. Results and Discussion

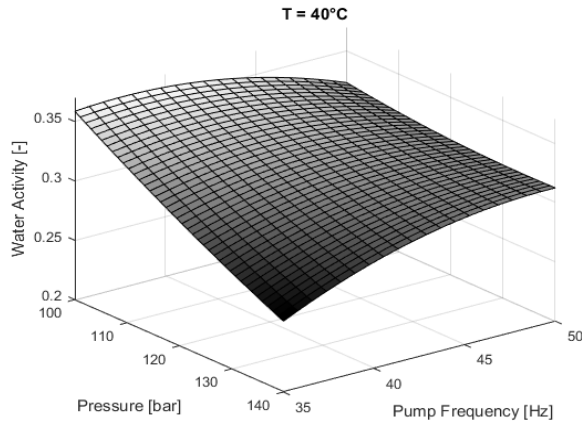

The drying kinetics, in terms of water activity and weight loss, were determined by increasing the drying time till a complete water removal. Figure 1 shows the water loss and water activity obtained during the drying of the red pepper. Similar behaviours were observed for the others food samples (data not shown).

**Fig. 1.**

**Water loss (left) and water activity (right) at different drying times for red pepper. Data are referred to three different heights of the reactors. Experiments were carried out at 40°C, 100bars and 150kg/h flow rate.**

The response surface methodology was chosen to quantify the relationship between the controllable input parameters and the obtained response surfaces, in order to find the influence of the process conditions over the product quality. Fig 2 shows results obtained at 40°C and 16 hours drying that highlight the influence of pressure and pump frequency on the final water activity of the sample. Response surface analysis on strawberry demonstrated a similar behavior (data not shown). To demonstrate the capability of the technology to retain the active components of the fresh products, some chemical analyses were performed on the Sc-CO<sub>2</sub> dried product.

**Fig. 2. Response surface for the water activity at 40°C and 16h drying as function of Pressure and Pump frequency.**

For red pepper, the amount of flavonoids obtained was about 880 mg/100g of dried sample, reported in Table 1, are consistent with the literature; for instance Deepa et al. (2007) [1] reported phenolics in the range of 20–40 mg/100g of fresh product, which is similar to our results considering a loss of weight of 90% compared to the fresh product.

**Table 1. Flavonoid and ascorbic acid content in dried red pepper (40°C, 100bar, 100kg/h flow rate)**

<b>Flavonoid</b>	<b>Ascorbic acid</b>
<b>[mg/100 g dry product]</b>	<b>[mg/100g dry product]</b>
880.45 ± 2.4	1163.20 ± 5.3

The average content of ascorbic acid in fresh bell pepper is in the range of 64-220mg/100g of fresh product [1, 15]. As for flavonoids, we measured a higher content of ascorbic acid after Sc-CO<sub>2</sub> drying compared to the fresh product; the data can be explained with an apparent concentration of micronutrients caused by water removal during the process. Considering a water loss of about 90%, data of dried and fresh products are comparable and we can assert that SC-CO<sub>2</sub> drying technique is able to preserve the ascorbic acid content in the red pepper.

Microbiological inactivation was demonstrated on coriander, apple, strawberry and chicken breast fillet for the natural flora and specific pathogens (data not shown). Supercritical drying was able to complete inactivate yeasts and molds in all the samples considered; as regards bacteria, only the most sensitive mesophilia were inactivated on fruits, while a complete inactivation was possible on chicken. *E.coli*, *Salmonella* and *Listeria monocytogen* were completely inactivate in all the food samples up to 8 log reduction.

## 4. Conclusions

Overall the results highlighted the potential of Sc-CO<sub>2</sub> drying technology to obtain a safe and dried products with unaltered nutritional value.

## 5. Acknowledgements

The research leading to these results received funding from the European Community's Horizon 2020, Call H2020-SFS-2014-2 "Future Food" project and from the Progetto Strategico di Dipartimento SID of the Department of Industrial Engineering (University of Padua). M.T. and G.P. thank Regione Veneto that supported their fellowship through the grant FSE.

## Ultrasound enhancement of osmotic dehydration and drying - Process kinetics and quality aspects

**Musielak, G.**

Institute of Technology and Chemical Engineering, Poznań University of Technology, Poznań, Poland

E-mail of the corresponding author: [grzegorz.musielak@put.poznan.pl](mailto:grzegorz.musielak@put.poznan.pl)

---

### **Abstract**

*The aim of presented studies is to investigate of influence of ultrasonic assistance on both osmotic dehydration and convective drying. A wide range of different materials, as well as several osmotic agents were tested.*

*The obtained results show that the use of ultrasound always accelerates the investigated processes. The application of ultrasound may reduce the energy consumption of drying. Qualitative studies of dried materials do not give a definite answer about the effect of ultrasound on the quality of the products. Mathematical modelling of the ultrasound assisted drying indicates that so named “vibration effect” plays the biggest role in convective drying acceleration.*

**Keywords:** *osmotic dehydration; convective drying; ultrasound; process kinetics.*

---

## 1. Introduction

Drying is one of the food preservation methods. The convective drying is the most commonly used technique. Unfortunately the method is slow and energy-consuming. Therefore, various methods to shorten the duration of the process and improve its energetical efficiency are investigated. One of the possibilities is the use of osmotic dehydration as drying pretreatment. During the last two decades a great interest is directed to ultrasonic assistance of both osmotic dehydration [1] and connective drying [1,2]. Also in the Department of Process Engineering, Poznan University of Technology, research in this area has been conducted for several years. The aim of this paper is to present a review of these research.

## 2. Materials and methods

### 2.1. Tested materials

A wide collection of various materials has been tested in the work of our team. Most of them are fruits and vegetables: apples [3-11], cherries [12], strawberries [9,13], raspberries [5,14], apricots [16], carrots [9,17-21], green pepper [22], red pepper [11], potatoes [23], beetroot [24], onion [10]. In addition, kaolin was also tested [11,20].

### 2.2. Osmotic dehydration – method

The simple osmotic dehydration and ultrasound assisted dehydration (frequency 25 kHz) were tested to get the effect of ultrasound on the process kinetics and product quality. Aqueous solutions of glucose [12], fructose [6,17,19] and d-sorbitol [6] as working fluids were used. Kinetics and effectiveness of osmotic dehydration were assessed on the basis of solid gain (*SG*), water loss (*WL*) and osmotic dehydration rate (*ODR*):

$$SG = \frac{m_{st} - m_{si}}{m_i}, \quad WL = \frac{m_i - m_t}{m_i} + SG, \quad ODR = \frac{dm_t}{dt} \quad (1)$$

where  $m_{st}$ ,  $m_{si}$  are masses of solid matter of osmotically dehydrated and fresh sample, respectively and  $m_i$ ,  $m_t$  are the initial and actual mass of sample, respectively.

### 2.3. Drying – methods

Several different dryers were used in the research. The laboratory chamber dryer was used for simple convective drying after osmotic dehydration [12,17]. Hybrid drying (convective – microwave – radiative) after osmotic dehydration was performed in prototype laboratory hybrid dryer [19]. All ultrasound assisted drying processes were carried out in one of two hybrid (convective – microwave – ultrasonic) laboratory dryers: cabinet dryer [3-5,7,8,10,11,13-16,18,20,22-24] and rotary dryer [6,9,21,24]. The influence of ultrasound assistance on convective drying [3-11,13-16,20-24] and on convective - microwave hybrid drying [11,13-16,18,19,21,22,24] was investigated. Continuous drying processes were studied in all papers, while in some works the intermitten drying was examined [2,11,12,15-17,20,24]. The samples mass and their temperature were measured continuously during

experiment. The moisture ratio  $MR = (m_t - m_{eq}) / (m_0 - m_{eq})$  as a function of drying time represents drying kinetics, where  $m_t$ ,  $m_0$  and  $m_{eq}$  are the instantaneous (for a given time of the process), initial and equilibrium sample mass, respectively.

Energy consumption was measured for the whole drying system with the electricity meter.

## 2.4. Quality assesment – methods

It is important to ensure the quality of the dried product. The basic parameters describing quality were: color change during drying (important from the consumer point of view) and water activity (responsible for durability of food).

The preservation of nutrients during the drying process is extremely important from the point of view of the food's value of the product. Retention of several nutrients were measured.

The dried product ability to irrigation was measured in rehydration tests. Texture of dried apple was determined by compression tests with the acoustic emission measurement. Change of plant tissue microstructure (onion and apple) was observed.

## 3. Experimental results

### 3.1. Osmotic dehydration

Osmotic dehydration could be treated as predrying process. During simple osmotic dehydration water loss ( $WL$ ) ranged between 18% [12] to 51% [17] and solid gain ( $SG$ ) ranged between 8% [17] to 12% [6,17]. The use of ultrasound to intensify the process caused  $WL$  increase by 14% [17] to 44% [19] and  $SG$  increase by 15% [17] to 45% [6]. It was also shown that osmotic dehydration rate ( $ODR$ ) increased [19].

After osmotic dehydration, the samples were dried. Then the water activity and the color change of the samples were examined. The results of these tests indicate that the effect of ultrasound application on final water activity is negligible. The color change results are ambiguous. In works [12,17] a reduction in color change was obtained due to the use of ultrasound. On the other hand, the works [6,19] indicate an increase of this parameter

### 3.2. Drying

#### 3.2.1. Drying kinetics and energetic effectiveness

Drying kinetics is described by drying curves (moisture ratio  $MR$  versus time) and temperature evolution. Figure 1 shows the results of convective drying ( $CV$ ), convective-microwave drying ( $CVMV$ ) and both methods ultrasound assisted ( $CVUS$  and  $CVUSMV$ , respectively). After the shortcut specifying the method ( $MV$  and  $US$ ) the used power in watts was written. The use of ultrasounds during drying results in the process acceleration and in a slight increase in the temperature of the dried material. A clear acceleration in convective drying was obtained, while convective-microwave drying was only slightly accelerated.

Ultrasonic assistance of convective drying shortened the drying process from 11% [5] to 60% [15]. This shortening of drying time resulted in a reduction of total energy consumption from 9% [3] to 21% [14]. A slight acceleration of the convective-microwave drying process was associated with an increase in energy consumption.

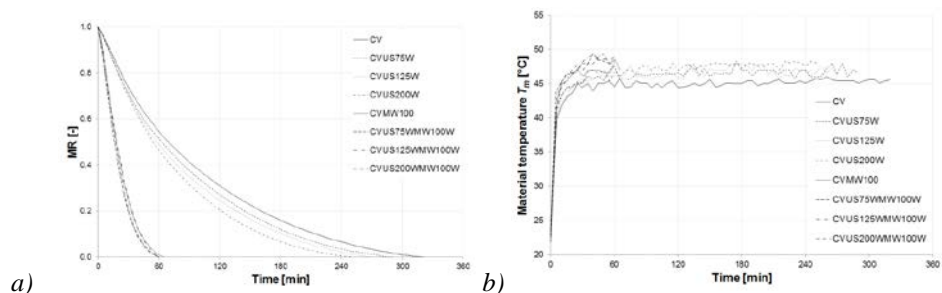

Fig. 1. Drying kinetics of carrots: a) drying curves; b) temperature of dried material [18]

### 3.2.2. Products quality

The use of ultrasound in each case resulted in a reduction in the color change. This reduction ranged between 12% [21,23] and 40% [13,18].

All studies indicate no impact of ultrasound on water activity. This parameter depends primarily on the final moisture content in the material, regardless of the drying method used.

Rehydration ratio is defined as ratio of sample mass after rehydration to initial sample mass (fresh material). Ultrasound application improved rehydratatin ratio from 14% [23] to 21% [16, 22]. This means that the use of ultrasound improves the internal structure.

The retention of vitamin C was improved due to ultrasound assistance (from 44% to 69% in green pepper [22] and from 68% to 70% in red pepper [11]). The obtained results regarding retention of phenolic compounds in carrot [18] are inconclusive. The use of ultrasound of low power caused a reduction in the phenolic compounds content while ultrasound of high power caused an increase in the content. The retention of carotenoids was improved due to ultrasound assistance (from 73,5% to 90% in carrot [18] and from 67% to 76% in red pepper [11]). The retention of betanin in red beetroot was improved from 27% to 33% [24]. The retention of anthocyanins in raspberries [11,15] was improved from 56% to 76%. Antioxidant activity of carrot [18] deteriorated due to the use of ultrasound. The activity decrease ranged between 13% to 33% (depending on US power) compared to simple convective drying.

Ultrasound assistance influenced changes in material texture [5]. Generally strenght and Young modulus of material increased due to ultrasound application. Ultrasound dried crisps were more brittle although less crispy that convective dried ones.

The effect of ultrasound on the material structure was examined using an optical microscope [4, 10]. The application of ultrasound caused the increase of pore dimensions, the creation of microchannels and disruption of the tissue. These results were confirmed by SEM photographs of convective and ultrasound-convective dried apple [10].

## 4. Modeling of US assisted drying

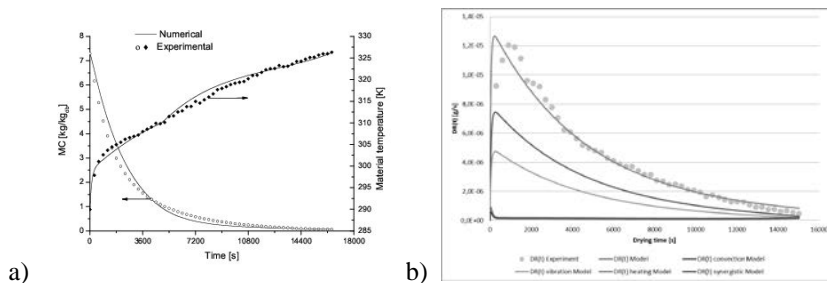

### 4.1. Lumped capacities model

The lumped capacities model was proposed [3,25] to describe drying kinetics. The final system of coupled ordinary differential equations is as follows:

$$m_s \frac{dX}{dt} = -A_m h_m \ln \frac{\varphi |_{\partial B} p_{vs}(T_m)}{\varphi_a p_{vs}(T_a)} \quad (2)$$

$$m_s \frac{d}{dt} [(c_s + c_l X) T_m] = A_T h_T (T_a - T_m) - A_m l h_m \ln \frac{\varphi |_{\partial B} p_{vs}(T_m)}{\varphi_a p_{vs}(T_a)} + \Delta Q \quad (3)$$

where:  $A_m$ ,  $A_T$  denote surfaces of mass and heat exchange, respectively;  $h_m$ ,  $h_T$  – coefficients of mass and heat exchange, respectively;  $\varphi_a, \varphi_{\partial B}$  – relative drying air humidity far and near dry material surface, respectively;  $p_{vs}$  – saturated vapor partial pressure (temperature dependent);  $c_s$ ,  $c_l$  – specific heat of a solid and liquid, respectively;  $l$  – latent heat of evaporation;  $\Delta Q$  – volumetric heat source describing ultrasound absorption.

**Fig. 2. Drying kinetics of carrots - experimental and numerical results: a) drying curves and temperature of dried material [12]; experimental and model drying rate and “vibration effect”, “heating effect” and “synergistic effect” as a function of time**

The model was applied to describe ultrasound assisted convective drying in [3,9,13,14,20,25]. The model shows very good compatibility with experimental data (Fig. 2a). The results of the process modeling make it possible to analyze the efficiency of ultrasound application. Additional parameters should be specified for this purpose. Drying rate DR expresses the rate of moisture decrease in the material during drying as a function of time and is determined as

$$DR(t) = -m_s \frac{dX}{dt} = A_m h_m \ln \frac{\varphi |_{\partial B} p_{vs}(T_m)}{\varphi_a p_{vs}(T_a)} \quad (4)$$

The ultrasound assistance improves the drying rate. This is due to three mechanisms associated with the use of ultrasound, namely “vibration effect”, “heating effect” and “synergistic effect” [13,22]. The model separates these effects and allows to determine their share in the drying rate (Fig. 2b). The results indicate that the vibrating effect has the largest share in the acceleration of drying. The impact of the other two effects is much smaller.

#### **4.2. Packed bed drying models and continuous model**

Three models of ultrasound assisted bed drying were proposed [26-28]. All of these models assume lumped capacities of grains and continuous description of the whole bed. Models by Kowalski [26] and Kowalski, Rybicki [27] treat material as not shrinking. Model by Musielak [28] takes into account high shrinkage of grains. All these models describe drying kinetics as well as distributions of moisture content and temperature in the bed.

The continuous model, describing mass and heat transfer in a single body during ultrasound assisted drying is proposed in [7]. The model was developed basing on irreversible thermodynamics. The model allows to calculate and describe the drying kinetics, the distributions of moisture content and temperature in dried body and the shrinkage of the body.

### **5. Conclusions**

The paper is a review of research, carried out in Department of Process Engineering, Poznan University of Technology, on the use of ultrasound to intensify osmotic dehydration and drying. In general, it can be concluded that the use of ultrasound significantly accelerates osmosis and convective drying. Thanks to this, energy efficiency of the processes increases. Ultrasonic assistance of microwave drying causes slight acceleration, therefore it is energy inefficient.

In most cases, the use of ultrasound has improved product quality. This is due to the shortening of the drying time and changes in the structure of the dried material.

Mathematical modeling allowed to describe the kinetics of the process. Thanks to this, the magnitude of the impact of individual phenomena on the intensification of drying could be determined.

## **1. Introduction**

Drying is known as a high energy consuming unit operation, representing between 12 to 25% of the global industrial energy consumption in developed countries. Consequently, drying contributes several environmental impacts associated to heat or electricity production. One can think, among others, to global warming via greenhouse gas emissions, acidification or photochemical ozone formation via nitrogen oxides emissions, human toxicity via particule matter emissions, ... Besides these impacts directly linked to energy consumption, industrial drying operations may also induce other environmental impacts, depending on the choice and the quantity of the materials it is made of, for example.

Life Cycle Assessment (LCA) is now considered as the most complete methodology to evaluate the potential environmental impacts associated with a process, product or service, following a cradle to grave approach. In addition to International Standards ISO 14040 [1] and 14044 [2], the European Joint Research Center developed guidance rules published in the International Reference Life Cycle Data System (ILCD) Handbook [3]. As mentioned in one guest editorial of A. Mumudar [4], LCA of competing systems has to be carried out before selecting the optimal one.

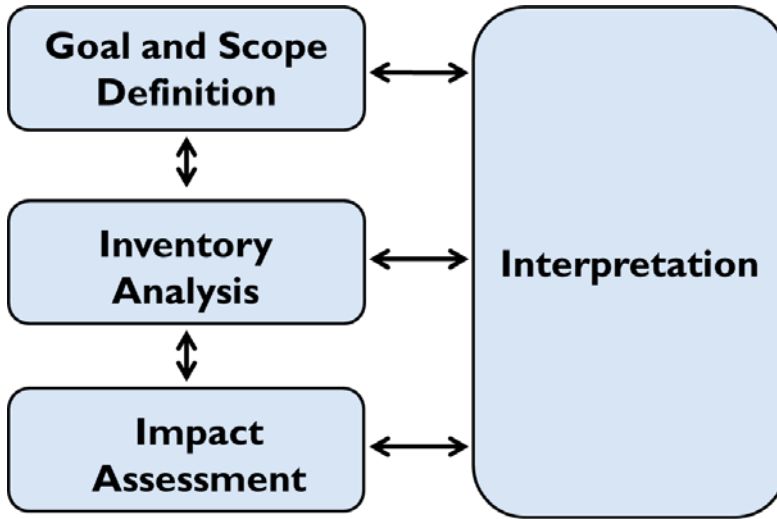

Based on a literature review and some dedicated case studies, this work will illustrate how this methodology can be used to assess the environmental impacts associated to a drying operation. The results will focus on the main process parameters influencing the environmental impacts in a way to indicate some eco-design strategies for dryers.

## **2. Materials and Methods**

This section will summarize the principles of the LCA methodology allowing to understand the results that will be extracted from the literature and from our case studies.

Following ISO standards, LCA studies include 4 phases. The first step consists in defining the “goal and scope”, namely determining the functional unit, to which all the results will be associated, the system boundaries, cut-off rules, time period, impact categories, etc. A typical functional unit could be ‘the drying of one ton of product’ with some specifications on final quality of the product (dryness, ...). The system boundaries specifies the different so-called ‘unit processes’ included in the scope, for example, the supply chain, the feed preparation, the packaging, the maintenance, treatment of exhaust gases, ...

The second step is called the Life Cycle Inventory (LCI). This phase involves data collection and modeling of the product system, as well as description and verification of data. The data must be related to the functional unit previously defined. Besides specific data, several databases can be used, as well as the scientific literature. The LCI provides information about inputs and outputs in form of elementary flows from and to environment for all the unit processes included in the system boundaries. In the context of drying, a part of the data can be obtained via process control softwares or energy audit systems allowing the report of any consumption or emissions.

*Fig. 1 The four steps of a Life Cycle Analysis.*

The third step aims to convert the LCI results into environmental impacts, using several recommended methodologies (following the ISO Standards and the ILCD handbook). Depending on the methodology (ReCiPe, ILCD, Impact World, etc.), the contribution of the functional unit to impact categories such as global warming, eutrophication, acidification, inorganic respiratory effects, tropospheric ozone formation, etc. can be assessed. Fig. 2 illustrate 15 midpoint (problem oriented) impact categories and 3 areas of protection at endpoint. Characterization factors are used to calculate the contribution of each elementary flow of substances to the impacts they are known to be related.

Fig. 2 Impact assessment according to the ILCD handbook.

The last step of a LCA is the interpretation of the results, with three significant steps: the identification of the significant issues, the evaluation of the quality of the study and the drawing of the conclusions, recommendations and reporting.

### 3. Literature review

Even through an increasing number of papers mention the importance of using an holistic approach to design drying in a sustainable way, the number of studies really using LCA as an eco-design tool is still low.

Ciesielski and Zbicinski [5] compared two spray dryers, one at laboratory scale and one at industrial scale using LCA. They found that both units generated the greatest environmental load at the usage stage of the life cycle and have an effect mainly in the damage category of resources depletion.

De Marco et al. [6] studied the industrial production of apple powders. Both the drum drying and the storage are the steps that have high impacts (more than 35% each one) on

global warming potential and aquatic eutrophication; for the other midpoint categories, the main contribution (> 67 %) is due to drum drying.

Romdhana et al. [7] developed a general eco-design model of biomass drying. Their idea was to develop an assessment computer-aided process engineering tool that compares environmental impacts of different operating conditions and fuel types to support decision-makers for an improved compliance to environmental criterion. However their optimization only includes carbon footprint, which is not representative of the overall process performance.

Prosapio et al.[8] used LCA to optimize the production of strawberries by freeze-drying. They found that that agricultural steps, packaging and end of life only marginally influenced emissions, whereas processing steps are the main contributors. Their analysis revealed that the process was sensitive to vacuum drying time and rather insensitive to freezing time; They proposed an improved solution using osmotic pre-treatment allowing reduced process times and a decrease of 25% of emissions.

Van Oirschot et al.[9] used LCA to evaluate the system design of seaweed cultivation and drying. They found that the drying step (using light fuel oil in a industrial furnace) had the highest contribution on the environment.

#### 4. Case study

In order to illustrate some information that can be used as decision support tool when designing dryers, a simplified LCA of a sludge dryer has been carried out, varying some parameters. The aim of the study is to compare the environmental impact associated to the evaporation of 1 ton of water, i.e. the functional unit, following the scenarios indicated in Table 1. Scenario 1 defines the base case.

*Table 1. Modeling scenarios*

Scenario	Thermal energy consumption kWh	Thermal energy production	Electricity consumption kWh	Electricity production
1	700	Gas boiler (EU-28)	80	EU-28 grid mix
2	700	Gas boiler (DE)	80	DE grid mix
3	700	Light Fuel Oil boiler (EU-28)	80	EU-28 grid mix
4	700	Biomass boiler (EU-28)	80	EU-28 grid mix
5	770	Gas boiler (EU-28)	80	EU-28 grid mix
6	700	Gas boiler (EU-28)	80	Wind power (EU-28)

The value of thermal and electrical energy consumptions correspond to the claimed performances of Innodry® 2E (Suez-Degrémont). Depending on the scenario, the thermal

energy is produced via gas, light fuel oil or biomass boiler, which technical characteristics corresponding to Germany (DE) or to the average situation found in EU-28. The electricity is taken from the grid, i.e. the German or average European one. All these scenario also include the transportation of the wet sludge (20% DS) on 100 km using a EURO 6 truck-trailer, up to 28 t gross weight. The dryer infrastructure in itself has been neglected. GaBi 7 software and associated datasets have been used to carry out the LCA, with ReCiPe 2016 v1.1 Midpoint (H) as impact assessment method.

Fig. 3 shows the results at the characterization stage: for each of the selected impact category, the highest score is put at a value of 100% and other scores are represented using a relative scale. The absolute values are given in Table 2. In order to facilitate the interpretation of the results, only the most relevant impacts are given.

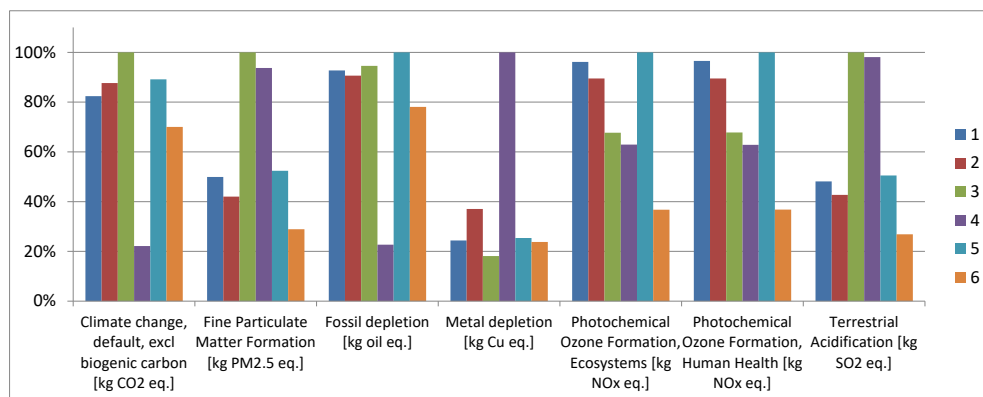

Fig. 3 Impact of the evaporation of 1 ton of water: characterization results.

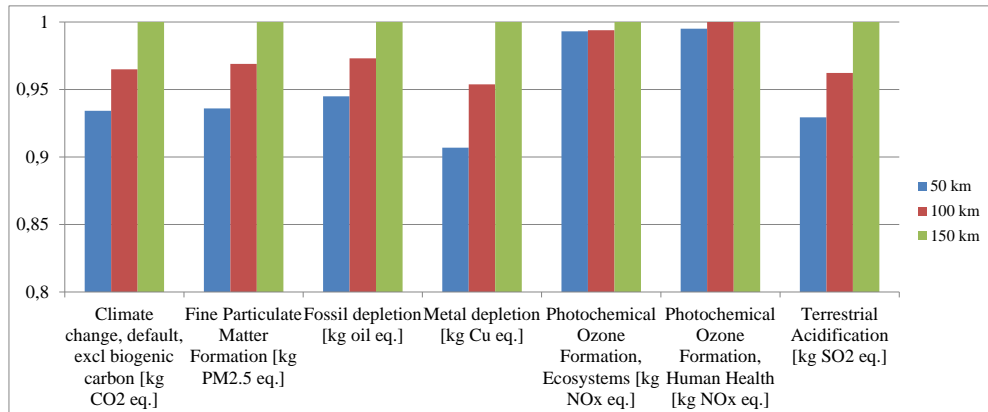

Table 2. Characterization results

	1	2	3	4	5	6
Climate change, default, excl biogenic carbon [kg CO <sub>2</sub> eq.]	220	234	267	59	238	187
Fine Particulate Matter Formation [kg PM <sub>2.5</sub> eq.]	0,050	0,042	0,100	0,094	0,052	0,029
Fossil depletion [kg oil eq.]	86,6	84,6	88,3	21,2	93,4	72,9
Metal depletion [kg Cu eq.]	0,089	0,135	0,066	0,364	0,092	0,087
Photochemical Ozone Formation, Ecosystems [kg NO <sub>x</sub> eq.]	162	151	114	106	168	62
Photochemical Ozone Formation, Human Health [kg NO <sub>x</sub> eq.]	101	94	71	66	105	39
Terrestrial Acidification [kg SO <sub>2</sub> eq.]	0,153	0,136	0,318	0,312	0,161	0,085

The results show clearly the influence of the choice of the energy source, either thermal or electrical, on the environmental impact. The use of a biomass boiler (4) allows to reduce the climate change by 80% in comparison with light fuel oil (3). This biomass scenario also

gives the lowest impact regarding fossil depletion but the highest one for metal depletion. With respect to the base case, an increase of 10% of the thermal energy consumption (7) induces a similar relative increase in all categories. Bigger changes are obtained when replacing the electricity of the grid by wind power (6), especially for photochemical ozone formation and fine particle matter formation. The comparison between scenarios 1 and 2 also shows the impact of the localization of the drying plant on its environmental footprint.

As a sensitivity study, the transportation distance, initially fixed at 100 km, was set to 50 and 150 km, using energy consumptions of scenario 1. Fig. 4 shows that an increase of the transport distance influences almost all impact categories, except the ones related with photochemical ozone formation. Nevertheless, Table 3 indicates, for example, that an increase of 100 km leads to an increase of 15 kg CO<sub>2</sub> eq. This illustrates that the transportation step is not prevailing in this case study (less than 10%), in regards with a total climate change indicator of 220 for the base case. A more detailed analysis shows, in this case, that the most impacting step is the production of thermal energy, contributing to 78% of the climate change score.

**Fig. 4 Influence of the transportation distance on the impact associated to the evaporation of 1 ton of water: characterization results.**

**Table 3. Influence of transport distance - Characterization results**

	50 km	100 km	150 km
Climate change, default, excl biogenic carbon [kg CO <sub>2</sub> eq.]	213	220	228
Fine Particulate Matter Formation [kg PM <sub>2.5</sub> eq.]	0,0482	0,0499	0,0515
Fossil depletion [kg oil eq.]	84,1	86,6	89
Metal depletion [kg Cu eq.]	0,084	0,089	0,093
Photochemical Ozone Formation, Ecosystems [kg NO <sub>x</sub> eq.]	162	162	163
Photochemical Ozone Formation, Human Health [kg NO <sub>x</sub> eq.]	100,4	101	101
Terrestrial Acidification [kg SO <sub>2</sub> eq.]	0,147	0,153	0,159

## 5. Conclusions

As already mentioned in 2011 by Haque [10] in his guest editorial, hopefully LCA will soon become one of the key tools that drying practitioners and R&D personnel will utilize on a regular basis. This very simple case study illustrates that LCA can be used to evaluate the influence on energy production source on the environmental impact. Besides logistical aspects, LCA could also include the infrastructure (building material options, ...), namely in the case where several configurations or technologies could be used. This tool could allow to predict whether energy intensification strategies are really worth and do not lead to impact shifting.

### **Abstract**

The complexity of biotherapeutics in development continues to increase as our capability in discovery and recombinant technology improves. While safety and efficacy remain the two critical aspects of all therapeutics, ensuring adequate stability is a challenge. Freeze-drying is a commonly-used processing technique to enhance the stability of biotherapeutic products, although the lengthy process time and low energy efficiency have led to the search for, and evaluation of, next-generation drying technologies, including spray freeze-drying and vacuum-foam drying. Both processes result in dosage forms that vary considerably from those produced by lyophilization and possess physical properties that may be deemed superior for their intended applications.

**Keywords:** *vacuum-foam drying; spray freeze-drying; lyophilization; biotherapeutics; stabilization*

---

## **1. Introduction**

Most biological materials contain high water content (typically  $\geq 80\%$  w/w). Removal of water through drying provides numerous benefits, including ease of handling and storage, reduction in transportation costs, and improved stability, to name a few. Though all drying techniques share a common objective (i.e., dehydration), conceptually they are different and require modification/adaptation based on the properties of the compound.

Numerous commercially-approved products are manufactured by freeze-drying,[1] thus lyophilization represents the gold standard to which novel drying methods must be compared. Despite its prevalent use, novel technologies are continuously being evaluated, including vacuum foam-drying and spray freeze-drying, as will be described herein. Furthermore, there are a great number of drying technologies that are available, if not already in use, in the food, agriculture, and textile industries.[2] As the sensitivity of pharmaceuticals is unique to the given compound, the selected drying technique may not be universally applicable. By understanding the drying mechanism and the stresses involved, the drying techniques can be tailored for effective use.

## **2. Materials and Methods**

### **2.1. Vacuum-Foam Drying**

#### **2.1.1. T cell sample preparation**

Primary human pan-T cells (STEMCELL Technologies Inc, Cambridge, MA) were expanded 3-4 fold and cryopreserved at  $-150^{\circ}\text{C}$ . During formulation, frozen T cells were thawed at ambient temperature, centrifuged, supernatant removed, and resuspended in the appropriate formulation matrix.

#### **2.1.2. Cell viability and count**

Viability measurements were obtained using a NucleoCounter® 3000 (ChemoMetec A/S, Allerød, DK). Neat samples were diluted 4:1 in PBS and cell viability and count assay was performed using a Vail-Cassette™. The procedure used membrane penetrating acridine orange (AO) and non-penetrating 4',6-diamidino-2-phenylindole (DAPI) fluorescent dyes to assess cellular membrane integrity. Dried samples were allowed to recover for 3 hours following reconstitution and diluted in PBS prior to analysis.

#### **2.1.3. Vacuum-Foam Drying and Freeze-Drying**

Vacuum-foam drying and freeze-drying were performed using LyoStar lyophilizers (SP Scientific, Warminster, PA). Vacuum-foam drying cycles utilized pressures and shelf

temperatures ranging from 0.05 to 5 Torr and 5 - 30°C, respectively. The freeze-drying cycle utilized -30°C shelf temperature for primary drying at a pressure of 0.05 Torr.

## **2.2. Spray Freeze-Drying**

Two process equipment types were utilized for spray freeze-drying. The first process step, spray freezing, was conducted at ambient pressure in a spray freezing chamber and the subsequent dynamic freeze drying of the frozen bulk was performed in a rotary bulk freeze dryer.

### **2.2.1. Spray Freezing**

Spray Freezing in all scales was performed in a spray freezing chamber unit (SprayCon, Meridion, Germany) with frequency driven droplet formation nozzle(s) placed in the top lid. The droplet formation is achieved by controlled laminar jet break up. The cylindrical process chamber is double walled and cooled with gaseous and liquid nitrogen.

For all trials, the spray liquid is a 20% (w/w) sucrose solution, and a 300 µm orifice opening for the nozzle was used. For the freezing step, the main process parameters are: (i) for lab and pilot scale trials: - 150 °C gas temperature; spray rate: 19 g/min (1 nozzle); droplet size  $550 \pm 10 \mu\text{m}$ ; (ii) for commercial scale trial: - 120 °C gas temperature; spray rate: 26 g/min / nozzle (3 nozzles), droplet size  $550 \pm 10\mu\text{m}$

For lab and pilot scale trials, the process equipment used was a stand-alone equipment with intermediate frozen storage of material at -60°C. For commercial scale, the trial was conducted in a fully contained process line that integrates both the spray freezing equipment and the rotary freeze dryer; e.g., the freezing chamber continuously discharges the frozen spheres into the precooled drum of the rotary freeze dryer.

### **2.2.2. Dynamic Freeze-Drying**

Lyophilization of the frozen sucrose pellets was performed in three different scales of rotary freeze dryer (RFD) equipment (all by Meridion, Germany); RFD LyoMotion LAB (lab scale), LyoMotion 30 (pilot scale), and LyoMotion 200 (commercial scale). All scales used a rotating, double walled drum which was positioned in a vacuum process chamber, to which a condenser was attached. The drum temperature was controlled in a range from - 55 °C up to +50 °C.

In all trials, sublimation energy was conveyed by contact heat, via the double wall of the rotating drum, and by infrared radiation emitted from one or more of the infrared sources that were positioned inside the drum above the moving bulk product surface. The pressure within the drying drum was maintained between 50 and 100 µbar at all three scales.

### 3. Results and Discussion

#### 3.1. Vacuum-Foam Drying

Vacuum-foam drying (VFD) transforms a solution or suspension into a dried static foam through a vacuum-induced evaporation and boiling process. VFD enables removal of water at low temperatures, which is required for heat labile biotherapeutics, through the use of a strong vacuum (e.g., 1 -10 Torr). For pharmaceutical applications, VFD can be performed using a lyophilizer capable of pressure control at a higher range than a typical freeze-drying (FD) cycle. In VFD, the boiling process results in a final product that has an expanded foam structure. Fig. 1 demonstrates that increasing sucrose concentration from 15 to 40% (w/v), while maintaining a 1 mL fill, correlated with increasing foam volumes in the final product. The reproducibility and heterogeneity of a VFD product appearance is a challenge that should be considered during formulation and process development.

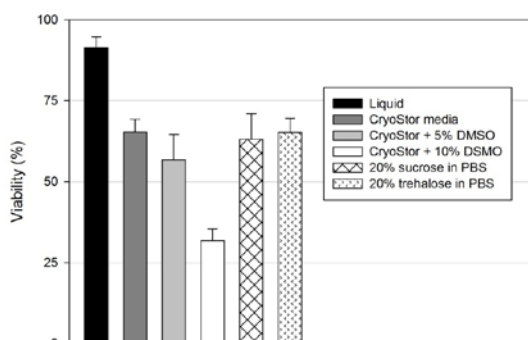

*Fig 1 Vacuum-foam dried (VFD) preparations of 15%, 30%, and 40% sucrose (left to right).*

Compared to other drying techniques, dry static foams have been reported to provide significant stabilization to biotherapeutics. For example, Abdul-Fattah and coauthors [3, 4] have demonstrated improved storage stability of a monoclonal antibody and live virus vaccine as a dried foam in comparison to those prepared by spray drying and freeze drying. Currently, the use of cryopreservation techniques are required to stabilize cell-based therapeutics since the health of cellular suspensions decreases over a short period of time. The ability to stabilize mammalian cells in the dried state may reduce the logistical challenges of a supply chain for therapeutics requiring extremely low storage temperatures.

The T cells used in this work are primary human pan-T cells that were stored at -150°C prior to preparation. T cell formulations evaluated include CryoStor® freeze media (with 0, 5 or 10% DMSO) and disaccharide-based formulations (20% sucrose/trehalose in PBS at pH 7.4) at 1E6 cells/mL with 1 mg/mL bovine serum albumin. CyroStor freeze media is a commercially available preservation medium utilized for cryopreservation of cells at multiple concentrations of DMSO. Disaccharide-based formulations have been reported to provide significant stabilization to mammalian cells though the drying process and in the dried state

[5, 6]. Viability of pre- and post-dried preparations were measured using a NucleoCounter® 3000 fluorescent cell counting and membrane integrity assay.

Prior to drying, viability of all formulations was measured and no significant difference was observed. The average viability of the liquid controls was  $91 \pm 3\%$  (Fig. 2). All formulations were vacuum-foam dried using a fixed shelf temperature of  $30\text{ }^{\circ}\text{C}$  and the pressure was incrementally decreased from 5 to 0.05 Torr with a total drying time of 90 minutes. Drying was completed prior to an extended secondary drying step to minimize dehydration stress which could lead to additional viability loss. Fig. 2 presents the membrane integrity of T cell formulations following vacuum-foam drying and reconstitution with water. The viability of T cells after drying in CryoStor media was 65%, with the addition of 5 and 10% DMSO resulting in post-drying viability of 57 and 32%, respectively. The 20% sucrose and trehalose formulations resulted in post-drying viability of 63 and 65%, respectively. While greater than 60% T cell viability was retained after drying various DMSO-free formulations, the recovery could be improved further through optimization of formulation, drying process parameters, and residual water content.[2]

**Fig. 2 Viability of human pan-T cell formulations after vacuum-foam drying compared to liquid controls. Data presented as average  $\pm$  SD.**

A follow-up evaluation compared the storage stability of 7E5 T cells/mL formulated in 30% trehalose and 3% BSA in PBS at pH 7.4 as liquid, freeze-dried and foam dried preparations at  $5^{\circ}\text{C}$  (Fig. 3). The freeze and vacuum-foam drying cycles were designed to target a residual water content of 9% (w.b.). There was a higher post-drying viability for the VFD preparation compared to FD, for which the process loss was 61 and 42% after FD and VFD, respectively. In order to decouple processing stress and storage stability, the viability results were normalized based on initial stability samples (post-drying). As shown in Fig. 3, the VFD preparation exhibited superior stability compared to liquid and FD preparations. At the same residual water content as a FD cake, these data provide evidence that T cells vitrified as a dried foam provides improved storage stability.

**Fig. 3 Normalized viability of a liquid, freeze-dried, and foam dried preparations of T cells on stability at 5°C. Data presented as average  $\pm$  83% CI.**

### 3.1. Spray Freeze-Drying

Spray freezing is often described as a process whereby the liquid droplets generated by spray nozzles (e.g., binary air nozzles or pressure nozzles) are directed into a cryogenic medium, often liquid nitrogen.[7] In such a case, the suspended frozen droplets are collected either by sieves or are collected after the cryogen has boiled off. For the spray freeze-drying technology presented herein, two unique processes have been developed and adapted for the use in the manufacture of parenteral pharmaceutical formulations.[8-10]

In the first process step, spray freezing, the frozen microspheres are generated as bulk by dispersing the substrate liquid into single droplets of homogeneous size,[11] utilizing a frequency nozzle, which fall through the cold gas (serving as cryogenic medium) and congeal to form frozen spheres. In contrast, the use of conventional spray nozzles results in a broader range of particle size with a significant amount of fines. The direct use of liquid nitrogen (LN<sub>2</sub>) is avoided to minimize internal mechanical stress encountered during freezing, in particular for large particles. The freezing chamber is therefore designed as a cylindrical, double walled column. The process takes place under ambient pressure conditions. Droplet size depends on parameters such as flow rate, frequency, viscosity (based on formulation and temperature), and orifice diameter; for the current application, a (selectable) range for the droplets between 300 to 1000  $\mu\text{m}$  was targeted. For scale-up, multiple nozzles were used, though the height of the freezing column remained unchanged.

The second process step is the freeze drying of the frozen bulk material. The dynamic lyophilization process conducted in a rotary freeze dryer provides process conditions that produce bulk product with high homogeneity (Fig. 4), while avoiding specific aspects of fluid bed processing.[12] Generally speaking, processing conditions such as pressure and temperature are quite comparable to parameters utilized in conventional freeze drying. There

are some differences to be noted, for example: the large surface of the frozen bulk increases heat and mass transfer, which generally allows for shorter drying times. Furthermore, the water vapor diffusion length is significantly reduced. A 10 mm lyo cake in a vial poses a maximum diffusion length of 10,000  $\mu\text{m}$ ; in a 1 mm microsphere, the maximum length is 500  $\mu\text{m}$ . In conventional shelf freeze drying, the heat to a large portion is conveyed across the bottom of the glass vial; the drying front is moving from the top to the bottom, i.e. the heat transfer takes place across the frozen product. In dynamic freeze drying, the energy both from radiators and drum surface is transmitted to the surface of a particle, at which the drying front initiates.

**Fig. 4** Spray Freeze-Dried microspheres generated for a 20% (w/w) sucrose solution.

The results for spray freeze-dried sucrose conducted at three scales are shown in Table 1. In all scales, residual water content less than 1% can be reached and that yield above 95% is possible in commercial scale. The lower yield in pilot scale is explained by the use of higher rpm of the drum in conjunctions with higher IR power. During drying, a pellet will loose 80-90 % of its weight. High water vapor flows would cause the pellets to get entrapped into the vapor flow, which would cause particles to leave the drum, reducing the yield. Additional factors need to be considered, such as solid content, as higher solid content reduces the loss in weight, and electrostatic phenomena, which may be significant if the particle size is too low. The level of residual water content achieved is comparable to that from conventional freeze drying.

**Table 1.** Results for 20% (w/w) sucrose solution processed at three scales

	Lab scale	Pilot scale	Commercial scale
Amount processed (kg)	1	6	107
Drying time (h)	5.5	16	29.25
Yield (% w/w)	98.6	81.6	97.3
Residual water content (%)	$\leq 1.0$	$\leq 1.0$	$\leq 0.6$
Reconstitution time (min)	$\leq 1.0$	$\leq 1.0$	$\leq 1.0$

#### 4. Conclusions

The complexity of biotherapeutics in development continues to increase as our capability in discovery and recombinant technology improves. While safety and efficacy remain the two critical aspects of all therapeutics, stability, both in terms of shelf-life and to stresses encountered during manufacturing, remains a challenge. Spray freeze-drying is a hybrid

processing technology comprising spray drying and bulk freeze-drying, while vacuum foam drying is a modified freeze-drying process that challenges the conventional processing conditions utilized in lyophilization. The former has matured to a level where the application of the technology even in commercial scale is in reach also for pharmaceutical applications, while the latter has provided enhanced stability to a complex biological beyond that provided by a conventional freeze-drying process. The development of *novel* drying technologies, such as the aforementioned processes, is a culmination of fundamental understanding gained in academia and leveraging the lessons learned through their utilization in orthogonal industries. For implementation, technical evaluation should include the scalability of the process, energy efficiency, as well as the capability to implement the technique in a GMP environment.

### **Abstract**

*The search for solutions to transform the by-products generated by the agri-food sector in high value-added ingredients is a priority. The aim of this research was to develop a microwave coupled with hot air drying technique allowing maximizing profits by reducing time and operational costs and to produce a dietary fiber ingredient with interesting technological properties for the development of healthy foods. The shrinkage-swelling phenomena occurred during drying changed the rehydration properties of the fibre ingredient obtained. An increase in particle size improved the fibre's swelling capacity when hydrated, allowing 50 % fat substitution in potato purees.*

**Keywords:** hot air-microwave drying; orange peel; thermodynamics; GAB model; dietary fibre

---

## **1. Introduction**

Sustainability is nowadays an investment for the future of any economic activity. The current situation of crisis has had an adverse impact in most industries, including the agri-food sector. However, this industry has been relatively the least affected when compared with other industrial sectors. This is mainly attributed to the fact that food products continue to be basic for consumers despite the economic downturn. Therefore, the agri-food sector is a key element in the European economy and can play a crucial role in the achievement of the objectives set in the EU's strategy for 2020: ensuring a sustainable framework of growth of a more competitive economy. The European agri-food industry has focused on energy efficiency and on reducing greenhouse gases emissions, along with better management of their resources as a way to improve its industrial competitiveness. In this sense, the search for solutions to transform the by-products generated in high value-added ingredients, is a priority. In this context, the juice industry, as fundamental sub-sector within the food sector, and large waste generator, must exploit the opportunity to transform their by-products into useful and profitable products for society. This transformation presents some difficulties which impede the profitability of the process. These difficulties are associated with the by-product, such as its compositional variability and its seasonality, and current techniques of transformation as the high energy cost in dehydration processes. This work represents an innovative and sustainable solution for overcoming the disadvantages associated with the high costs of stabilization, turning this by-products into high value-added ingredients, from both, nutritional and technological, points of view. The main aim was to develop a microwave coupled with hot air drying technique (HAD + MW) allowing maximizing profits by using the following strategy: reducing time and operational costs, producing a new ingredient rich in dietary fiber, with interesting technological properties for the development of healthy foods, studying the proposed comprehensive process and analyzing the new generated by-products.

The specific objectives were (i) to develop a thermodynamic model for understanding internal heating and water transport mechanisms occurring from the inside to the outside of orange peels during HAD + MW drying and to predict the chemical and structural transformations, (ii) to determine the sorption isotherms and the isosteric heat of sorption and to study its effect on the macrostructure and microstructure of the orange peel, (iii) to develop and to determine dielectric tools to predict the moisture and water activity by using dielectric spectroscopy and sorption isotherms, (iv) to compare the energy consumption of hot air drying (HAD) versus HAD + MW by analysing the physico-chemical and technological properties of the dietary fibre obtained and (v) to assess the technological and sensory properties of the new fiber obtained by using it as a fat replacer in potato pures.

## 2. Materials and Methods

Oranges (*Citrus sinensis* (L.) Osbeck var Washington Navel) were bought from a local supermarket in Valencia (Spain), and their peel was used for the experiments. Sixty orange peel cylinders (20 mm diameter and 3 mm thickness) were obtained using a core borer.

The size and shape of the samples were designed to resemble the small pieces of orange peel left after mechanical extraction of juice and the cuts made by a hammer crusher machine in the processing of orange peel. A diagram of the experimental procedure is shown in Fig. 1.

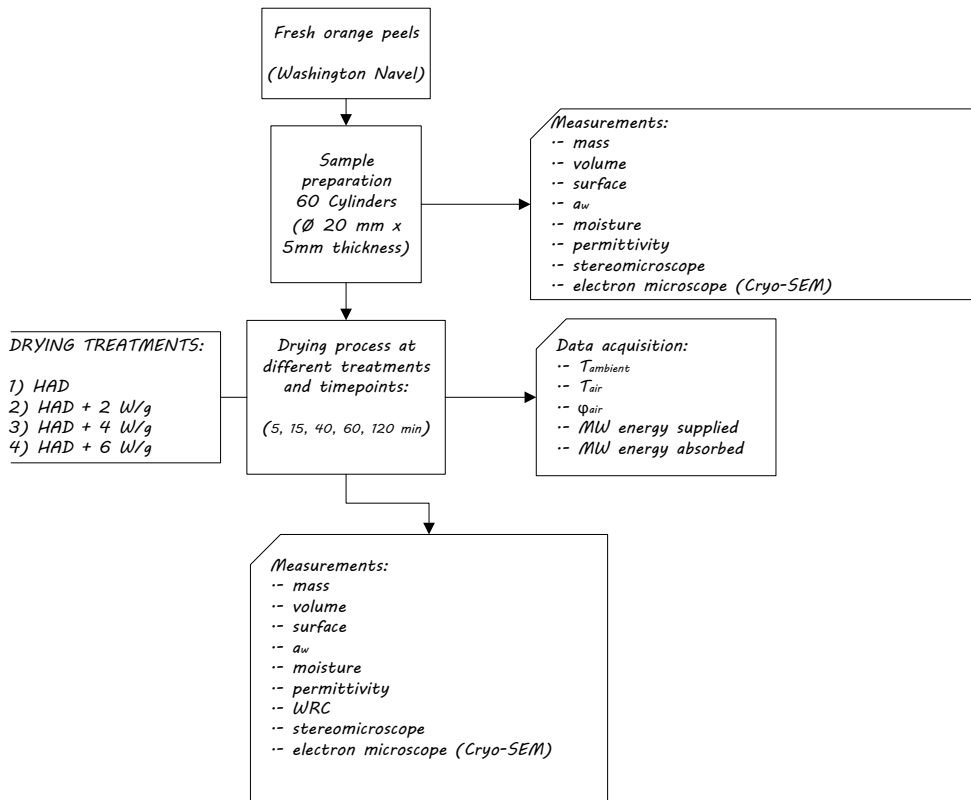

Fig. 1: Experimental procedure

Samples were subjected to HAD + MW, using a specially designed MW-air drying oven with a maximum output of 2000 W at 2450 MHz. For the experiments, the air velocity was 2.5 m/s, hot air temperature, 55 °C, and the MW energy, 0, 2, 4 or 6 W/g. Four drying experiments were carried out (HAD, HAD + 2 W/g, HAD + 4 W/g and HAD + 6 W/g). Three orange peels samples (triplicate) were used for each drying time (5, 15, 40, 60 and

120 min) in each drying experiment. For fiber production, samples were milled after drying, using an ultracentrifuge mill (ZM 100, Retsch, Haan, Germany) with a sieve of 500  $\mu\text{m}$ . At this stage, powder samples were sealed in plastic bags for further characterization.

### **2.1. Mass, volume, surface, $a_w$ and moisture content**

Samples were weighed using a precision balance Mettler Toledo AB304-S (precision:  $\pm 0.001$  g). Surface water activity was determined employing a dew point hygrometer Decagon Aqualab®, series 3 TE (precision:  $\pm 0.003$ , dimensionless) (Decagon Devices Inc., Pullman, WA, USA). Measurements were performed using structured (not minced) samples; thus, the obtained  $a_w$  was considered the surface  $a_w$ . The water content of representative fresh orange peel sample and the samples dried for 120 min was determined. The samples were dried in a vacuum oven at 60 °C until constant weight was reached (AOAC method 934.06 2000). The moisture content of the samples at the intermediate stages was calculated from the weight loss during drying. Volume was determined by image analysis (Sony T90, Carl Zeiss optics), using Adobe Photoshop© software, obtaining the diameter and thickness of the samples in triplicate.

### **2.2. Microstructure**

The microstructure of fresh and dried samples was analysed using Cryo-SEM. A CryoACryostage CT-1500C unit (Oxford Instruments, Witney, UK), coupled to a Jeol JSM-5410 scanning electron microscope (Jeol, Tokyo, Japan), was employed.

The samples were also examined under a Leica MZ APO™ stereomicroscope (Leica Microsystems, Wetzlar, Germany) with a magnification of 8 $\times$  to 80 $\times$ .

### **2.3. Permittivity**

The permittivity was measured with an Agilent 85070E open-ended coaxial probe connected to an Agilent E8362B Vector Network Analyser. The system was calibrated by using three different types of loads: air, short-circuit and 25°C Milli®-Q water. All determinations were made from 500 MHz to 20 GHz.

### **2.4. Water retention capacity and swelling capacity**

For the determination of WRC, approximately 0.5 g of each sample (precision  $\pm 0.0001$  g) was hydrated in 20 mL of distilled water in a 50 mL (adapted from Robertson et al. 2000). Swelling capacity, defined as the ratio of the volume occupied when the sample is immersed in excess of water after equilibration to the sample weight, was measured by the method of Raghavendra, Rastogi, Raghavarao and Tharanathan [39]. To 0.2 g of dry sample placed in a graduated test tube; around 10 mL of water was added to hydrate the sample for 18 h; then the final volume attained by fiber was measured and expressed as volume/g of original sample (dry weight).

## 2.5. Rheology

The rheological characterization of the samples was carried out using a controlled-stress AR 2000 rheometer (TA Instruments, Leatherhead, United Kingdom). Stainless steel parallel plate geometry of 40 mm diameter was used with a gap of 2 mm.

## 2.6. Sensory analysis

The sensory analysis of the purées was carried out by a panel formed by 7 trained tasters applying a quantitative descriptive analysis (QDA) according to the UNE-ISO 6658: 2008 and UNE 87025: 1996 standards. Unstructured scales of 10 points were used to analyze 6 sensorial attributes: 2 visually (homogeneity and viscosity) and 4 on the palate (granularity, fat character, creaminess and viscosity). Each taster evaluated 6 samples of potato puree in triplicate: HAD, HAD + 2 W/g, HAD + 4 W/g, commercial fiber, no fiber and the reference puree.

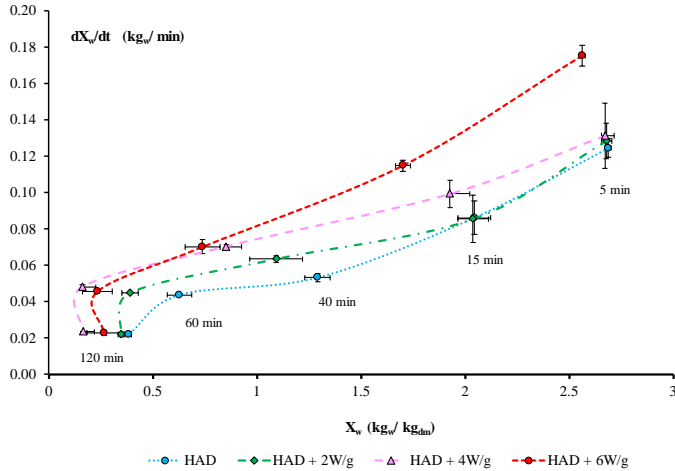

## 2.7. Statitcal analysis

To determine the statistical significance of the results, an analysis of variance (ANOVA) was carried out with confidence levels of 95 % ( $p \leq 0.05$ ) and 99 % ( $p \leq 0.01$ ) using the Statgraphics Plus 5.1 programme.

For the sensory analysis the statistical analysis was carried out through the R-project program (R version 3.0.1.) applying a one-way ANOVA to determine the significance of the differences between samples for the parameters analyzed. In addition, a contrast test (Tukey test) has been applied to establish among which samples these differences exist.

## 3. Results and discussion

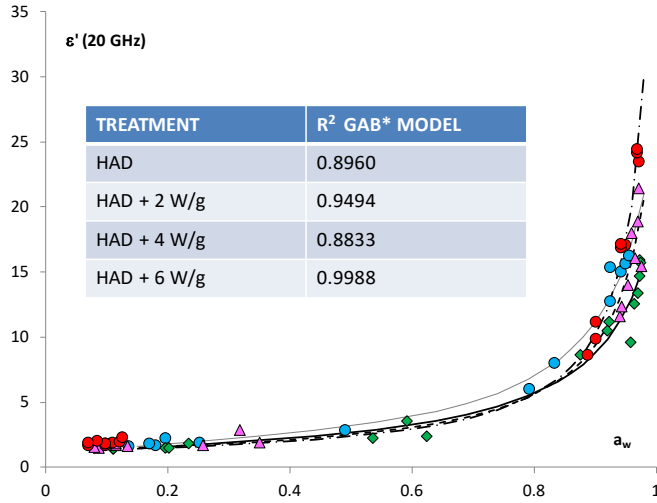

A thermodynamic model was developed to explain the mechanisms involved in mass and energy transports throughout the combined drying by hot air and microwave. A continuous shrinkage in HAD samples was produced by the internal liquid water losses, and the samples treated by HAD+MW showed an internal swelling caused by the internal evaporation produced by the microwave energy. Depending on the predominant mechanisms (HAD shrinkage and MW swelling) samples suffer volumetric expansions or contractions (Fig. 2).

**Fig. 2** Drying rate of orange peel samples dried by HAD and HAD + MW at different power intensities. Data represent means and standard deviation of experiments performed in triplicate.

The desorption isotherms of orange peel dried using different treatments (HAD + MW) were obtained and analysed. The results showed that the GAB model could be used to predict the moisture levels using the  $a_w$  measurements. The macrostructural and microstructural transformations were demonstrated and discussed in [1], taking into account the interactions of water with the tissue. The observed shrinkage/swelling phenomena clearly depended on the MW power and on the nature of the tissue.

It was possible to develop a dielectric isotherm technique (Fig. 3) by adapting the GAB model to predict the water activity in dried orange peel by using  $\epsilon'$  (20 GHz). The physical meaning of the dielectric isotherm parameters ( $\epsilon_0'$  and Cd) was studied and explained in [2]. The value of  $\epsilon_0'$  at 20 GHz ( $\gamma$ -dispersion) represents the induction effect of the minimum quantity of adsorbed water or the monomolecular moisture layer. The parameter Cd is related with isosteric heat or the adsorption energy of the monomolecular moisture layer, as well as the C parameter of the GAB model. The application of MW power produced an increase of the isosteric heat or adsorption energy of the monomolecular layer, improving the surface tension of samples and thus the hygroscopicity, explaining the reduction of the  $\epsilon_0'$  independently of the quantity of the water molecules adsorbed.

**Fig. 3** Dielectric isotherm at 20 GHz of orange peel treated by different drying treatments. Color code same as Fig 2.

An important reduction in processing time (92 %) and energy consumption (77 %) was achieved compared to HAD. The drying treatment did not affect chemical composition or water retention capacities orange fibers. Total dietary fiber content was about 60 % with a ratio of soluble to insoluble fiber of 1:1. Although viscosity of both treatments showed similar values [3], the higher swelling capacity of HAD + MW treated fiber provoked a significant decrease in the viscoelasticity of the samples. An increase in particle size due to an increase in porosity during drying [4], improved fiber swelling capacity (Fig. 4).

**Fig. 4.** Micrographs of orange peel samples dried by HAD + 2 W/g.

The fat content of processed potato purées with cream was reduced by 50% using different types of citrus fiber. All the fibers increased the visual viscosity and in mouth of the purées, as well as their behaviour viscoelastic. The fibers obtained by air combined drying hot-microwave (4 W / g) presented a swelling capacity similar to commercial fiber. In addition, these fibers were perceived as more granular in the mouth which can be explained due to the greater volume increase when rehydrating.

#### **4. Conclusions**

This study has analyzed the microwave coupled with hot air process, developing tools that allow the adequate upscaling of the drying operation by adapting it to the best standards of quality of the final product. A monitoring system that ensures these standards has been designed. This model allows optimizing the traditional hot air drying, by coupling microwave, of orange peel waste as a novel process for citrus by-products valorization, reducing the process time and, therefore, process costs.

The quality and the energy consumption of the dietary fiber production process has been improved. The properties associated with its inclusion in food matrices have been optimized. Therefore, it can be concluded that combining the microwave treatment with hot air drying not only reduced the processing time but it also generated microstructural changes in the dried tissue that increase its water retention capacity. This improved the technological properties of this stabilised by-product, which will be of benefit during its further conversion into the dietary fibre.

### **Abstract**

*To better understand the influence of processing on the bioaccessibility of bioactive compounds during digestion, the microstructure of beetroot samples was observed prior to and after 180 min of in vitro digestion, by using scanning electron microscopy. Beetroot samples were subjected to convective drying at 60 °C and 2 m/s and freeze-drying at -50 °C and 30Pa. Dried beetroots were rehydrated prior to digestion by immersion in distilled water at 37 °C during 90 min. To extract quantitative information related to cell size from the visual texture of beetroot, grey level granulometric methods from mathematical morphology were applied.*

**Keywords:** *freeze drying; convective drying; scanning electron microscopy; image analysis; image texture analysis.*

## 1. Introduction

The nutritional values of plant foods are usually estimated according to their natural concentrations of nutrients, phytochemicals, and total antioxidant activity. These data are usually obtained by direct extraction with organic solvents.<sup>[1]</sup> However, these conditions are different from the physiological conditions that occur in the digestive tract. Furthermore, the biological properties of bioactive compounds found in vegetables depend on their bioaccessibility and bioavailability.<sup>[2]</sup> Bioaccessibility refers specifically to the quantity of nutrients which are released from the food matrix and presented to the intestinal brush border for transport into the cell.<sup>[3]</sup> Meanwhile, bioavailability refers to the quantity of nutrients which actually pass through the cell membrane and are available for use within the cell.<sup>[4]</sup> It is known that the influence of processing on food may be the result of cellular and structural changes. For example, freeze drying and convective drying have been shown to cause cellular changes in the food matrix. Huang et al.<sup>[5]</sup> found that freeze drying (-40 °C, 100 Pa) in a microwave vacuum dryer (75-300 W, 5 kPa) resulted in cell wall shrinkage in apples (var. Red Fuji). Moreover, there is wide evidence that the physical state of the food matrix plays a key role in the release, mass transfer, accessibility, and biochemical stability of many food components.<sup>[6]</sup>

Microscopy is a useful tool for visualizing food structure at the tissular and cellular levels and for studying the influence of processing on *in vitro* digestion.<sup>[7,8]</sup> The characterization of samples by imaging techniques is completed by applying image analysis to quantify the structure observed. Techniques based on image texture analysis can be envisioned in order to quantify information on object size. There are four different types of image texture analysis: structural texture, statistical texture, model-based texture and transform-based texture. Among them, statistical texture is the most widely used in the food industry for its high accuracy and less computation time. Statistical texture, has been successfully applied to extract quantitative information related to cell size<sup>[9]</sup>. The methodology of statistical texture reflects changes in the intensity values of pixels. These may well contain information about the geometric structure of objects as this can be often reflected by such a change in intensity values. In food images, texture can, to some extent, reflect cellular structure of foodstuffs and thus can be used as an indicator of food quality. For example, texture can be used to reveal the tenderness of beef when colour and size features are not adequate. For this reason, among the large scale of applications of image analysis in the food industry, which is one of the top ten industries using computer vision, texture has been used regularly and its usage covers a variety of foods including baked products, cereal grains, fruits and vegetables.<sup>[10]</sup>

Thus, the objective of this study was to evaluate the effects of different drying methods and *in vitro* gastric digestion on the microstructure of beetroots (*Beta Vulgaris*) with image texture analysis using a statistical texture methodology.

## 2. Materials and Methods

### 2.1. Samples

Beetroot (*Beta vulgaris* var. *conditiva*) were purchased from a local supermarket (initial moisture content of  $6.67 \pm 0.04$  g water/g dm and total soluble solids of  $10.8 \pm 0.4$  °Brix). The beetroot were stored at 4 °C for a maximum of one week. Cubes were cut (0.01 m edge) from the center regions of the beetroot tissue, not including the peel, and immediately processed.

### 2.2. Convective drying and freeze drying processes

Convective drying (CD) was carried out in a laboratory-scale hot air dryer previously described by Rodríguez et al.<sup>[11]</sup> operating at 60 °C with an air velocity of 2 m/s. Samples were dried until a final moisture content of  $0.17 \pm 0.03$  g water/g dm. Freeze drying (FD) of beetroot cubes was carried out in a freeze-drier (Telstar LyoQuest, Spain) operating at -50 °C and a vacuum pressure of 30 Pa until a final moisture content of  $0.07 \pm 0.01$  g water/g dm. Before *in vitro* digestion, CD and FD samples were rehydrated by immersion in distilled water (25:100 (g beetroot/ml water)) at 37 °C until they reached final moisture content similar to raw samples ( $6.67 \pm 0.04$  g/ g dm) (aprox. 90 and 80 min, respectively).

### 2.3. *In vitro* digestion procedure

The beetroot samples were digested following the *in vitro* gastric digestion method reported by Bornhorst & Singh<sup>[12]</sup>. Beetroot cubes (ca. 200 g) were mixed with 80 ml of simulated saliva for 30 s, followed by immersion in 800 ml of simulated gastric juice previously heated to 37 °C. The mixture was incubated in a shaking water bath (Unitronic 320 OR, Selecta, Spain) at 37 °C and 100 rpm for up to 3 h. Samples were taken initially (no digestion), and after 180 min of gastric digestion, microstructural analyses were made.

### 2.4. Microstructural analysis

#### 2.4.1. Scanning electron microscopy (SEM)

Cell walls were observed by SEM of raw and drying samples before and after digestion. Beetroot cubes were soaked in liquid nitrogen in order to be fractured with a sharp razor blade, and freeze dried. Gold coating was performed using (E-5400, Polaron, UK) equipment (10-4 mbar, 20 mA, 80s). Samples were then observed in a S-3400N Hitachi SEM (Germany), accelerated at 15 kV and under a vacuum pressure of 40 Pa.

#### 2.4.2. Image texture analysis

To quantify the effect of drying and gastric *in vitro* digestion on the beetroot structure, cell cavities of the raw and drying cubes before (CD and FD samples) and after (raw180, CD180 and FD180) 180 min of gastric *in vitro* digestion, were characterized in terms of their cell area and cell number per unit of area. Thus, scanning electron microscope photographs were analyzed by using an automatic image processing method which is based on the statistical

texture method and was performed using Image J 2.0.0. software. (Creative commons license). The real cell area value was correlated to a standard image whose dimensions were known. To establish a representative structural analysis, fifteen scanning electron microscope photographs of each sample were analyzed.<sup>[9]</sup>

Statistical analysis of the results was performed by using the “prctile” function of Matlab 2017b software (Mathworks Inc., USA). Thus, the percentile profile of cell number per unit of area of each sample was obtained. Analysis of variance (ANOVA) was applied to analyze the effects of processing in respect of the raw sample and the effects of *in vitro* digestion on microstructure parameters. Means were compared by Tukey’s test at  $p < 0.05$ .

### **3. Results and discussion**

#### **3.1. Microstructural images (SEM)**

The images of raw and processed samples before and after 180 min of *in vitro* gastric digestion are shown in Fig 1. Fig 1a<sub>1</sub> shows the microstructure of raw samples prior to *in vitro* gastric digestion. The raw samples are composed of almost isodiametrical and polyhedral cells with few intercellular spaces, as was previously observed by Nayak et al.<sup>[7]</sup>. After 180 min of digestion (Fig 1a<sub>2</sub>) a significant cell lysis was observed, resulting in a smaller number of cells per unit area, along with increases in the intercellular space between remaining cells. Carnachan et al.<sup>[8]</sup> studied the microstructure of kiwi pulp after *in vitro* gastric digestion observed an increase in the intercellular space after *in vitro* digestion.

Cells exhibited shrinkage during the convective drying process, as can be observed in Fig 1b<sub>1</sub>, resulting in a greater disruption of the cellular structure than in raw samples. The effects of different convective drying conditions on the microstructure of apple have been previously evaluated.<sup>[13]</sup> These authors agreed that during drying, one of the most important phenomena is cell shrinkage, which leads to a major modification of the product structure and allows the release of water. Convective drying causes cells to rupture and dislocate which usually results in increased density with varying porosity.<sup>[14]</sup> It was also observed that cell shrinkage increased in CD samples after *in vitro* gastric digestion (Fig 1b<sub>2</sub>), completely eliminating the open pores on the surface of the structure and rupturing many of the interior cell walls.

**Fig. 1. SEM images of beetroot samples: a-Raw, b-CD and c-FD. 1- of initial beetroot samples (prior to *in vitro* digestion). 2-after 180 min of *in vitro* gastric digestion**

Fig 1c<sub>1</sub> shows the microstructure of FD samples before *in vitro* digestion. A certain disruption of the cell structure was observed. This effect was also observed by Huang et al.<sup>[5]</sup> in freeze-dried Red Fuji apples, and in freeze-dried Idared apple by Lewicki & Pawlak.<sup>[15]</sup> An increase in the destruction of cell wall material can be observed as a result of the *in vitro* gastric digestion process (Fig 1c<sub>2</sub>). These changes resulted in almost a complete elimination of the initial porous structure seen in undigested, raw beetroots. The same result was observed by Dalmau et al.<sup>[16]</sup> in freeze dried Granny Smith apples after 180 min of *in vitro* gastric digestion, when the changes during digestion eliminated most of the pore structure observed in undigested raw apples. Overall, microstructural changes were observed as a result of both drying process and *in vitro* gastric digestion compared to the undigested raw beetroot samples. Compared to the raw beetroots, CD beetroots exhibited the greatest changes, both before and after digestion.

### 3.2. Image texture analysis

Cell number per unit area of raw beetroot, drying beetroots (CD and FD samples) and beetroots after gastric *in vitro* digestion (raw180, CD180 and FD180) are presented in table 1. All beetroot drying samples present significantly higher cell number per unit of area

( $p < 0.05$ ) than raw beetroots. Moreover, CD samples presented significantly higher cell number ( $p < 0.05$ ) than FD samples. The highest cell number per unit of area increase was observed in CD samples ( $47 \pm 2$  % compared to raw samples). This result may be due to the drying causing a collapse of the cell walls thus producing a volume shrinkage that results in a greater cell number per unit<sup>[8,21]</sup>. All samples after gastric *in vitro* digestion present significantly lower cell number per unit ( $p < 0.05$ ) than beetroot before *in vitro* digestion. No significant differences ( $p > 0.05$ ) were observed between the cell number per unit of raw samples and all drying beetroot samples. This result may be due to the fact that *in vitro* digestion causes a certain disruption of the cell structure which results in a lower cell number per unit. Different values of cell number per unit compared to raw sample (34–66% of reduction) after different treatments (immersion in boiling water, vacuum impregnation, freezing/thawing and compression) were also reported by Ramírez et al.<sup>[17]</sup>.

Fig 2 represents the cell area percentile profiles of raw and drying samples before (raw, CD and FD samples) and after 180 min of gastric *in vitro* digestion (raw180, CD180 and FD180 samples). In this figure, the percentile represents the percentage of cell whose area is equal or smaller to one value. As can be seen in fig 2, different percentile profiles were obtained for each sample.

**Table 1. Cell number per unit of area of the raw and drying (CD and FD) beetroot before and after 180 min of gastric *in vitro* digestion. Different lowercase letter indicate significant differences ( $p < 0.05$ ) for cell number per unit in a sample before and after *in vitro* digestion. Different capital letters indicate significant differences between the different method of processing (Tukey's test,  $p < 0.05$ )**

	Cell number/mm <sup>2</sup>
Raw	289±4 aC
Raw 180	171±5 b
CD	425±1 aB
CD180	250±18 b
FD	370±40 aA
FD180	190±20 b

The percentile profiles of raw and drying samples (CD and FD samples) were coincident until ca 25. From there onwards, two groups of samples can be observed, one consisting of raw samples, and the second, of CD and FD samples, indicating that drying processes cause similar changes in cell structure. In raw samples the percentage of larger areas was higher; for example, 80% of areas were smaller than 0.067 mm<sup>2</sup> in raw samples and smaller than 0.016 mm<sup>2</sup> and 0.025 mm<sup>2</sup> in CD and FD samples, respectively. In all samples after *in vitro* digestion the percentage of larger areas was the lowest; for example, 80% of areas were smaller than 0.067 mm<sup>2</sup> and 0.310 mm<sup>2</sup> in raw samples before and after 180 min of gastric *in*

*in vitro* digestion, 0.016 mm<sup>2</sup> and 0.116 mm<sup>2</sup> in CD samples before and after 180 min of gastric *in vitro* digestion, 0.025 mm<sup>2</sup> and 0.130 mm<sup>2</sup> in raw samples before and after 180 min of gastric *in vitro* digestion. The percentile profiles of raw and raw180 samples were coincident up to ca percentile 45. However the percentile profile of drying samples (CD and FD samples with CD180 and FD180 samples) were coincident ca percentile 25 and 50, respectively.

**Fig. 2.** Cell area percentile profiles of raw and drying samples before (A) and after (B, C and D) 180 min of gastric *in vitro* digestion.

#### 4. Conclusions

Drying modified the microstructure of beetroots compared with that of raw beetroots. Microstructural analyses indicated significant cellular damage and changes as a result of drying and of *in vitro* gastric digestion. These structural modifications resulted in behavioral changes in beetroots during *in vitro* gastric digestion. The drying process caused cell wall collapses and gastric *in vitro* digestion caused a certain disruption of the cell structure. Given the limited knowledge available on this subject at present, it would be interesting to investigate this area more deeply to better understand how processing and *in vitro* digestion can modify structural characteristics.

### **Abstract**

*Simultaneous wetting and drying occur in processes such as fluid bed (top spray) granulation, Wurster coating and tablet film coating. This gives control challenges, as the spraying and evaporation processes must be carefully balanced and the operating window is significantly narrower than for standalone drying processes. Significant recent advances in modelling have led to effective scale-up and operational strategies. Factors such as flow cessation during filter bag shaking can have a major effect. A design space can be predicted which is often non-orthogonal, and pharmaceutical regulatory authorities have accepted filing submissions using a design space justified by mechanistic modelling.*

**Keywords:** *pharmaceuticals; peak moisture content; bed temperature; conduction; design space.*

---

## 1. Introduction

Most drying processes involve drying of a pre-wetted material, either a wet solid liquid or a liquid solution/suspension as in spray drying. However, a few processes involve simultaneous wetting and drying of the solids. This gives significant effects on the drying behavior, and additional challenges result in modelling, design and practical operation. This paper focuses on two processes of this type, both employed in the pharmaceutical industry: fluid bed (top spray) granulation and tablet film coating. Both have been previously described in texts such as Pandey and Bharadwaj [1] and Lyngberg et al. [2]. However, modelling of these processes has been relatively neglected compared to standalone drying processes, even though successful operation is only possible within a narrower operating range, particularly for fluid bed granulation, as shown below. Recent advances in modelling and process understanding have led to improved methods for design, scale-up and operation, and are described in this paper. Applications in the pharmaceutical industry are described, in particular the development of an appropriate Design Space and operational ranges.

## 2. Fluid bed granulation

In fluid bed granulation, binder solution is sprayed on to a fluidized bed of particles and evaporated off simultaneously. The initial mixture of powders is gradually transformed into granules held together by solid bridges. Normally, the bed moisture content (LOD, loss-on-drying) increases gradually during spraying and then falls during a final drying phase, as in Fig. 1. However, if the solution spray rate is too fast, uncontrolled agglomeration can result, with potential adverse effects both on product quality (dissolution or content uniformity) and operation (partial or complete defluidisation, and potential loss of the batch).

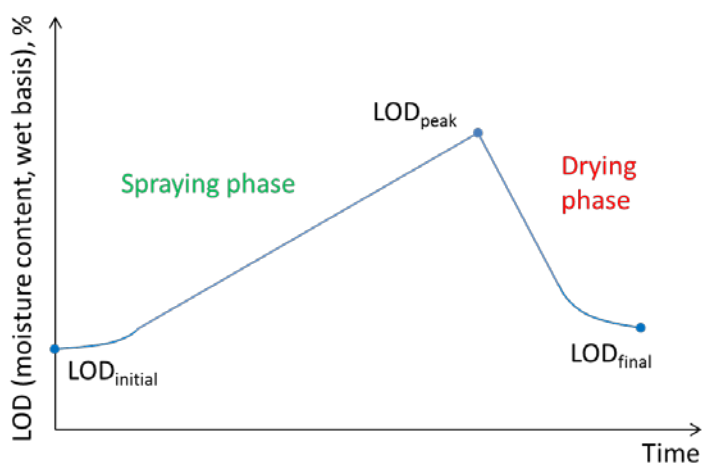

Fig. 1 Moisture content (LOD) during fluid bed granulation cycle.

## 2.1. Modelling - basic

The rate of moisture accumulation, and hence the peak LOD, can be calculated using a heat and mass balance. The fundamental approach was described by Gupta [3], and a similar model was presented by Lyngberg et al [2]. The water accumulation rate in the granules,  $m_{accu}$  (kg/h), is the difference between the water in the incoming spray and that removed by evaporation:

$$m_{accu} = m_{sol} (1 - x_b) - \left( \frac{Q_{air} - Q_{loss}}{h_{fg}} \right) \quad (1)$$

Here,  $m_{sol}$  = solution spray rate (kg/h),  $x_b$  = binder concentration as mass fraction (kg/kg),  $h_{fg}$  = latent heat of evaporation (kJ/kg),  $Q_{loss}$  = heat loss rate (kJ/h), and  $Q_{air}$  (kJ/h) is the heat released from the air, defined in (2):

$$Q_{air} = m_{air} C_{p,air} (T_{in} - T_{out}) = F_{air} \rho_{air} C_{p,air} (T_{in} - T_{out}) \quad (2)$$

Where  $\rho_{air}$  = air density (kg/m<sup>3</sup>),  $C_{p,air}$  = specific heat capacity of air (kJ/kgK).

Equations (1) and (2) show that four significant parameters affect the energy balance;

- Solution spray rate ( $m_{sol}$ , kg/h)
- Inlet air volumetric flow rate ( $F_{air}$ , m<sup>3</sup>/h) or mass flow rate ( $m_{air}$ , kg/h)
- Inlet air temperature ( $T_{in}$ , °C)
- Outlet air temperature ( $T_{out}$ , °C).

In fluid bed drying or granulation, if the particle surfaces remain fully wetted, the outlet air is close to saturation conditions, and is approximately equal to the wet bulb temperature  $T_{wb}$  (°C), which depends only on inlet air temperature and inlet air humidity  $Y_{in}$  (g/kg). Hence the four operating parameters which can affect heat input  $Q_{air}$  are  $m_{sol}$ ,  $F_{air}$ ,  $T_{in}$  and  $Y_{in}$ .

The mass accumulated is summed over the spraying period and can be transformed into a peak value of the loss on drying, LOD, which is a wet-basis moisture content:

$$LOD_{peak} = \frac{M_{sol}}{M_{bed,final}} \left[ (1 - x_b) + \frac{Q_{loss}}{h_{fg} m_{sol}} - \frac{Q_{air}}{h_{fg} m_{sol}} \right] + \frac{M_{W,initial}}{M_{bed,final}} \quad (3)$$

Where  $M_{bed,final}$  is the total mass of the bed at the end of granulation (including dry solids, binder and moisture) and  $M_{W,initial}$  is the total mass of water in the bed before granulation.

## 2.2. Modelling - extended

The standard model allows for heat losses, but Kemp et al [4] pointed out that several other factors affect the heat balance:

- i. Atomisation air flow from the two-fluid atomiser, normally at ambient temperature
- ii. Additional heat from the initial preheated bed of solids
- iii. Additional heat released when sprayed water becomes bound moisture
- iv. Adjustments for periods when the spray or airflow are turned off or reduced, for example during filter bag shaking.

(i) can be handled by a small adjustment to  $Q_{air}$  and (ii) and (iii) by small adjustments to  $LOD_{peak}$ , which like heat losses are best obtained by back-calculation from experimental measurement, and are the cause of the initial flatter section in the moisture-time curve. However, (iv) can have a significant effect. Exhaust air filters may operate with either “simultaneous” or “consecutive” cleaning. In consecutive cleaning, only a proportion of the filter bags are shaken or reverse pulsed at any moment, and the air flow and spray both continue. However, in simultaneous cleaning, all the filter bags are shaken at the same time, and air flow and spray are usually stopped. Typically, the spray is stopped, the airflow is ramped down, the bag is shaken, the airflow is restarted and finally the spray is restarted. Hence the spray is off for a longer period than the airflow and the balance between heat input and evaporation is changed. We can define fractional times  $\tau_{spray}$  and  $\tau_{air}$  as the proportion of the cycle that the water and air are flowing. Equation (3) now becomes:

$$LOD_{peak} = \frac{M_{sol}}{M_{bed,final}} \left[ (1 - x_b) + \frac{Q_{loss}}{m_{sol} h_{fg} \tau_{spray}} - \frac{Q_{air} \tau_{air}}{m_{sol} h_{fg} \tau_{spray}} \right] + \frac{M_{w,initial} - M_{corr}}{M_{bed,final}} \quad (4)$$

Where  $M_{corr}$  (kg) is a correction factor allowing for the preheating and binding effects.

For a given granulation formulation and equipment, most of the terms in equation (4) are fixed or nearly constant, and the only two which depend on operating parameters are  $Q_{air}$  and  $m_{sol}$ . Hence, peak LOD is predicted to vary with the ratio ( $Q_{air}/m_{sol}$ ). From (1) and (4), high values of  $Q_{air}/m_{sol}$  will give less accumulation and low peak LOD; conversely, low  $Q_{air}/m_{sol}$  gives more accumulation and may give an excessive peak LOD.

Therefore, we can verify whether the mechanistic model fits well to a set of experimental data by plotting peak LOD against  $Q_{air}/m_{sol}$ . The expected slope and intercepts for peak LOD can be evaluated from equation (4).

### 2.3. Design space

Historically, operating conditions for pharmaceutical processes were often defined as a single set point, which was inconvenient and inflexible. The modern approach as defined in ICH Q8 [5] is to define a set of ranges for each key parameter, creating a “Design Space”. The process can be operated anywhere within this envelope, but during development, it must be verified that the process can achieve key quality parameters under all possible operating conditions.

The analysis above shows that four operating parameters,  $m_{sol}$ ,  $F_{air}$ ,  $T_{in}$  and  $Y_{in}$ , can affect  $Q_{air}/m_{sol}$  and hence peak LOD. It is convenient to represent these as a two-dimensional design space by combining the first 3 parameters into  $Q_{air}$  (see Fig. 3 for an example). However,  $Q_{air}/m_{sol}$  plots as sloping lines on this diagram, and is a minimum at the bottom right-hand corner, giving a maximum value for the peak LOD. If this leads to overwetting and defluidisation, this region will not be acceptable for operation. However, if the maximum peak LOD for successful granulation is found by experiment, the corresponding value of  $Q_{air}/m_{sol}$  can be calculated and the available design space can be maximized by truncating the bottom right-hand corner. Likewise, if the top left-hand corner is too dry and gives poor granulation, this can also be truncated.

#### 2.4. Application to a real pharmaceutical process

The model was applied to a real process for which experiments showed that stable granule size was obtained with a peak LOD of 12.2% or less [4]. Experimental data for peak LOD at both pilot-plant and commercial scale fitted well to a straight line when plotted against  $Q_{air}/m_{sol}$ , as shown in Figure 2. However, there was a substantial offset between the two sets of data. Using standard scaling rules based on the basic model in section 2.1, the LOD at commercial scale was significantly higher than predicted, and defluidisation was observed on a batch under “wet” conditions (high spray rate, low temperature, low airflow). The extended model in section 2.2 showed that the adjustments for atomization, moisture binding, bed preheating and heat losses were small, but that there was a substantial difference between the filter bag shaking regimes at pilot and commercial scale. The ratio  $\tau_{air}/\tau_{spray}$  was much greater at pilot scale, and when equation (4) was applied instead of (3), this correctly predicted the observed difference between pilot and commercial scale.

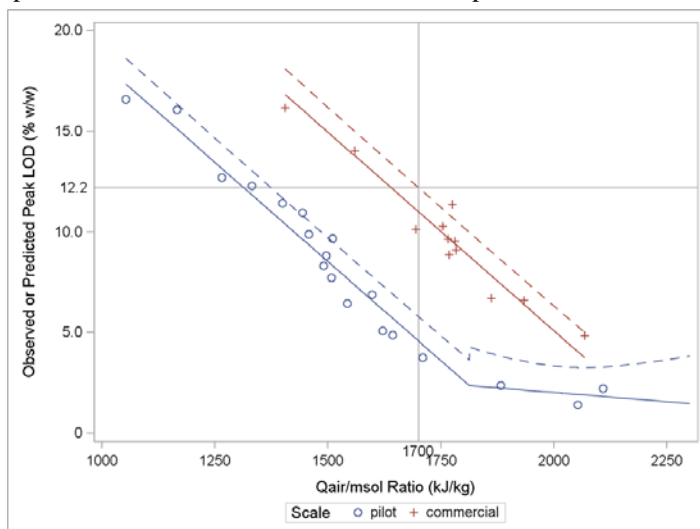

Fig. 2 Experimental results for peak LOD plotted against  $Q_{air}/m_{sol}$  ratio

The resulting commercial design space is shown in Figure 3. For operational simplicity, ranges can be defined for all the individual operating parameters, which plot as a rectangle which always falls within the design space. Moreover, the effect of changes in equipment can be anticipated, for example moving from a unit with simultaneous bag shaking (E1, broken lines) to consecutive shaking, where the air and liquid flows are continuous and  $\tau_{spray} = \tau_{air} = 1$  (E2, solid lines). The value of  $Q_{air}/m_{sol}$  corresponding to the peak LOD is increased, the design space shrinks and the operating conditions need to be altered.

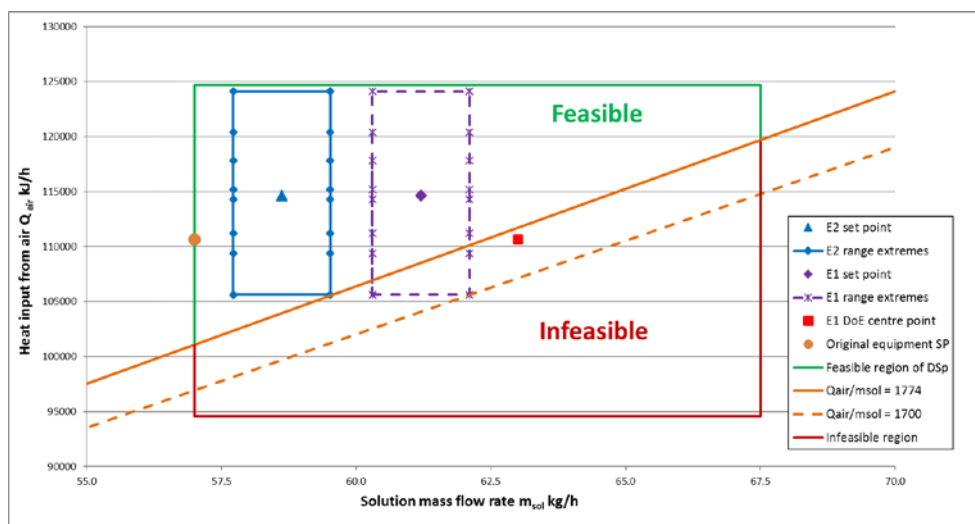

Fig. 3 Design and operating space at commercial scale with simultaneous bag shake and air cutoff (dotted lines) and consecutive bag shake with continuous flows (solid lines)

### 3. Tablet film coating

The most common type of pharmaceutical tablet coater is the perforated pan batch coater, in which coating solution is sprayed on to a region of the surface of a rolling bed of tablets. These tablets move back into the bulk bed within a few seconds and their surface must be sufficiently dry to avoid them sticking together, causing surface damage or “twinning”.

Current models were reviewed by Kemp et al [6], and can include four main aspects:

1. Mass balance - relates spray rate, suspension concentration and solids throughput
2. Heat balance - relates air flow rate, inlet and exhaust temperature and spray rate
3. Drying kinetics - calculates heat transfer and evaporation rates at the tablet surface
4. Spray effects - relates spray rate, spray area, coating film thickness and coating time.

The first two categories are routinely used in operation [7] – van den Ban et al. However, little had previously been done to study tablet surface kinetics, although Ebey [8] noted that

heat and mass balances could not explain all observations and proposed an Environmental Equivalency (EE) factor to allow for this. Kemp et al [6] demonstrate that the locus of the boundary where overwetting and other adverse effects occur is dependent mainly on exhaust temperature and secondarily on spray rate. Again, this leads logically to the conclusion that if the size of the design space is to be maximized, it will have a sloping lower boundary. In practice, fixed operational ranges for exhaust temperature and spray rate will usually be more convenient, but the model also demonstrates that the key point where failure is most likely is the bottom right corner (low temperature, high spray rate). The modelling at tablet level also explains the long-standing observation that the bed temperature is significantly higher than the wet bulb temperature, unlike fluidised beds. At the tablet surface, the heat for evaporation is coming not primarily from the hot air, by convection, but by conduction from the warm tablet itself. The dry tablet bed is heated up by the air. For example, a coater with an air inlet temperature of 60°C will typically have a bed temperature of 40-45°C whereas the wet bulb temperature is 25°C.

#### 4. Comparison between the processes

Although fluid bed granulation and tablet film coating show many similar effects, there are some important conceptual differences. As noted above, in a fluidised bed of granules the heat of evaporation comes by convection from the hot air and the bed is normally at  $T_{wb}$ , whereas in a rolling bed of tablets the heat to evaporate the surface liquid film comes mainly by conduction from the tablet and the bed temperature is significantly above  $T_{wb}$ .

##### 4.1. Modelling

Kemp [9] noted the distinction between models that can be “used once” (complex models to enhance process understanding) and “used regularly” (simple operational calculations). Both types of model are useful in these processes.

For fluid bed granulation, the full model can be “used once” for scale-up calculations and to establish the design space. A basic calculation of  $Q_{air}/m_{sol}$  can be used to ensure that the everyday operating conditions remain within the design space.

For tablet coating, the full model demonstrates the effects of surface drying kinetics, the design space shape and the number of coating passes. For normal operation, the heat and mass balance is sufficient, e.g. to give new coating times if the coating type is changed (Opadry® II can work at higher concentrations than Opadry® I), or required inlet temperature for a given exhaust temperature and spray rate when developing a DoE.

##### 4.2. Design space

The analysis shows that both processes can have a trapezoidal design space with a sloping lower boundary regulated by overwetting effects [8]. However, the governing factors are

different. For fluid bed granulation the boundary line is given by the  $Q_{air}/m_{sol}$  value which is dependent on the macroscopic heat and mass balance. In contrast, for tablet film coating the boundary is regulated by kinetic effects, balancing the incoming spray rate with the evaporation rate at the tablet surface due to the local tablet temperature, and the slope is given by the variation of vapour pressure with temperature.

## 5. Conclusions

Processes involving simultaneous wetting and drying have significant differences from those involving only drying. Design, scale-up and control present specific challenges, and operating windows are often narrower. These effects can now be modelled successfully.

## 1. Introduction

Electrohydrodynamic (EHD) drying appears to be a viable technology alternative to conventional thermal drying for certain thermally-labile materials, such as high-value bioactive components of fruits and medicinal plants (polyphenols, flavonoids, dietary fiber, etc.), living cells (bacteria, yeasts and viruses), and non-living substances of biological origin (blood plasma, serum, hormones, antibiotics, probiotics, nutraceuticals, etc.).<sup>[1-4]</sup>

The benefits of EHD compared to hot air drying on food quality include lesser shrinkage<sup>[15, 16]</sup>, higher rehydration ratio<sup>[15]</sup>, preserved content of ascorbic acid (vitamin C)<sup>[17]</sup> and no discernible color degradation<sup>[16-20]</sup>, though Li et al.<sup>[21]</sup> reported distinctive browning of okara cake just under the needle electrode. The quality-related benefits can be attributed to increased drying rate respectively by 1.5 to 4 times at high ( $5 \text{ ms}^{-1}$ ) and low ( $1 \text{ ms}^{-1}$ ) cross-flow air velocity, which translates into shorter drying time<sup>[22, 23]</sup> Although the sole ionic wind can favorably affect mass transfer, the combinations of EHD with low-temperature air drying<sup>[4-6]</sup>, vacuum freeze drying<sup>[7]</sup> and auxiliary contact heating<sup>[8]</sup> have also been reported.

Energy consumption in EHD drying is much lower than that in hot air drying, likely because of targeted supply of energy for moisture evaporation and practically no heat lost with exhaust air. However, the favorable low energy consumption given in published papers is based on the "net" energy calculated from the applied voltage and current. Even though the real energy consumption by EHD and peripheral equipment ranges from 90 to 5000  $\text{kJkg}^{-1}$ <sup>[2]</sup> it is still attractive for end use of EHD dryers. The energy-related issues in EHD drying have been reviewed by Kudra and Martynenko.<sup>[23]</sup>

Aside from purely experimental research on EHD drying of apples, carrot, potato, tomato, mushrooms, spinach, rapeseed, grapes blueberry, cranberry, etc., as well as model materials such as water, paper tissue, agar gel, wet sand and glass, theoretical studies on EHD drying are focused on determination of the ionic wind characteristics, such as space charge and corona current distributions<sup>[9, 10]</sup> or numerical solution of the mathematical model with experimental validation through drying experiments.<sup>[11-14]</sup>

Electrohydrodynamic (EHD) drying relies on the so-called corona (electric or ionic wind), originating from a sharp electroconductive needle or horizontal fine wire under high AC or DC voltage.<sup>[24]</sup> As a result, ions leaving discharge electrode impinge the surface of the drying material located on the metallic and electrically grounded plate-type electrode. The partially ionized gas molecules along with residual non-charged molecules create a jet-type gas flow between the discharge (needle or wire) electrode and the collecting (solid or perforated plate) electrode. Since some factors affecting EHD drying (e.g., voltage, current, temperature) are well presented in topical literature<sup>[25]</sup>, this paper is focused on less elaborated factors, such as desirable geometry of electrodes and air humidity on EHD drying. Examples of large-scale dryers are also given.

## 2. Key factors in EHD drying

### 2.1. Geometry of discharge electrode

The fundamental studies on EHD drying were performed mostly with a single pin or wire, and only few of them used multi-pin electrodes, yet placed arbitrarily regarding geometrical arrangement (e.g., rectangular or triangular) and spacing between pins. However, because of conical form of the ionic wind <sup>[26]</sup>, the impact surface of the wind from a single pin electrode on the plate electrode is circular unless disturbed by the air cross-flow, for example. Referring to multi-pin electrode it is intuitive to expect that the minimum distance between pins at a definite pin-to-material gap should result in a series of circular areas on the material surface which almost touch each other.<sup>[22]</sup>

It should be noted that the gaseous jet of ionic wind impinging the material under drying rebounds from the material surface along with the stream of evaporated moisture, which affects the aerodynamics of neighboring jets emitted from a multi-needle or multi-wire electrode. It means that the optimum spacing of pins is larger than theoretically predicted. This conclusion is supported by our own research <sup>[26]</sup> and literature data which indicate that single-pin electrode performs better than the multi-pin electrode.<sup>[27]</sup> The same effect is expected for multi-wire discharge electrode.

### 2.2. Effect of air humidity

Even though the air humidity plays significant role in the process of drying, its effect on the EHD performance has rarely been studied. Air humidity was measured in several studies by Lai<sup>[28]</sup> to calculate the Sherwood number but no explicit relationship for relative humidity was given. Bai et al.<sup>[29]</sup> presented results of vacuum freeze drying, which revealed better performance of EHD drying at ambient temperature 18°C and relative humidity of 45% versus vacuum freeze drying (conditions were not specified, however).

To fill this gap in the knowledge we performed targeted research on EHD drying of sliced white champignons at various humidity levels controlled by dehumidifier.<sup>[30]</sup> The results show that high air humidity is detrimental for the performance of EHD drying. Decreasing air humidity from 70 to 30% significantly increased drying rate (drying rate constant increased more than threefold from 0.12-0.13 to 0.45-0.5 h<sup>-1</sup>). These experiments confirmed that low air humidity is definitely desirable in EHD drying.

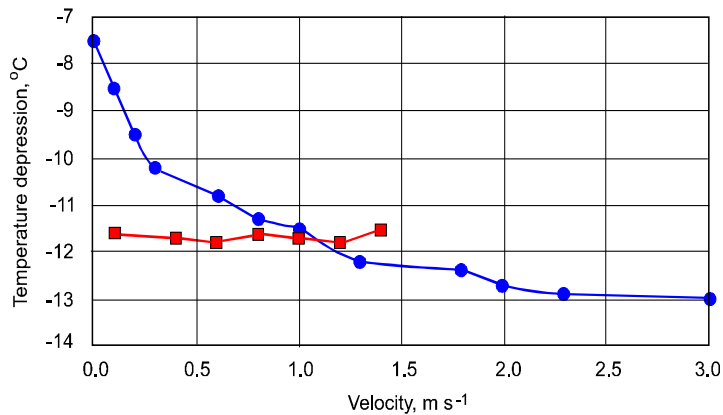

### 2.3. Depression of material temperature

Among various electrically-induced phenomena in EHD drying<sup>[2, 25]</sup> is a noticeable temperature drop in the boundary layer at the liquid-gas interface<sup>[31, 32]</sup>, which was identified as large as 8 K per 100 micrometers.<sup>[33]</sup> Usually temperature depression of wet material is a result of water evaporation, which depends on the gradient of water vapor

pressure at the liquid-gas interface. The maximum value of temperature depression could be calculated through absolute air humidity  $Y$  (kg H<sub>2</sub>O) (kg<sup>-1</sup> dry air)

$$T_{DB} - T_{WB} = \frac{\Delta H_{WB}}{c_H} (Y_{s_{WB}} - Y) \quad (1)$$

where  $T_{DB}$ ,  $T_{WB}$  denote respectively the dry- and wet-bulb temperatures (K),  $\Delta H_{WB}$  is the latent heat of evaporation at wet bulb temperature (kJ kg<sup>-1</sup>),  $c_H$  quantifies the humid heat (kJ kg<sup>-1</sup> K<sup>-1</sup>), and  $Y_{s_{WB}}$  stands for the absolute air humidity at wet bulb temperature.<sup>[34]</sup> Our own research aimed at measuring temperature of the wet paper towel with thermal imaging camera revealed noticeably difference between air/material temperatures during EHD drying under controlled humidity of 11% and different air velocities.<sup>[35]</sup>

**Fig. 1 Magnitude of temperature depression for paper towel exposed to forced air flow at 21.6°C (blue points) and ionic wind (red points) generated at 9.5-15 kV.**

It is evident that the temperature drop in humid air reflects typical psychrometric curve leveling off at high air velocity (above 6 ms<sup>-1</sup>). Thus, the cooling effect of air flow is directly related to air velocity. In contrast, temperature drop due to ionic wind demonstrated completely different behavior. The range of ionic wind velocities below 1.0 ms<sup>-1</sup> corresponded to electric field strength 3-4 kVcm<sup>-1</sup> (9.5-12 kV), whereas ionic wind velocity above 1.0 ms<sup>-1</sup> was induced by electric field above 4 kVcm<sup>-1</sup> (13-15 kV). Interestingly, temperature drop due to ionic wind is larger than the effect of similar air flow at the range of low velocities, while is smaller for the velocity above 1.0 ms<sup>-1</sup>. However, it should be noted that EHD-induced temperature of the material surface never attains the wet bulb temperature at convective air flow, which in this case is 13°C at RH=11%. Interestingly, the cooling effect of EHD was found practically independent of ionic wind velocity up to 1.5 ms<sup>-1</sup> above which the breakdown occurred because of excessively high electric field intensity.

## 2. Large-Scale EHD dryers

### 2.1. Prototype EHD dryers

It appears that the first prototype EHD dryer has been designed in Ukraine, in 1989 and tested for sliced apples.<sup>[36]</sup> The dryer has been built as a three-band conveyor unit fed with wet material at the upper band and discharged from the lower band. Although the dryer operates continuously with respect to material flow down from band-to-band the air in the dryer is basically stagnant. It means that moisture released from wet material builds-up air humidity and concentrations of volatile compounds and ionization products such as ozone. Therefore, after certain period the feeder is stopped and the empty dryer is blown with fresh ambient by a draft fan. The drying cycle is then repeated with the new batch of a drying material. The bands  $0.8 \times 0.3$  m are driven at controlled velocity from 0.1 to 1 m/min. The needles in discharge electrodes with optimum packing density of 500 needles per  $1 \text{ m}^2$  are made from molybdenum and powered with 10 to 30 kV AC at 50 Hz. The density of current about  $0.01 \text{ A m}^{-2}$  and power of  $100 \text{ W m}^{-2}$  results in apple temperature by 20 deg higher than the ambient temperature. Energy consumption for drying apple slices from 85 to 20% wb is on the order of 0.95-1.1 kWh per kg of evaporated water.

Another prototype of EHD continuous dryer is based on two belt conveyors 0.3 m wide and 3 m overall length with inter-stage mixing of the material.<sup>[37]</sup> Belts tilted at  $11.5^\circ$  are driven at fixed velocity of  $0.33 \text{ ms}^{-1}$ . Wire-type discharge electrode is made from stainless steel wire 0.5 mm in diameter with 5 cm spacing between neighboring wires. The wires arranged in parallel through a cable bus are connected to reversible polarity DC power supply with regulated voltage from 1 to 50 kV and current from 0 to 0.3 mA.

Tests with wet sand at 8-12 % wb in a 2-cm layer with 2.52 cm gap between discharge electrode and the material surface revealed drying enhancement by 1.35 at 12 kV and throughput of 3.1 kg of evaporated water per 1 hour. This dryer can be used for processing of granular materials in size up to 10 mm such as sand, gravel, preformed (extruded) pastes as well as sliced or diced fruits and vegetables.

### 2.2. Pilot-scale EHD dryers

As of year 2018 there is no information on commercially available EHD dryers. However, large EHD dryers of various designs have been custom-made in China for research purpose<sup>[38]</sup>. These dryers are basically of two types: (i) multi-band dryer in vertical arrangement (GXJ-2) that can be aggregated into one unit (GXJ-16), and (ii) vertical cylindrical dryer (GTJ-1.7) with vibrated shelves (Fig. 2).

The overall size is  $1.6 \times 1.7 \times 2.4$  m (for GXJ-2) and  $5.2 \times 3.5 \times 3.1$  m for GXJ-16 where numbers in the model signify drying area in  $\text{m}^2$ . Depending on the material, drying rate is over 3 kg of water per  $\text{m}^2\text{h}$  at corona power of 0.4 and 3.2 kW, respectively. The dryer is

equipped with dehumidifier with power 0.37 and 5.5 kW, respectively. The dryer GTJ-1.7 is 1.7 m in diameter with 5 shelves with drying area of 10 m<sup>2</sup> vibrated with amplitude 0-4 mm. Drying rate is over 5 kg of evaporated water per m<sup>2</sup>h at corona power 2.2 kW. These dryers were used to dehydrate various whole and cut fruits and vegetables including specific plants used in Chinese medicine.

**Fig. 2** The picture and schematics of the EHD dryer model GTJ-1.7. [38]

### **Abstract**

*Convective drying is a common process for the treatment of particulate solids also operated in continuous mode. Continuous operation is characterised by operation in steady-state with constant product throughput and constant product quality. Due to external influences, i.e. seasonal or local variations in the properties of the initial wet material, deviations in the product quality can result, for example over- or under-drying, or on-set of unwanted reaction. In this contribution a new feedback control concept is developed that is robust with respect to variations and uncertainties in the drying kinetics of the material and can reject and attenuate process disturbances.*

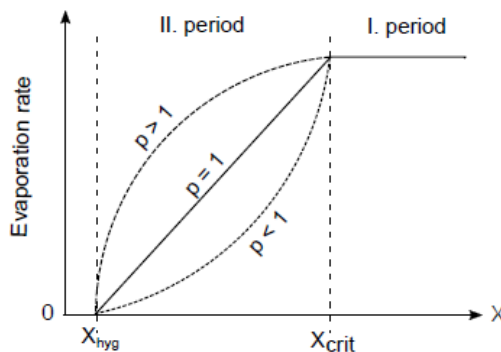

**Keywords:** *Process control; drying kinetics; robustness; fluidized bed; yeast.*

## 1. Introduction

Drying, the removal of liquid from a solid material, is one of the major unit operations in solids processing, e.g. chemicals, pharmaceuticals, food and paper<sup>[1,2]</sup>. The liquid can be removed mechanically, e.g. draining, wringing, filtering, or thermally by induction of a phase change, e.g. by evaporation or sublimation of the liquid. Thermal drying is extensively used and is one of the most energy-intensive processes, taking up approximately 10-25% of a nation's energy output<sup>[1]</sup>.

Considering convective drying of particulate solids, characteristic evaporation rates as a function of moisture content  $X$ , i.e. the mass of liquid per mass of dry solid, are shown in Fig. 1: For moisture contents  $X > X_{cr}$ , where  $X_{cr}$  is the material-specific critical moisture content, a constant evaporation rate is observed; for moisture contents  $X_{hyg} < X < X_{cr}$  a material-dependent falling rate is observed. If the moisture content reaches  $X_{hyg}$ , thermodynamic (adsorption) equilibrium is attained and the evaporation rate vanishes.

*Fig. 1. Schematic overview of experimentally observed evaporation rates in drying of solids.*

The first (constant) drying period refers to the surface-wet particle, i.e. direct heat and mass transfer between liquid and gas. In this period, the heat and mass transfer is gas-side controlled, i.e. the gas conditions, e.g. temperature and mass flow rate, directly determine the evaporation rate. In the second drying period, the falling rate period, moisture is mostly located in the (porous) interior -- heat and gas now have to penetrate the solid by conduction and diffusion first in order to evaporate the liquid; also the vapour has to be transported to the particle surface, e.g. by vapour diffusion or capillary pumping, before it can be taken up by the main gas flow. The farther inside the moisture is located, the longer diffusion and conduction processes take and thereby reduce the evaporation rate in the second drying period.

From this phenomenological description, two different aspects can be identified that influence the drying process: (1) gas-side conditions and (2) material properties. A variation of gas-side conditions only will yield different evaporation rates; the material-specific part, however, remains the same, i.e. the evaporation rates are qualitatively but not quantitatively similar.

An approach to model this effect is given by the concept of normalized drying curve  $v$  (NDC), originally developed by van Meel<sup>[3]</sup>. Here, the second drying period rate is expressed in terms of the (known and constant) gas-side controlled first drying period rate. Main advantage of the NDC is that it can be obtained directly from considerably simpler measurements than effective diffusivity; main drawback is that it only allows describing the evolution of the average moisture content,  $X$ . However, as this value is of primary concern in many practical applications, the concept of normalised drying curve has found widespread use for dryer design, optimisation and troubleshooting.

The normalised drying curve is defined as:

$$\dot{v}(\eta) = \frac{\dot{m}_{evap,II}}{\dot{m}_{evap,I}}, \quad \eta = \frac{X - X_{hyg}}{X_{cr} - X_{hyg}}, \quad (1)$$

where  $\eta$  denotes the normalised moisture content, with values  $0 \leq \eta \leq 1$  denoting the second drying period. Given experimental data, the normalised drying curve can be fitted and used for process modelling and feedback controller design as will be shown in the following.

In this work, we present a general approach to robust feedback control of continuously operated convective dryers. In the following section, we present the dynamic drying model equations. Afterwards, the robust controller is designed and its main features are discussed. In the Results section, the performance of the controller, designed for a nominal operating point, is presented with respect to model uncertainties and different operating points. The work closes with Conclusions and Outlook on future work.

## 2. Process Modelling

For the purpose of this work, we pose the following assumptions: (i) The particulate phase in the apparatus can be (at least theoretically) considered as well-mixed. (ii) The gas-phase is also considered as well-mixed, i.e. no spatial gradients. (iii) The particulate phase is either mono-disperse or represented by a constant Sauter mean diameter  $d_{32}$ , i.e. a particle size distribution is not considered. Each particle dries as if it were a single particle. (iv) Drying is kinetically-controlled, i.e. drying gas is not close to saturation. (v) Drying takes place under approximately adiabatic conditions, i.e. sufficient insulation of apparatus provided to avoid significant heat loss to the environment. (vi) Particles enter the apparatus

with an average moisture content  $X_{in}$  at a dry mass flow rate  $\dot{m}'_{dry,in}$ . (vii) Evaporation takes place from the total surface area of all particles. (viii) The average residence time of particles in the continuously operated dryer is  $\tau$ , which can be regulated, e.g. by speed of conveyor, or hold-up mass control.

Then, starting from a mass balance of the wet solid  $\dot{m}_{wet} = X \dot{m}_{dry}$ , the following mass balances for the dry solid (hold-up) and the average moisture content can be derived:

$$\begin{aligned} \frac{dX}{dt} &= \left( \dot{m}_{dry,in} X_{in} - \frac{\dot{m}_{dry}}{\tau} X - \dot{m}_{evap} - X \frac{d\dot{m}_{dry}}{dt} \right) / \dot{m}_{dry}, \\ \frac{d\dot{m}_{dry}}{dt} &= \dot{m}_{dry,in} - \frac{\dot{m}_{dry}}{\tau}. \end{aligned} \quad (2)$$

The evaporation rate is written as

$$\dot{m}_{evap} = \dot{m}_{evap,I} A \dot{\nu} = \rho_g \beta (Y_{sat}(T_{in}) - Y_{in}) A \dot{\nu} \quad (3)$$

wherein  $A$  denotes the total particle surface area available for evaporation; and  $Y_{sat} - Y_{in}$  the maximum drying potential of the gas, which is determined by the inlet gas moisture content  $Y_{in}$  and the inlet gas temperature  $T_{in}$ . If significant heat losses occur (violation of assumption (v)), then  $Y_{sat} - Y_{in}$  decreases in value to  $Y_{out} - Y_{in}$ ; the model structure, however, does not change.

The total surface area of particles can be determined from the hold-up mass  $A = 6\dot{m}_{dry}/(\rho d_{32})$ . The mass transfer coefficient  $\beta$  is in general a function of the Sherwood, Reynolds, Prandtl and Schmidt number.

The normalised drying curve is denoted by  $\nu(\eta)$ ; in order to use the normalised drying curve in process models, some functional form needs to be fitted. In this work, the following form is used:

$$\dot{\nu}(\eta) = \frac{p\eta}{1 + (p-1)\eta} \quad (4)$$

The virtue of this functional form is that one fitting parameter  $p$  suffices to describe the different curvatures. At  $p=1$ , corresponding to the linear relation  $\nu(\eta) = \eta$ , a change in curvature occurs that can be smoothly related to values  $0 < p < 1$  and  $p > 1$ . It has to be noted that all material characteristics are lumped into the parameter  $p$ .

Under the stated restrictions, the presented model is able to calculate the dynamic and steady-state behaviour of a continuous convective dryer.

### 3. Robust Controller Design

The aim of the robust controller is to provide comparable performance of the uncertain drying process with respect to the nominal process conditions and parameters. Specifically, it should provide at different steady-states the required steady-state output (controlled output), provide not too slow process dynamics in doing so, avoid excessive control action, respecting known limits of the actuators and operating conditions, e.g. a maximum operating temperature.

These requirements can be met in (linear) controller design within the  $H_\infty$  framework<sup>[4]</sup>. Within this framework, a (linear) controller with transfer function  $H_\infty(s)$  is determined such that a) the closed-loop process is asymptotically stable and b) the following functional is minimised:

$$\min_{H_\infty \text{ stabilizing}} \left\| \begin{array}{c} S(s) \cdot W_1(s) \\ H_\infty(s)S(s) \cdot W_2(s) \\ T(s) \cdot W_3(s) \end{array} \right\|_\infty \quad (5)$$

Therein,  $s$  denotes the variable of the Laplace domain,  $S$  denotes the closed-loop sensitivity function,  $T^*$  the closed-loop complementary sensitivity function, and  $W_i$  ( $i = 1, 2, 3$ ) are weight functions.

To assess and quantify the process uncertainty, different models can be used. In this work, we restrict ourselves to the multiplicative uncertainty model: Given a linear open-loop stable nominal transfer function  $G_{nom}(s)$ , and a second, uncertain but open-loop stable transfer function  $G(s)$ , the multiplicative model uncertainty can be expressed as

$$\Delta_m(s) = (G(s) - G_{nom}(s))G_{nom}^{-1}(s) \quad (6)$$

A variation in parameters generates a family of transfer functions  $G(s)$  and a set of multiplicative uncertainty models  $\Delta_m(s)$ . Let the upper-bound of  $\Delta_m(s)$  for a given set of variations be denoted by  $\Lambda_m(s)$ .

For design of performance, the weights  $W_i$  can be used:  $W_1$  is used to design good disturbance rejection over a wide frequency region;  $W_2$  directly influences the controller gain, thus limiting the control energy; and  $W_3$  is used to achieve good reference tracking. For a multiplicative uncertainty model,  $W_3(s) = \Lambda(s)$  is set.

Given the nominal model, the upper bound on model uncertainty and the weight functions, a robustly stabilising feedback controller can be readily computed by established control software, e.g. Matlab's Control System Toolbox.

## 4. Results

In the following, specific results of the design and performance of the controller are presented for fluidized bed drying of spherical baker's yeast pellets. Uncertain parameters are:  $p$  ranges in the interval  $[0.5, 2.5]$  with a nominal value of 1.5, and  $X_{crit}$ , the point of onset of the second drying period which is known to slightly depend on drying temperature:  $X_{crit}$  in the interval  $[0.8, 1.2]$  with a nominal value of 0.98.

The manipulated variable is the gas inlet temperature  $T_{gas,in}$ , the controlled output is the average moisture content of the yeast pellets,  $X$ , i.e. a SISO control problem. Unmeasured disturbances are the solids and gas inlet moisture contents,  $X_{in}$  and  $Y_{in}$ , respectively. For reasons of comparison a standard SISO PI controller and a linear quadratic regulator (LQI) are also designed for the nominal case.

Both controllers are applied to the nonlinear model to assess their performance and robustness of the closed-loop. We start the presentation with the discussion of disturbance rejection. At the nominal steady state, a stepwise disturbance ( $X_{in} -15\%$ ) is applied at  $t=30$  minutes and ends after additional 10 minutes. At 50 minutes a second disturbance ( $Y_{in} + 115\%$ ) is applied for 10 minutes. The closed-loop response under both controllers is shown in Fig. 2. It can be seen that in the nominal scenario, both controllers have comparable performance, i.e. the settling times after a disturbance.

To investigate the impact of the (uncertain) parameter  $p$ , additional simulations were performed under otherwise nominal conditions. Figure 3 shows the results of a simulation with the maximum value  $p=2.5$ . One can clearly observe that the performance of the  $H_\infty$ -controller is constant in the parameter range, even at a different set-point. Contrary, the PI-controller and LQI-controller lose performance at a non-nominal set point and the decrease in performance is higher with increasing value of  $p$ .

## 5. Conclusions

We presented an application of robust controller design to a wide range of continuously operated convective drying processes, where the main process uncertainty is in the parameters of the kinetics of the second drying period. We could show that these processes are asymptotically open-loop stable for practically relevant operating parameters. Suitable feedback controllers can be designed in the  $H_\infty$  framework given the knowledge of a nominal operating point and bounds on the parameters.

Future work will focus on the extension of this approach to MIMO problems, considering additional manipulated variables, e.g. the gas mass flow rate, and controlled outputs, e.g. product temperature or water activity.

Fig. 2. Response of the controlled nominal system ( $H_{\infty}$ , PI and LQI controller) for the described disturbance scenario for the set points  $X = 350$  (g water)/(kg dry solid).

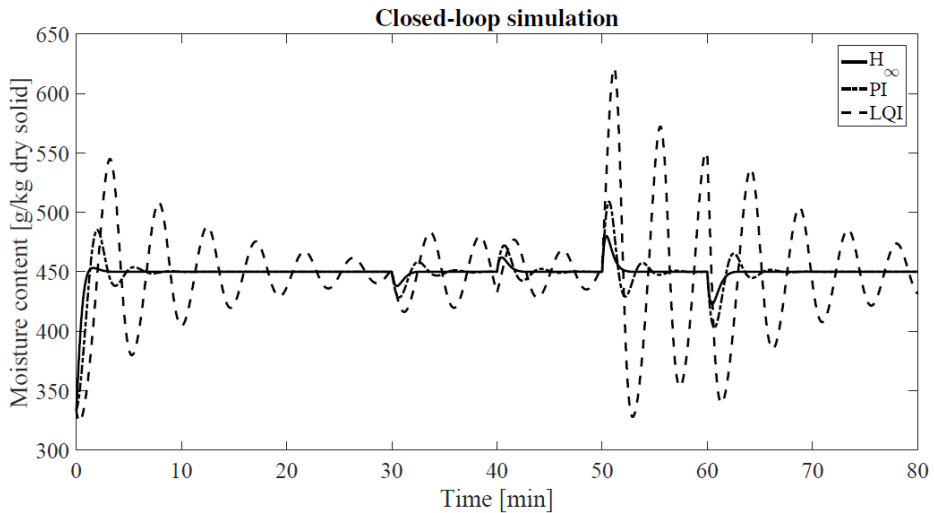

Fig. 3. Response of the controlled system ( $H_{\infty}$ , PI and LQI controller) for the described disturbance scenario for the non-nominal set-point  $X = 450$  (g water)/(kg dry solid) and  $p = 2.5$  (right).

### **Abstract**

*Two models of foam drying are presented in the paper: single droplet drying and perfect mixing of phases spray drying models to describe mechanism of drying of droplet containing bubble.*

*Analysis of drying curves shows that in constant drying rate period and in the falling drying rate period, evaporation rate decreases due to particle shrinkage and increasing of resistance of moisture diffusion inside the solid crust. Increase of gas pressure in the bubble might cause particle breakage.*

*Slight differences between theoretical and experimental results caused by disregarding broken particles in the simulations proves accuracy of the developed model.*

**Keywords:** *spray drying, modeling, foamed materials, particle morphology*

## 1. Introduction

Foaming of slurry in spray drying processes is a method to control rheological properties of feed like viscosity and density and morphology of powder. Powders obtained in foam spray drying process are characterized by lower bulk density, high porosity and particle sizes, enhanced solubility and wettability in relation to conventional spray drying. However, to control product quality, foam spray drying process must to be carried out in specific window of the process parameters selected individually for dried material.

In the literature there is lack of mathematical description of foamed spray drying process; existing models refer only to the constant drying rate period [1].

The aim of this work was to develop and validate mathematical model of foam spray drying process to determine morphological changes of particles and to estimate the quality of the product.

## 2. Foam spray drying model

Two models of foam drying were developed in the frame of the work: single droplet drying (SDD) model to check correctness of applied correlations and perfect phase mixing foam spray drying model to simulate drying process. All calculations were performed in Matlab and validated on a base of data obtained from the foam spray drying experiments performed at Lodz University of Technology [2].

### 2.1. Single droplet drying model

SDD model describes moisture evaporation of maltodextrin solution (DE12) from stationary droplet which contains a single saturated nitrogen bubble in constant ambient air temperature  $T_G$ , and humidity  $Y_G$ . In constant drying rate period, droplet shrinks due to water evaporation whereas in falling drying rate period, particle shrinkage stops because of crust solidification. In this period pressure in the gas bubble increases and might cause particle brakeage. The model allows to determine drying curves, particle density, porosity, crust thickness and pressure in the internal bubble.

#### 2.1.1. Heat transfer

Moisture from the particle evaporates to surrounding air in temperature which, taking into account heat capacity of air and internal bubble, can be calculated from equation (1):

$$\frac{dT_p}{dt} = \frac{A_p \alpha_p (T_p - T_G) + h \left( \frac{dm_{p,a}}{dt} + \frac{dm_{p,b}}{dt} \right)}{m_p c_p + m_b c_b} \quad (1)$$

### 2.1.2. Mass transfer

Mass transfer model was based on the concept of characteristic drying curves [3]. Overall evaporation from the droplet/particle is a sum of moisture evaporation to the surrounding air and to the internal bubble, eq. (2):

$$\frac{dm_p}{dt} = \frac{dm_{p,a}}{dt} + \frac{dm_{p,b}}{dt} \quad (2)$$

Evaporation rate to drying air is calculated from the equation:

$$\frac{dm_{p,a}}{dt} = f M_w A_p \beta_p (C_s - C_G) \quad (3)$$

where heat and mass transfer coefficients ( $\alpha_p$  and  $\beta_p$ ) were calculated from McAdams correlations. Amount of water transferred to the bubble was determined from eq. (4):

$$\frac{dm_{p,b}}{dt} = m_N \frac{M_w}{M_N} \left( \frac{P_{st}}{P_a - P_{st}} \right) \frac{1}{dt} \quad (4)$$

To take into account decrease of drying rate (eq. (3)) in the falling drying rate period, coefficient  $f$  defined by relation (5) was used [5]. In constant drying rate period coefficient  $f$  is equal  $f = 1$ . After critical moisture content, due to increase in internal mass transfer resistance,  $f$  decreases to  $f = 0$  at the equilibrium point. According to Woo et al. [4] coefficient  $f$  can be expressed as a function of moisture content:

$$f = \left( \frac{X - X_{eq}}{X_{cr} - X_{eq}} \right)^{3.22} \quad (5)$$

Critical moisture content for maltodextrin was determined experimentally in a frame of this work and calculated from eq.(5), ( $T_G$  in °C):

$$X_{cr} = 21555 \cdot T_G^{-2.106} \quad R^2 = 0.976 \quad (6)$$

Equilibrium moisture content was calculated from GAB equation [5]:

$$X_{eq} = \frac{X_{mo} c k a_w}{(1 - k a_w) [1 + (c - 1) k a_w]} \quad (7)$$

Where constants  $c = 10.866$  and  $k = 0.971$ . Monolayer moisture content ( $X_{mo}$ ) for maltodextrin is equal to 0.0518 kg/kg.

### 2.1.3. Particle morphology

Particle diameter was calculated from the sum of the volumes of liquid and internal gas bubble:

$$d_p = \sqrt[3]{\frac{6(V_L + V_b)}{\pi}} \quad (8)$$

In the constant drying rate period, change of liquid shell volume resulting from evaporation of moisture can be calculated from equation (9):

$$V_L = \frac{\rho_{L,0}(1+X_{cr})\pi}{\rho_L(1+X_0)} \frac{\pi}{6} d_{p,0}^3 \quad (9)$$

In the falling drying rate period, particle can shrink due to thermal deformations of solidified crust. Particle shrinkage can be determined using modified equation proposed by Chen [6]:

$$V_L = \frac{\pi}{6} \left[ d_{p,cr} \left( b + (1-b) \frac{X}{X_{cr}} \right) \right]^3 \quad (10)$$

Shrinkage coefficient  $b$  was calculated as a ratio of particle diameter when particle moisture content is equal to critical moisture content, to the final particle diameter measured experimentally. Equation (11) describes  $b$  as a function of drying air temperature ( $T_G$  in °C):

$$b = 0.41 + 0.0038T_G - 6.97 \cdot 10^{-6}T_G^2 \quad R^2 = 0.971 \quad (11)$$

Volume of the internal bubble was calculated from the current bubble mass and density (12):

$$V_b = \frac{m_b}{\rho_b} \quad (12)$$

Density of the bubble depends also on the gas humidity and can be determined from equation (13):

$$\rho_b = \frac{P_b}{\frac{R}{M_N} T_p} (1 + Y_b^*) \frac{1}{1 + Y_b^* \frac{M_N}{M_w}} \quad (13)$$

Equation (12) can be transformed to equation (14) to calculate bubble diameter:

$$d_b = \sqrt[3]{\frac{6V_b}{\pi}} \quad (14)$$

Having diameter of particles ( $d_p$ ) and bubbles ( $d_b$ ), crust thickness (particle wall thickness) can be determined.

In constant drying rate period, pressure inside the particle was equal to the ambient pressure  $P_b = P_a$ . To calculate gas pressure inside the bubble in the falling drying rate period, we assumed proportional grow of pressure with particle temperature in isochoric process according to the equation (15):

$$P_b = P_a \frac{T_p}{T_{p,cr}} \quad (15)$$

Selected results of calculations are presented in Fig. 1. Fig. 1 shows grow of solid concentration and drying curve for the same initial bubble diameter and different initial droplet diameters.

*Fig. 1 Solid concentration and evaporation rate from SDD model.*

We may observe that as bigger droplet contains more liquid to be evaporated (initial bubble diameter is the same), particle solid concentration grows slower. Analysis of drying curves shows that in constant drying rate period evaporation rate slightly decreases due to particle shrinkage; in the falling drying rate period ( $X < X_{cr} = 0.5 \text{ kg/kg}$ ), drying rate falls down due to increasing of internal resistance of moisture diffusion inside the solid crust. Shape of drying curves is characteristic for evaporation from single droplets which confirms correctness of physical model of the process.

## 2.2. Co-current foam spray drying model

In co-current foam spray drying model air temperatures, particle velocities and air humidity were calculated from the heat, mass and momentum balance, equations (17) - (22) [7]. Foam spray drying calculations were carried out for perfect mixing of phases, axisymmetrical flow of air and particles and monodispersed atomization. Momentum transfer between drying air and particles was determined from classical equations:

$$\frac{dv_{p,x}}{dt} = g \left( 1 - \frac{\rho_G}{\rho_p} \right) - \frac{3}{4} C_D \frac{v_p(v_{p,x} - v_{G,x})\rho_G}{\rho_G d_p} \quad (17)$$

$$\frac{dv_{p,r}}{dt} = -\frac{3}{4} C_D \frac{v_p(v_{p,r}-v_{G,r})\rho_G}{\rho_G d_p} \quad (18)$$

$$\frac{dv_{p,z}}{dt} = -\frac{3}{4} C_D \frac{v_p(v_{p,z}-v_{G,z})\rho_G}{\rho_G d_p} \quad (19)$$

where  $v_p$  is relative particle velocity. Air humidity was calculated from mass balance:

$$\frac{dY_G}{dt} = \frac{-\dot{M}_L}{\dot{M}_G \rho_G} \left( \frac{\frac{dm_p}{dt}(1+X)}{m_{p,0}c_0 + m_{p,w}} \right) \quad (20)$$

Particle moisture content was determined from equation (21):

$$\frac{dX}{dt} = \frac{\frac{dm_p}{dt} + (Y_{eq} \cdot m_N - m_{G,W})(1+X)}{m_{p,0}c_0 + m_{p,w}} \quad (21)$$

Air temperature was determined from heat balance (22):

$$\frac{dT_G}{dt} = \frac{1}{\dot{M}_G c_G} \left( -\dot{M}_G (c_v T_G + h) \frac{dY_G}{dt} - \dot{M}_L (X c_w + c_s) \frac{dT_p}{dt} - \dot{M}_L c_w T_p \frac{dX}{dt} \right) \quad (22)$$

Selected results of calculations are shown in Fig.2. Figure 2 presents comparison of theoretically and experimentally determined wall thickness and particle density for different air temperatures and foaming gas rate. Final density of the material determined from the mathematical model decreased from 1300 kg/m<sup>3</sup> to 600 kg /m<sup>3</sup>, which is in line with the experimental results. Differences in relation to the experiments are caused by disregarding broken particles in the simulations. Decrease in the wall thickness depends on the amount of gas introduced into the interior of the droplet. The higher degree of foaming, the larger gas bubble is trapped in the particle and the less material forms the particle.

**Fig.2 Wall thickness and particle apparent density for a different air temperatures and different foaming gas rate.**

### 3. Conclusions

Model of co-current foamed spray drying was developed to determine mechanism of droplet drying containing a single bubble.

Analysis of theoretical and experimental results shows that particle solid concentration grows slower for bigger droplet as it contains more liquid to be evaporated as initial bubble diameter is the same. In constant drying rate period evaporation rate slightly decreases due to particle shrinkage which typical for evaporation from droplets and confirms correctness of physical model of the process.

Density of the material determined from the mathematical model decreased twofold in relation to the initial which was in line with the experimental results. Decrease in the wall thickness is a function of the amount of gas introduced into the interior of the droplet. Particle wall thickness and particle density for different air temperatures and foaming gas rate are in line with the experimental results. Differences in relation to the experiments are caused by disregarding broken particles in the simulations.

### ***Abstract***

*In this study, we apply the drying model of polymer solution coated on a flat substrate to the spray drying granulation process in formulation. In order to apply the former model to the drying of this spherical object, we consider this spherical object to be a stack of solution films applied on the spherical shell and discuss the drying process of each solution film. As a result, we see that the smaller the radius of curvature of the droplet, the more the fine particles tend to be unevenly distributed on the surface of the droplets during drying.*

**Keywords:** *model, numerical simulation, spray drying granulation, spherical, droplets*

---

## **1. Introduction**

Drying process of polymer solution coated on a substrate is very important in various industrial applications such as fabricating flat polymer thin films [1] and inkjet printing [2, 3]. Then we have proposed and modified a model of drying process of polymer solution coated on a flat substrate for flat polymer film fabrication [4 – 14]. Then we have proposed the method of thickness control of a thin film after drying [15 – 17]. And we have clarified dependence of distribution of polymer molecules on a flat substrate after drying on various parameters based on analysis of many numerical simulations of the model.

On the other hand, the demand that a flat polymer film should be formed not only on a flat substrate but also on a three-dimensional uneven substrate after drying a polymer liquid film coated on the substrate has been increasing with the advancement in microfabrication technology. Therefore, we expanded the above-mentioned model into the drying model of a polymer liquid film coated on three-dimensional structure. Then we analyzed dependence of distribution of polymer molecules on the three-dimensional structure on various parameters through many numerical simulations. The results were reported at IDS 2016 [18].

Then, in this study, we apply the drying model to the spray drying granulation process in formulation. Spray drying granulation is a type of wet granulation method in formulations. In the spray drying granulation, the slurry raw material is made into minute droplets and dried. Therefore, the object to be dried is spherical. In order to apply the former model to the drying of this spherical object, we consider this spherical object to be a stack of solution films applied on the spherical shell and discuss the drying process of each solution film. The difference in area between the upper surface and the lower surface in the minute volume of each solution film can be represented by the radius from the center of the spherical shell and is related to the difference in diffusion in the vertical direction.

As a result of numerical simulation of this modified model, it was found that the smaller the radius of curvature  $r$  of the droplet, the more the fine particles tend to be unevenly distributed on the surface of the droplets during drying.

## **2. Model**

### **2.1. Theory and basic equations**

As mentioned in previous papers, there are two dynamic models of the drying process of polymer solution coated on a flat substrate, namely, an evaporation model and a transport model for a non-equilibrium polymer solution (Kagami et al., 2002; Kagami, 2011; Kagami

and Kubota, 2011). The latter can be divided into two basic types of transport, that is, the following two diffusion paths (Kagami et al., 2002):

(1) Diffusion of solvent containing solutes (polymers) in the direction of evaporation of the solvent

(2) Change in concentration in a solution

Because details of theory and the basic equations have been reported in previous papers (Kagami et al., 2002; Kagami, 2011; Kagami and Kubota, 2011; Kagami, 2014a; Kagami, 2015), only the basic equations are shown here.

First, we consider the following evaporation model (Kagami et al., 2002).

$$G = \gamma(1 - \beta C) \quad (1)$$

Here,  $G$  is the evaporation rate,  $C$  is the concentration of the solution, and  $\beta$  is a constant. Furthermore,

$$\gamma = K \sqrt{\frac{M}{2\pi RT}} P_0 \quad (2)$$

is a correction factor, where  $P_0$  is the vapor pressure,  $M$  is the molecular weight,  $R$  is the gas constant,  $T$  is temperature, and  $K$  is a correction factor for the theoretical evaporation rate (Hickman and Trevoy, 1952).

Then, the two diffusion models are formulated as follows. First, the diffusion equation for solvent containing solutes is written as

$$\frac{\partial V}{\partial t} = K_v \nabla^2 V \quad (3)$$

where  $V$  is the volume of solvent containing solutes included in a space and  $K_v$  is the diffusion coefficient of the solvent (Kagami, 2011). An evaporation term (Eq. (1)) is added to Eq. (3), which describes the interface between liquid and gas (vacuum), so Eq. (3) is modified to (Kagami, 2011)

$$\frac{\partial V}{\partial t} = K_v \nabla^2 V - \gamma(1 - \beta C) \quad (4)$$

Next, the diffusion equation governing the change in concentration in solution is written as (Kagami, 2014a; Kagami and Kubota, 2011)

$$\frac{\partial N}{\partial t} = K_c \nabla^2 N + \frac{N}{V} (K_v - K_c) \nabla^2 V - \frac{2K_c}{V} \nabla N \cdot \nabla V \quad (5)$$

where  $N$  denotes the number of solute molecules included in a space and  $K_c$  is the diffusion coefficient of the solution.

In this study, we consider a solution containing one type of solute and one type of solvent for simplicity. Therefore, we build our model mainly using Eqs. (1)–(5).

The diffusion coefficient,  $K_c$ , of the solution changes with time. As mentioned in previous studies, is written as (Kagami, 2011)

$$K_c = \frac{k_b T}{6\pi R \eta_0 \{[\eta]C + 1\}} \quad (6)$$

where  $k_b$  is the Boltzmann constant,  $\eta_0$  is the viscosity of the solvent, and  $[\eta]$  is the intrinsic viscosity.

## 2.2. Improvement of the avobe model in the case of spherical dry solution

Now consider the drying of spherical solution as in the case of spray drying granulation. In order to estimate the diffusion in each direction in the minute region in the spherical solution, consider the minute region  $S$  in the spherical solution between the distance  $r$  and  $r + dr$  from the center  $O$  of the sphere.

For the sake of simplicity, let us consider a circle  $C$  of a cross section of this sphere cut by a plane passing through the center  $O$  of the sphere. Considering the cross section  $S_c$  of the micro region  $S$  cut off at the deviation angle  $\theta$  in the circle  $C$ , it is as shown in Fig. 1, and the length in the circumferential direction and the length in the radial direction of the cross section  $S_c$  can be expressed as shown in Fig. 1.

Fig. 1 The cross section  $S_c$  of the micro region  $S$  cut off at the deviation angle  $\theta$  in the circle  $C$

Now, if  $r\theta = dq$ , the length of the circular arc of radius  $r$  and the length of the circular arc of radius  $r + dr$  in cross section  $S_c$  can be represented as  $dq$  and  $dq \left(1 + \frac{dr}{r}\right)$ , respectively. Assuming now that  $dr = dq$ , only the length of the arc of the radius  $r + dr$  among the lengths in the circumferential direction and the radial direction of the cross section  $S_c$  is other  $\left(1 + \frac{dr}{r}\right)$  times.

By replacing the deviation angle  $\theta$  with the solid angle  $\Theta$  and doing the similar consideration, only the area of the spherical surface with the radius  $r + dr$  among the areas of each surface formed by cutting the minute region  $S$  at the solid angle  $\Theta$  is other

$\left(1 + \frac{dr}{r}\right)^2$  times. Namely, in diffusion in the spherical object, it is estimated that the ratio of the diffusion coefficients of the upper surface and the lower surface is  $\left(1 + \frac{dr}{r}\right)^2$ .

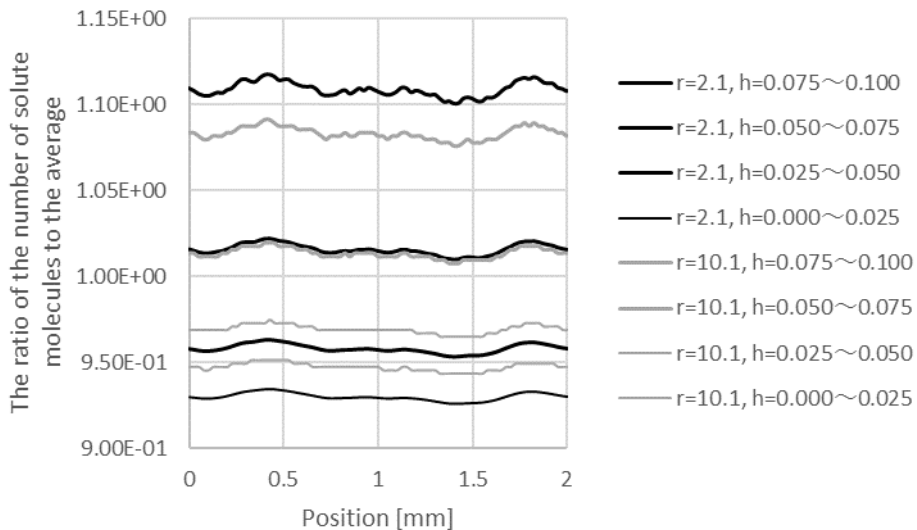

### 3. Results and Discussion

#### 3.1. Condition of numerical simulation

In order to discuss the drying of the solution film of thickness  $dr$  coated on the surface of spherical body with curvature radius  $r$ ,  $r$  is regarded as a parameter and  $dr = 0.1[mm]$ . Solvent vaporizes only on interface between liquid and gas (vacuum) and boiling is out of imagination. Volume of solvent  $V$  and the number of solute  $N$  in solution are homogeneous except for surface coming in contact with gas (vacuum). Concerning surface, 10% unevenness about  $N$  is given only to the upper surface of the solution film by homogeneous random number.

Simulation is ended when total volume of solvent become less than a fixed value, for it is thought that drying is completed, that is, solutes can move in solution no more then.

Initial values of parameters are set as follows;  $K_c = 1.8750 \times 10^{-8}[m^2/s]$ ,  $K_v = 1.2500 \times 10^{-8}[m^2/s]$ ,  $\gamma = 5.7000 \times 10^{-14}[m^2/s]$ .

*Fig. 2 The  $r$  dependence of the amount of solute present in each layer of height from the bottom of the solution film after drying*

### 3.2. Results of numerical simulation

Figure 2 shows the  $r$  dependence of the amount of solute present in each layer of height  $h$  from the bottom of the solution film after drying. From this result, it can be seen that as the radius of curvature  $r$  is smaller, the uneven distribution of the solute (or the fine particles) on the surface of the solution (or the slurry) film after drying becomes conspicuous.

## 4. Conclusions

In this study, we apply the drying model to the spray drying granulation process in formulation. In order to apply the former model to the drying of this spherical object, we consider this spherical object to be a stack of solution films applied on the spherical shell and discuss the drying process of each solution film.

As a result, we see that the smaller the radius of curvature of the droplet, the more the fine particles tend to be unevenly distributed on the surface of the droplets during drying.

### **Abstract**

*The flow mechanics and heat transfer phenomena within a bed of milli-metric size spherical beads rotated and heated by contact in a horizontal drum were simulated by means of commercial discrete element software EDEM. Mono-dispersed and bi-dispersed beds (two particle sizes or two particle densities) were considered. The mechanical segregation index (standard deviation of local bed compositions) and the thermal segregation index (standard deviation of beads temperatures) were calculated for the different types of bed and same operating conditions. The thermal segregation was found to be enhanced by mechanical segregation and was much stronger for bi-dispersed beds than for monodispersed one.*

**Keywords:** rotating drum; particulate solid; segregation; contact heat transfer; DEM simulation.

---

## 1. Introduction

Modeling and simulation of processes involving stirred beds of particulate solids is a difficult task. The classical macroscopic and continuous medium approach gives a global scope of average trends but do not provide the local information which in some high added value processes like the pharmaceutical ones may be critical. In some cases even tiny processing discrepancies between individual particles must be avoided. During drying of granular beds, stirring is very often combined with contact heating and the powder flow mechanics is then coupled with heat transfer. For instance, vacuum contact heating is widely used in the pharmaceutical industry to dry granular products which are sensitive to oxygen and temperature. The vacuum contact drying of powder stirred bed has been firstly investigated in a macroscopic way (“penetration” model) by Schlünder and Mollekopf<sup>[1]</sup> for a mono-dispersed non sticky granular material. Kwapinska et al.<sup>[2]</sup> compared results obtained by the “penetration” analytical method with those obtained by numerical DEM.

More recently, several authors have independently investigated the effect of operating conditions on mixing and heating rates of rotated monodispersed granular material. Figueroa et al.<sup>[3]</sup> have studied various tumbler filling levels and cross-sectional shapes; Chaudhuri et al.<sup>[4]</sup> various revolution speeds, material types and baffles number and shapes; Gui et al.<sup>[5]</sup> and Komossa et al.<sup>[6]</sup> different revolutions speeds; Emady et al.<sup>[7]</sup> different revolution speeds and material thermal conductivities. However, to our best knowledge, no results were published to date concerning dispersed beds composed of particles of different sizes and materials. This is a major issue because real, industrial materials, even if carefully controlled before processing, are always slightly dispersed.

Rotating mixing of imperfectly monodispersed solid particulate beds unavoidably leads to mechanical segregation, i.e. to accumulation of smaller or/and denser particles in the core of the bed. In the previous study<sup>[8]</sup>, radial and axial segregations were experimentally observed for a bi-dispersed bed with two particle sizes or two particle densities. The radial segregation index was measured for different drum filling ratios and for different baffles numbers and heights. The axial segregation index was found to be influenced by the friction coefficient on both drum front and rear walls.

It is thus expected that the bed spatial heterogeneities will lead to thermal heterogeneities because the beads temperature time evolutions depends on their trajectories and especially on their cumulated contact times with the heating wall. The aim of this paper was to investigate the impact of mechanical segregation on the thermal segregation in bi-dispersed beds as compared to a perfectly monodispersed (not mechanically segregated) bed. DEM was applied for modeling and simulation of spherical milli-beads flow and heat transfer in a rotating ‘slice’ type (nearly bidimensional) drum.

## 2. Materials and Methods

The simulations of the stirring and contact heating of milli-beads were realized with the commercial software EDEM 2017 (DEM Solutions, Edinburgh, UK). This software is based on the discrete elements method (DEM) which is a very powerful modern tool to investigate and develop granular solid processes. In the DEM framework, each particle of the granular bed is considered to be distinct and has its own trajectory and speed. The particle-particle and particle-boundary interactions are checked at each time step and the resulting individual particle positions are updated. The main assumption of DEM modeling is that the particles are rigid (nondeformable) solid bodies but have the capability of small interpenetration during their contacts. The resulting decrease of the distance between the centers of two adjoining particles is called the penetration depth ( $\delta$ ) or overlap. The overlap is the fundamental variable which is directly related to the normal contact (interaction) force between the particles and the mechanical stiffness of the particles. This overlap is also the basis for evaluating the heat conductance between the particles as described in the next sections.

### 2.1 Mechanical DEM modeling

The determination of the position and speed of a given particle (identified by index  $i$ ) is the time solution of the Newton second law for translational and rotational movement of a solid body. For translation, it writes :

$$m_i \frac{d^2 \vec{x}_i}{dt^2} = \sum_j F_{ij} + m_i g \quad (1)$$

where  $m_i$  is the particle mass,  $x_i$  its position vector and the right hand side of the equation is the resulting force, cumulating interactions with all adjoining ( $j$ ) particles (and the wall of the vessel) and gravity. A similar equation can be written for the rotational movement.

For the purpose of this study, default modeling option in EDEM, the Hertz-Mindlin contact model<sup>[7]</sup> was used. In this model, the particle-particle mechanical interaction involves the normal impact force and the tangential friction force. The normal force is essentially elastic but both normal and tangential forces include damping components. The normal force is thus expressed by means of non linear visco-elastic behavior law :

$$F_{ij} = \alpha \delta_{ij}^{3/2} - \beta v_{ij} \quad (2)$$

where  $\alpha$  is the elasticity coefficient depending on the material Young's modulus and particles radius,  $\beta$  is the damping coefficient depending on the kinetic energy restitution factor of the particles,  $\delta_{ij}$  is the overlap between particle  $i$  and  $j$  and  $v_{ij}$  is the relative velocity of the two particles. The maximal tangential friction force is given by the *Coulomb* law which involves a material dependent friction coefficient.

## 2.2 Thermal DEM modeling

In tumbler systems, several heat-transfer phenomena coexist between neighboring particles and including walls : direct solid-solid heat conduction, conduction and convection through the interstitial fluid and surface radiation. In this study, convection and radiation are neglected. The direct particle-particle conduction is expected to largely dominate due to the high ratio of conductivity of particles to the conductivity of interstitial gas and due to moderate surface temperatures.

In DEM framework, as already stated in the preceding section, two particles in contact interpenetrate each other at a depth depending on their dynamics and mechanical properties. For spherical particles, the contact radius  $R_c$ , which is the radius of the circle resulting from the two particles (spheres) overlapping, can be straightly derived from the penetration depth. Approximate analytical solutions of the *Fourier* conduction equation between two smooth, elastic particles with a finite small contact area have been proposed in the literature<sup>[5,6,7]</sup> and applied to evaluate the thermal conductance  $K_{ij}$  between the two particles centers :

$$K_{ij} = 2\lambda_{\text{eff}}R_c = 2\lambda_{ij}\sqrt{R_{ij}}\sqrt{\delta_{ij}} \quad (3)$$

where  $\lambda_{ij}$  is the harmonic mean of the thermal conductivities of the two materials,  $R_{ij}$  is the harmonic mean of the particles radii. The conductive heat flux between particle  $i$  and particle  $j$  writes simply :

$$\dot{Q}_{ij} = K_{ij}(T_j - T_i) \quad (4)$$

The total heat flux transferred to or from a given particle ( $i$ ) is the sum of heat fluxes exchanged with all neighboring ( $j$ ) particles and the thermal energy balance of a single particle writes :

$$m_i c_{pi} \frac{dT_i}{dt} = \sum_j \dot{Q}_{ij} \quad (5)$$

where  $c_{pi}$  is the particle specific heat capacity. The time integration of the above equation provides the thermal history of the considered particle.

## 2.3 Particulate bed global characteristics

In order to characterise globally and macroscopically the geometrical distribution (mechanical segregation) of each kind of beads and their temperature distribution (thermal segregation) within the bed, statistical indexes already introduced in the literature<sup>[3]</sup> were used. The mechanical segregation index was defined by :

$$MSI' = \sqrt{\frac{1}{N-1} \sum_{i=1}^N (C'_i - \langle C \rangle)^2} \quad (6)$$

where  $C_i'$  is the number fraction of one kind of beads (of the considered size or density) in a control volume  $i$  among  $N$  other control volumes,  $\langle C \rangle$  is the average number fraction of this kind of beads in the entire bed divided in  $N$  equal size control volumes. By analogy, the overall thermal segregation index was defined as :

$$TSI = \sqrt{\frac{1}{N-1} \sum_{i=1}^N (T_i - \langle T \rangle)^2} \quad (7)$$

where  $T_i$  is the temperature of the bead  $i$  among all other beads,  $\langle T \rangle$  is the average temperature of all  $N$  beads of the bed. This index represents simply the standard deviation of beads temperatures. However, in case of bi-dispersed beds, two beads populations coexist, according to their size or density. These two populations are mechanically separated (segregated) by the drum rotations and this will influence directly their thermal dispersion (segregation). In order to observe separately the thermal evolution of the two populations, a population (density or size) specific thermal segregation index was therefore defined :

$$TSI' = \sqrt{\frac{1}{M-1} \sum_{j=1}^M (T_j' - \langle T \rangle)^2} \quad (8)$$

where  $T_j'$  is the temperature of bead  $j$  of a given kind among  $M$  other beads of the same kind.

#### 2.4 Solver settings, material properties and process parameters

The simulations were realized on a DELL workstation (T7910) with two 10 cores processors (Intel Xeon E5-2660v3). The maximum processing time step was set at 40 % of the theoretical Rayleigh time step. This is the time taken for a shear wave to propagate through the particle which depends on the particle size and mechanical properties. The adjoining particles numerical search distance was set at 5 fold particle radius. The “Hertz-Mindlin with Heat Conduction model” was selected and a user defined routine called “Heat conduction for Geometry” was incorporated for implementing particles-wall direct heat conduction.

*Table 1. Beads number for different bed types.*

CA-2	-	-	27905
CA-3	16366	8183	8183
PP-3	-	8055	-

Polypropylene (PP) and cellulose acetate (CA) spherical beads of millimetric size (2 mm and 3 mm diameter) were used. The compositions of the three studied particulate beds are shown in Table 1. All materials mechanical and thermophysical properties needed for EDEM simulations are given in Table 2. The friction coefficients for pairs of materials were obtained by model identification (fitting experimental data) and are given in Table 3. The drum used in this study was a ‘slice’ type one with a large diameter to depth ratio. It had an internal diameter of 300 mm and an internal depth of 42 mm.

The front panel was made of glass, the rear one and the peripheral wall were made of stainless steel. The drum was equipped with 4 equidistant straight baffles with a height of 15 mm. All these dimensions corresponds to the set-up used in the previous experimental study<sup>[8]</sup>. The default revolution speed was 3 rpm which corresponds to very slow rotations often encountered for drying of pharmaceuticals. The initial beads temperature was 25 °C and the peripheral heating wall temperature was 50 °C.

### 3. Results and discussion

The simulations were realized for the 3 types of bed presented in Table 1. The mechanical segregation index (MSI) and the thermal segregation index (TSI), as defined in section 2.3, were calculated with MATLAB from EDEM data extracted for each simulation and were plotted as function of time on Figures 1 and 2.

According to Figure 1, except for a very short initial period, thermal segregation was the most important for the bi-density bed. Moreover, from the moment the bi-size bed MSI approached the bi-density MSI, the bi-size TSI fell below the mono-dispersed TSI. The bi-density bed TSI was significantly higher than the bi-size TSI, while the the MSI for both bi-

dispersed beds were rather close to each other near the simulation end. The correlation between MSI and TSI is thus not straightforward and must be further investigated.

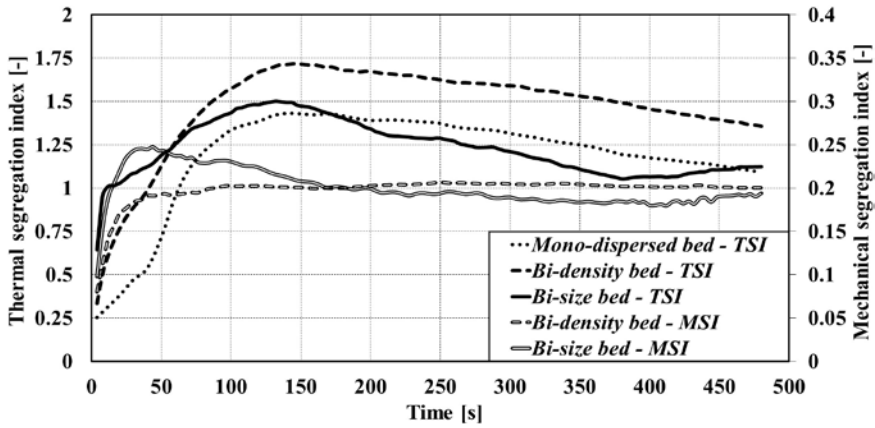

Fig. 1 Mechanical and thermal segregation indexes for different bed types.

As observed on Figure 2, the small beads specific TSI followed closely the overall TSI. The reason could be that the bi-size bed contained much more small than big beads (see bed compositions in Table 1). Therefore small beads thermal dispersion would have a much larger impact than the dispersion of big beads.

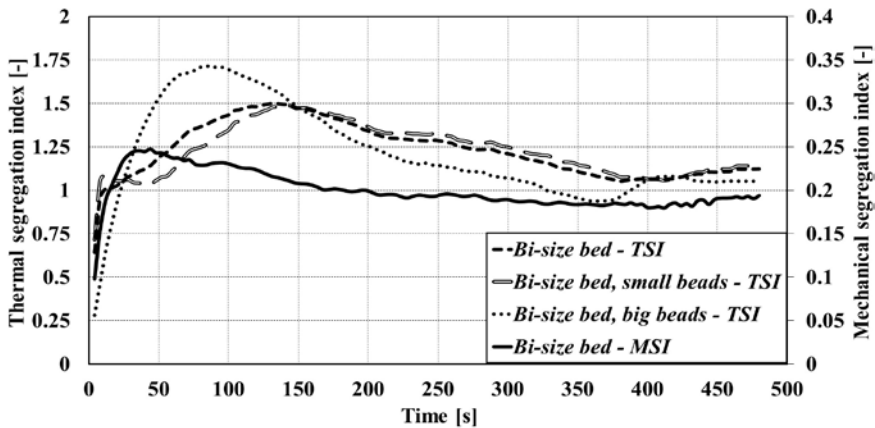

Fig. 2 Mechanical and thermal segregation indexes for the bi-size bed.

For the bi-density bed, the overall TSI was practically the average of the two specific TSIs (Figure not shown) because there was an equal number of light and heavy beads. As concerns average bed temperatures, plotted on Figure 3, the heating rate (curve slope) was stronger for the bi-size bed than for bi-density and mono-dispersed beds and this deviation increased with time. This seemed rather odd because for the bi-size bed the small beads were in the core and the big ones at the periphery.

Fig. 3 Average temperatures for different bed types.

As there was much more small beads than big ones in the whole bed, one could expect that the average bed temperature would rather follow the temperature of the small ones which were colder and that the overall heating rate would be slower than for a bi-density bed. These results must be confirmed by carrying out the simulations for much longer times.

#### 4. Conclusion

The mechanical segregation index (standard deviation of local bed compositions) and the thermal segregation index (standard deviation of beads temperatures) were calculated for mono-dispersed, bi-size and bi-density beds of spherical milli-beads submitted to same operating conditions. The thermal segregation was found to be enhanced by mechanical segregation and was much stronger for bi-dispersed beds than for monodispersed one. The bi-density bed exhibited unexpectedly stronger thermal segregation than the bi-size one.

## **1. Introduction**

Ceramics is one of the oldest man-made materials and finds wide applications eg. in building sector (bricks, tiles), electric power industry (insulators), home and garden utensils (pottery) and advanced industries (ceramic filters, refractory materials etc.) [1].

Traditionally the cost of a product of the ceramic industry includes 30-40% of energy costs. The mass of which green ceramics is formed is based on clay, a natural aluminosilicate mineral, with necessary additives and water.

The removal of water from green ceramics consists of several stages, each of them requires properly selected drying process parameters in order to avoid deformation and cracking of the preformed elements [2]. Although the shrinkage of green ceramics in drying is small it is enough to cause these adverse effects if the evaporation rate is too high or uneven.

The losses caused by cracking in the production of ceramic tiles in the EU countries alone are estimated as 200 million euro per annum. Losses due to cracking and deformation are also inevitable in the production of decorative ceramics – stove tiles, ornaments or sculptures [3].

Literature survey and industrial experience indicate that this negative outcome of drying can be eliminated by slow or better intermittent drying. In intermittent drying the ceramics is dried in two repeating cycles: in hot air and in ambient air. During hot air drying the process is fast, which causes shrinkage and resulting build-up of internal stresses, while in ambient air the process is slow and the stresses relax. The cycles are repeated and may be of equal or of variable duration. The time of each cycle is set on the basis of on-line measurement of drying kinetics and/or the exiting air temperature and humidity. The time of the cycle is calculated on the basis of an earlier developed drying model [4].

Drying related stresses in shrinking solids are important in drying many industrial products. Gradient of moisture content and related stresses lead to deformation and cracking [5].

From theoretical analysis it follows that internal pressure in the wet solid varies during the process of drying. So far the values of capillary and liquid pressure in the wet solid were predicted [6,7]. The direct measurement of this pressure was difficult. One of the first works published in 1996 used a complex experimental procedure to measure drying induced stresses in colloidal capillary-porous solids such as peat. To measure the internal pressure 4 to 5 mm rubber hollow spheres filled with water were placed in the sample during casting. They were connected by thin lines to external manometers. Stresses were measured with microtensometers. The distributions of capillary and internal pressure as a function of moisture content were presented [8]. Experimentally the internal capillary pressure was measured by Holt [9] in autogenous shrinkage of concrete. Using a thin tube immersed in the middle of the block height and an external pressure transducer it was found

that the internal pressure is initially negative in the CRP and then turns positive in the FRP and at the end of the proces this pressure relaxes to the ambient value. In general, due to wide variety of wet solids an universal method of internal pressure measurement and interpretation is still being sought. Such measurement may provide valuable information on development of stresses in the material during drying [10].

The aim of this work is the analysis of transport of moisture in drying using the evolution of experimentally measured internal pressure in both wet green and fired clay. By using minature pressure transducers and telemetry such pressure can be messured in situ an the results transmitted to the required place. The obtained results may be used for control of the drying air parameters in response to the developing stresses in industrial scale, possibly also for many other shrinking materials.

## **2. Materials and Methods**

### **2.1. Material specification**

In the experiments performed in this work a clay material produced by Bolesławiec Refractory Materials Works, Bolesławiec, Poland was used. It is commonly used for manufacturing of artwork pieces, sculptured tiles etc. As plastifier 0.25 to 0.3% w.b. of water glass is added to mineral clay by the manufacturer.

The skeletal density of dry (non fired) clay measured by helium pycnometer is 2626.96 kg/m<sup>3</sup> and its porosity 0.3. The purchased press formed clay block of moisture content 0.3 kg/kg was directly used (in order to eliminate introduction of additional stresses) to cut cylindrical samples of 32.2 mm diameter and 27 mm tall.

### **2.2. Drying experiments**

The convective drying experiments were preformed in a drying tunel described in detail elsewhere [11].

Two samples were used simultaneously in the experiment. One of them was placed on a rotating tray suspended under an electronic balance. This sample was armed with two thermocouples, one with its bead close to the periferal surface of the sample and the other placed axially. Both were connected to a transducer/transmitter situated on the tray and their signal transmitted to the computer. Both bases of the clay cylinder were covered tightly by perspex disks to eliminate heat and mass transfer to these surfaces.

The tray slowly rotated in order to equalize heat and mass transfer of the peripheral surface. The actual mass of the sample was continuously monitored by an electronic balance. The other sample was stationary and had a syringe needle with miniature pressure transducer inserted axially to measure axial pressure variations in time. Accurcy of measurements was: weight 10 mg, temperature  $\pm 1^\circ\text{C}$ , pressure  $\pm 16$  Pa.

Drying experiments were performed in temperatures of 50°C and 60°C with air velocity 1 m/s. Each experiment continued for ca. 10 hrs until equilibrium. The dried samples were then dried in an oven at 105°C to measure the remaining moisture. The difference of measured internal absolute pressure and actual atmospheric pressure was used for the analysis in Section 3.

### 3. Results and discussion

#### 3.1. Shrinkage curve

The value of moisture content where shrinkage stops is on the level of critical moisture content ca. 0.19 kg/kg. All data points show a characteristic linear shrinkage behavior which is reported in literature for many other clays[13,14].

Fig. 1. Shrinkage curve

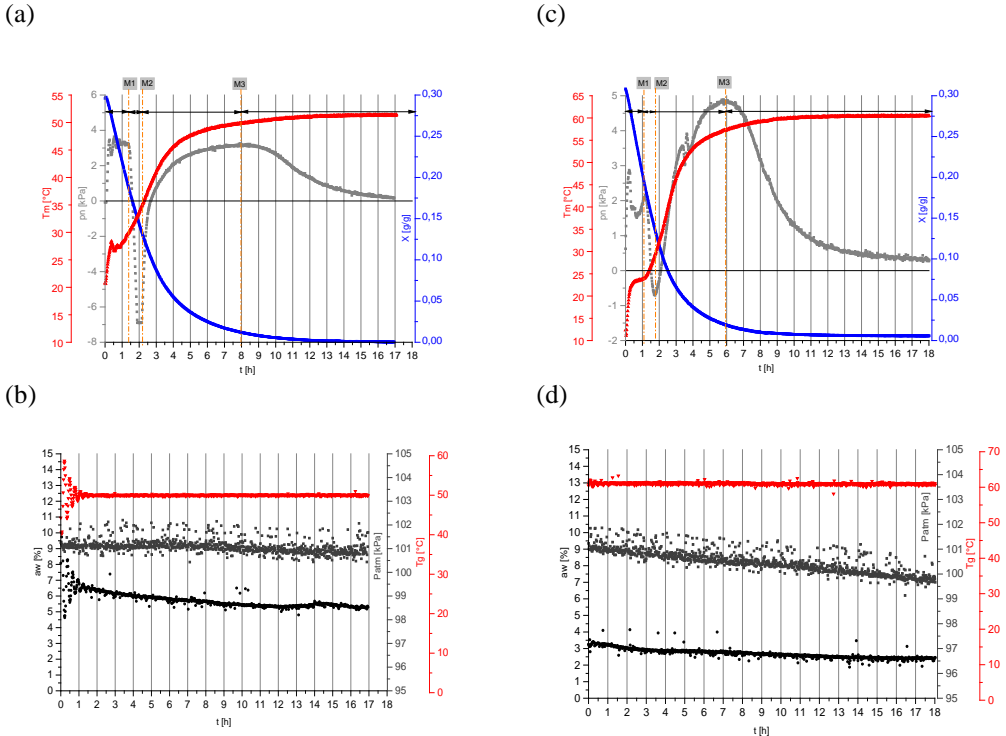

The dependence of sample dimension on its moisture content can be approximated with a straight line of the following form:

$$\frac{L}{L_0} = 0.855 + 0.4852X \quad (1)$$

By theory the linear shrinkage coefficient  $\epsilon_L=0.4852$  which will be used in drying process simulation, is one third of the volumetric shrinkage coefficient  $\epsilon_V$ . During drying the linear shrinkage is only ca. 5%, yet it is enough to create stresses above the strength of the solid.

#### 3.2. Results of drying experiments

Fig. 4 presents the experimental results (only data points –no curves fitted) for green clay at 50°C and 60°C. Fig. 4a and 4c contain the internal pressure (gray), moisture content (blue) and solid temperature in the axis of the sample (red) evolution. Fig. 4c and 4d show the external conditions in the tunnel. The air temperature was the only controlled parameter.

**Fig. 4.** The results for green clay drying at: (4a) 50°C (4c) 60°C where internal pressure (gray), moisture content (blue) temperature in the axis of the sample (red) and drying agent parameters for (4b) 50°C (4d) 60°C where atmospheric pressure (gray), water activity (black) gas temperature (red)

Four distinct stages can be identified in the process. First for 1.5 hr (from 0 to M1) an overpressure up to 2 kPa at 50°C and 3kPa at 60°C develops during the heating-up period when the sample reaches the wet-bulb temperature and during a short CRP. It is a result of sample heating and thermal expansion of water. Second stage begins at transition from CRP to FRP ( $X_{crit}=0.19$  kg/kg) when a rapid fall of internal pressure is observed leading finally to underpressure (M1 to M2). Third stage (M2 to M3) starts after the shrinkage ceases i.e. after ca. 2 hrs and pressure begins to rise again simultaneously with solid temperature, which approaches the external temperature. The maximum of pressure is observed after 6-7 hrs and reaches 3 kPa at 50°C and 5kPa at 60°C. In the final stage pressure is relaxed to atmospheric pressure. For the fired clay wetted with distilled water, which shows no drying shrinkage, the results are shown in Fig.5. In this case three characteristic stages are observed. Here during heating stage (0 to W1) the internal pressure rises rapidly (there is no initial sustained overpressure as for green clay) and then falls to underpressure of -2kPa at 50°C and -0.8 kPa at 60°C which is less than for green clay. CRP begins after ca. 0.5 hr and lasts longer than for green clay. At that stage the internal pressure begins to rise. When FRP

is reached ( $X_{crit} = 0.165 \text{ kg/kg}$ ) rises to a maximum of 2.5 kPa at 50°C and 3 kPa at 60°C, however, at 60°C the maximum is reached at the final segment of this stage when the solid temperature approaches air temperature (W1 to W2).

So far the evolution of internal pressure was only predicted by some advanced models. No experimental work, including [9], so far has presented the evolution of internal pressure in such detail as the present work.

#### 4. Conclusions

Based on the presented results, it can be concluded that the internal pressure is more sensitive to changes occurring in the material than the temperature or mass changes are. The analysis of pressure changes inside the drying both in non-shrinking and shrinking material, enables more precise observation of phenomena of moisture transport and changes in the nature of stresses generated in the dried material (initially compression and then

stretching of the material). The obtained results will enable us to build a mathematical model to describe the convective drying process taking into account the internal pressure rate of change. Due to that, it will be possible to monitor the drying stresses generated in the material on a regular basis and control the process parameters so as to obtain the desired product without defects. Due to miniaturization of pressure sensors and the use of telemetric measurements, the method can be easily applied in an industrial scale to control the drying process.

### **Abstract**

*Due to the ongoing development and implementation of process control and observation techniques in production processes of particulate products, the research on complexly designed process apparatuses has become of great interest. The work presented in this paper is focused on a model-based study on a multi-chamber horizontal fluidized bed apparatus for fluidized bed layering granulation. The model for the solid phase is extended by a new drying model. Because of the great variety of parameters that influence this complex system a preliminary model-based study on a simplified setup shall show which construction or process parameters influence the product quality.*

**Keywords:** *fluidized bed granulation; population balance modeling; surface moisture content; drying*

---

## **1. Introduction**

The demands on industrial processes in terms product quality are increasing due to continuing implementation of process control and observation techniques in production processes. In order to meet the quality requirements developed particulate products should consist not only of specified composition, but they should also have defined size distribution and structure. One process widely used for particle size enlargement and coating is the fluidized bed layering granulation process [1]. In earlier works on this issue a multi-zone and multi-compartment model for the dynamic simulation of a horizontal fluidized bed spray granulator has been derived and described [2,3]. In this paper the extension of this model by an additional drying model considering the wetted surface area is presented. The novel drying model is integrated in the existing dynamic multi-zone and multi-compartment layering granulation model.

## **2. Dynamic model and parameter study**

The full model for the fluidized bed granulation plant includes the dynamic model for the time dependent particle and gas properties in the fluidized bed. The purpose of the fluidized bed model is to calculate quality features of the product, e.g. particle size distribution  $n$ , particle moisture content  $X_p$  and relative wetted surface area of the particles  $\psi_p$ , as well as the outlet gas properties such as temperature  $T_g$  and moisture content  $Y_g$ . A detailed description of the population balance model of the multi-zone and multi-compartment model for spray layering granulation used in this study can be found in [2,3].

Most dynamic drying models for fluidized bed drying and granulation contain mass and energy balances for the description of gas and particle phase. Greatest differences between these models can be found in the calculation of the evaporating mass flow rate or the assumed gas flow pattern. Established drying models for fluidized bed drying and layering granulation are presented in [5, 6, 7]. In this work a novel drying model is presented which takes the size of the initial spray droplets and the geometry of sessile droplets on the particles surface into account. In contrary to common models it allows a consideration of the wetted surface area as transfer area of the heat and mass flow due to evaporation.

In the following the main assumption and simplifications of the regarded model are stated. The particles of each compartment are considered to be ideally mixed. The gas phase in each chamber is also assumed to be ideally mixed. Heat losses to the environment are neglected. The spray droplets are distributed monodispersly. They will exclusively attach to the dry particle surface in a monolayer; overlay of sessile droplets is not considered. Also no percolation or diffusion of surface water into the core particle takes place. The impact area of single droplets on the particle surface as well as the contact area between gas and liquid remains constant during the drying process. Evaporation will only change the number of

droplets deposited on the particle surface and therefore the total wetted surface area. Sessile droplets have the shape of a ball scraper, therefore three parameter are sufficient to describe the geometry of the sessile droplet, the maximum height of the droplet  $h_{dr}$ , the contact angle  $\theta_{dr}$  and the radius of the impact area  $a_{dr}$ .

Mass and energy balances for the solid phase, the liquid film and the gas phase for each chamber and compartment have been derived. Heat transfer coefficients between either the dry particle surface and the gas phase and the liquid film and the gas phase are calculated by standard Nusselt correlation for forced convection around a sphere under fluidized bed conditions. Whereas the heat transfer between the liquid film is assumed to be free convection around a sphere and the respective heat transfer coefficient is calculated with  $Nu = 2$ . The corresponding transfer areas are determined by the geometric specifications of the sessile droplets and water mass of the film.

To investigate the influence of the separation properties and the novel drying model on the product quality a parameter study is carried out. The model system consists of an apparatus divided in two chambers.

*Fig. 1. Schematic representation of the apparatus used in parameter study.*

Each chamber is divided into two compartments. The lower compartment is the spray zone, i.e. only particles contained in this compartment are directly in contact with the spray solution or suspension. In the upper compartment, the drying zone, particles are mixed and dried. In presently studied case the particle transport between the chambers can only take place between the upper compartments, the drying zones, of the chambers accounting for the use of overflow weirs.

In order to evaluate the influence of the shape factor of the separation function and the outlet probability on the product quality are studied. To show the dependencies of the drying model water mass flow rate of the spray, the initial droplet diameter, and contact angle of the sessile droplets are varied.

The following particle properties and process conditions at steady-state are observed within the scope of the parameter study. To represent the product particle size distribution particle

Sauter diameter and standard deviation are chosen. Furthermore the properties of the outlet flow, temperature and moisture content, as well as the product moisture content and the relative wetted surface area are recorded to show the main influence of the introduced drying model.

### 3. Results and Discussion

This section shows selected results of the 14 simulations that have been carried out. In this paper the results for the three influencing factors,  $k$ ,  $\dot{M}_{sus,w}$  and  $d_{dr}$ , are shown and discussed in the subsequent paragraphs.

The shape factor of the SF  $k$  has an effect on particle Sauter diameter and the particle diameter standard deviation. The model results for particle Sauter diameter and the corresponding standard deviation of particle inlet, chamber 1 and 2, as well as particle outlet for the three examined shape factors for the SF are presented in Figure 2 and 3. Particle processing leads to an increase of particle Sauter diameter and standard deviation of the particle diameter. During the process the particle Sauter increases in each subsequent chamber and reaches the highest value at the outlet. Due to the separation effect of the weirs between the chambers and at the outlet the standard deviation of the particle diameter decreases on the particles' path through the plant. Increasing the shape factor  $k$  leads to more narrow separation functions and results in higher product Sauter diameters and decrease of the standard deviation particle diameter on the particles' path through the plant. The manipulation of the shape factor  $k$  shows no significant effect on gas outlet conditions, particle moisture content and wetted particle surface.

Fig. 2. Particle Sauter diameter for different shape factors of SF.

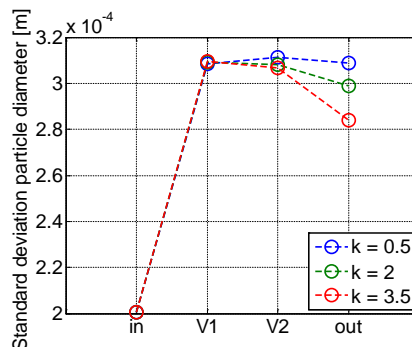

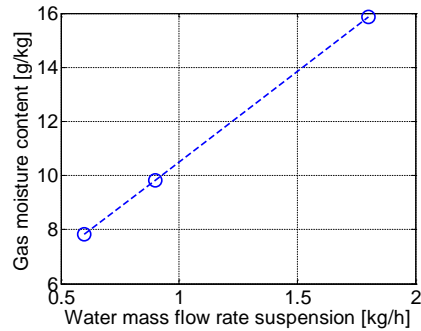

Fig. 3. Standard deviation of particle diameter for different shape factors of SF.

Figure 4 to Figure 7 show the simulation results for outlet gas temperature and outlet gas moisture content, product moisture content and wetted surface area depending on the mass flow rate of water contained in the spray. Increasing the mass flow rate of water in the spray

decreases the outlet gas temperature and increases the outlet gas moisture content due to the increased evaporation rate.

**Fig. 4. Gas outlet temperature depending on water mass flow rate.**

**Fig. 5. Gas outlet moisture content depending on water mass flow rate.**

Product moisture content and the corresponding wetted surface area are increasing with higher water mass flow rates of the spray. Due to the enhanced relative humidity of the process gas at higher water mass flow rates more water accumulates on the particle surface. Thus both product moisture content and wetted surface area are increasing.

The model results for product moisture and wetted surface area depending on the initial droplet diameter are presented respectively in Figure 8 and Figure 9. An increase of the initial droplet diameter leads to an increase of the product moisture content and wetted surface area. A reduction of the initial droplet diameter increases the contact area between the liquid film and the gas phase which leads to an enhancement of the evaporation rate and consequently to a reduction of particle moisture content and wetted surface area. An effect of the initial droplet diameter on gas outlet conditions cannot be observed.

**Fig. 6. Product moisture content depending on water mass flow rate.**

**Fig. 7. Wetted surface area depending on water mass flow rate.**

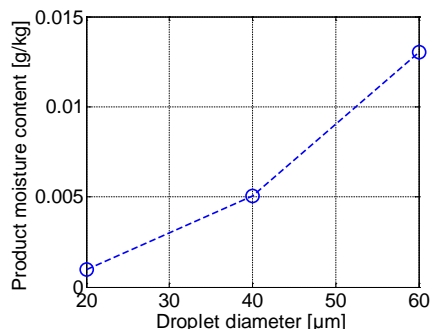

Fig. 8. Product moisture content depending on initial droplet diameter.

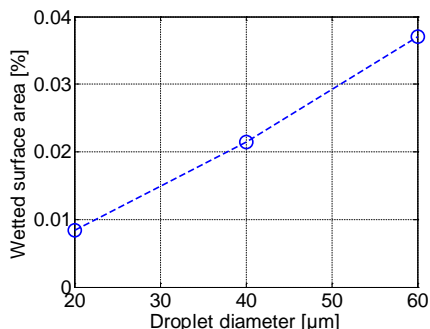

Fig. 9. Wetted surface area depending on initial droplet diameter.

#### 4. Conclusions

The aim of the presented preliminary study was to identify what and how the chosen model parameters influence the most important product properties.

Manipulation of the parameters of the separation function only affects the particle growths and has no influence on thermal gas phase and particle properties, such as gas outlet conditions, product moisture content and wetted particle surface. However, a significant effect of the shape factor of the SF on the particle size distributions of the chambers and the product has been observed. Additionally a variation of the thermal process conditions in form of the water mass flow rate of the spray solution has been performed. The introduced water mass flow rate affects the outlet gas properties as well as the product moisture content and wetted surface area. Furthermore the influence of the initial droplet diameter on the product properties has been examined. Results show that the variation of the spray droplet features only influences product moisture content and wetted surface area and has no significant effect on the gas outlet conditions.

### Abstract

*The reaction engineering approach (REA) has been proposed and implemented for modeling a number of challenging drying cases. While the modeling is simple and accurate, it is effective to generate the drying parameters. The relative activation energy is the fingerprint of the REA which describes the changes of internal behaviors inside the materials during drying. In this paper, a new method, based on combined heat and mass balance, is proposed and implemented to retrieve the relative activation energy of flat materials. The results indicate that the new approach can be used to retrieve well the activation energy of flat materials. The relative activation energy retrieved by the new approach is independent on the external drying conditions. This new approach can also potentially be used to evaluate the change of surface area of materials during drying*

**Keywords:** *reaction engineering approach (REA); modeling; relative activation energy; mass transfer; heat transfer.*

---

## 1. Introduction

The reaction engineering approach (REA) is a ‘middle path’ approach to model drying in which the changes of material structure during drying is encapsulated in the relative activation energy. It has been successfully applied to model a number of challenging drying cases including intermittent drying, infrared-heating drying and microwave drying [1]. While the modeling is accurate, it has been found that the REA is effective in terms of generating the drying parameters. The relative activation energy calculated based on one accurate drying run can basically be used to project drying at other conditions since the relative activation energy is independent on the drying conditions. The relative activation energy of different drying conditions would collapse to the similar profiles [2]. In these studies, the activation energy is retrieved based on the mass balance where measurements of surface area, temperature and surface area of materials being drying are required.

In this study, for the first time, a new approach based on combined heat and mass balance is proposed and implemented for retrieving the activation energy of flat materials. The study is aimed to evaluate the applicability of the new approach to generate the relative activation energy as well as assess its applicability to mode drying kinetics of flat materials. Initially, the reaction engineering approach is reviewed briefly followed up by the proposal of new approach and applications of the new approach for generating the relative activation energy and modeling of drying of flat materials.

## 2. Materials and Methods

The reaction engineering approach (REA) was first proposed as a lumped parameter model where the drying rate (flux multiplied by surface area) of the moist materials can be expressed as the following:

$$m_s \frac{dX}{dt} = -N_c A = -h_m A (\rho_{v,s} - \rho_{v,\infty}) \quad (1)$$

Equation (1) is basically correct for all cases where water leaves solid in vapor form. Even in the case of the lumped approach, there is no assumption of uniform moisture content in this REA approach. It was characterized with the mean moisture content.

The surface vapor concentration ( $\rho_{v,s}$ ) can be correlated in terms of saturated vapor concentration of water ( $\rho_{v,sat}$ ) by the surface relative humidity ( $RH_s$ ) in the following equation [3]:

$$\rho_{v,s} = RH_s \cdot \rho_{v,sat}(T_s) = \exp\left(-\frac{\Delta E_v}{RT_s}\right) \rho_{v,sat}(T_s) \quad (2)$$

One can see that the surface  $RH$  is represented in an *Arrhenius* form.  $\Delta E_v$  represents the increasing difficulty to remove moisture from materials as moisture content reduces (in

addition to the free water effect). Being a semi-empirical model,  $\Delta E_v$  is ideally to be the mean moisture content ( $\bar{X}$ ) dependent.  $T_s$  is the surface temperature of the material being dried (K). For a small temperature range say from 0°C to just over 100°C,  $\rho_{v,sat}$  (kg.m<sup>-3</sup>) can in fact be approximated with the following equation [3]:

$$\rho_{v,sat}(T) = K_v \exp\left(-\frac{E_v}{RT}\right) \quad (3)$$

The approach of the activation process for moisture removal is thus claimed. On the other hand, condensation is a kind of precipitation process thus is not an activation process. The activation energy of the pure water evaporation reaction is equivalent to the value of the latent heat of water evaporation, which is also in line with the classical physical chemistry.

By using the REA, equation (1) can be expressed as:

$$m_s \frac{d\bar{X}}{dt} = -h_m A \left( \exp\left(\frac{-\Delta E_v}{RT}\right) \rho_{v,sat}(T_s) - \rho_{v,\infty} \right) \quad (4)$$

Noting that the above equation has a parameter that is the surface temperature ( $T_s$ ) for the moist porous material being dried, it can be troublesome to measure under certain circumstances.

It has been found, based on many previous practical experiences of using the REA approach, that drying experiments for generating the REA parameters need to be conducted where the air (or gas) humidity is very low in order to cover the widest possible range of  $\Delta E_v$  versus  $\bar{X}$ .

The dependence of the additional activation energy on moisture content can then be normalized as:

$$\frac{\Delta E_v}{\Delta E_{v,\infty}} = \zeta(X - X_{\infty}) \quad (5)$$

where  $\zeta$  is a function of moisture content difference (the current moisture content less the final equilibrium one),  $\Delta E_{v,\infty}$  is the maximum when the moisture concentration of the sample approaches relative humidity and, for convective drying, the temperature of the drying air (gas):

$$\Delta E_{v,\infty} = -RT_{\infty} \ln(RH_{\infty}) \quad (6)$$

$X_\infty$  is the equilibrium moisture content corresponding to  $RH_\infty$  and  $T_\infty$ , which can be related to one another using the equilibrium isotherm. It is noted again that so far the experiments for gaining the relevant equation (7) has to be under the very dry condition so the final water content attained in experiments is usually fairly small.

For convective drying, the lumped energy balance can be represented as:

$$mC_p \frac{d\bar{T}}{dt} = hA(T_\infty - \bar{T}) + H_{drying} m_s \frac{d\bar{X}}{dt} \quad (7)$$

The relative activation energy is usually found by rearranging equation (4) into:

$$\Delta E_v = -RT \ln \left[ \frac{-\frac{m_s}{h_m A} \frac{d\bar{X}}{dt} + \rho_{v,\infty}}{\rho_{v, sat}(\bar{T})} \right] \quad (8)$$

If the surface area  $A$  and the mass transfer coefficient  $h_m$  are known, or measured by separated experiments, one good run of drying experiment under the same drying air (gas) condition is sufficient for establishing equation (6), which is the core of the REA approach.

Here, now, we introduce *another kind* of approach based on the temperature-moisture content relationship. The lumped energy balance can be written as:

$$m_s(1 + \bar{X}) \left( C_{pw} \frac{\bar{X}}{1 + \bar{X}} + C_{p,s} \frac{1}{1 + \bar{X}} \right) \frac{d\bar{T}}{dt} = hA(T_\infty - \bar{T}) + H_{drying} m_s \frac{d\bar{X}}{dt} \quad (9)$$

On both sides, we now divide them with the rate of drying, incorporating equation (9), we can obtain:

$$(C_{pw} \bar{X} + C_{p,s}) \frac{d\bar{T}}{d\bar{X}} = - \left( \frac{h}{h_m} \right) \frac{h(T_\infty - \bar{T})}{\exp\left(\frac{-\Delta E_v}{RT}\right) \rho_{v, sat}(\bar{T}) - \rho_{v,\infty}} + H_{drying} \quad (10)$$

For flat sample geometry and parallel flow, one may have:

$$Nu = \frac{hL}{k_f} = CRe^m Pr^n \quad (11)$$

$$Sh = \frac{h_m L}{D_f} = CRe^m Sc^r \quad (12)$$

Combining equations (10) and (12) results in the expression of relative activation energy retrieved by the new approach:

$$\Delta E_v = -RT \ln \left[ \frac{\frac{D_f}{k_f} \left(\frac{Pr}{Sc}\right)^n (T_b - T)}{\rho_{v,sat} (\Delta H_v - (X C_{p_w} + C_{p_s}) \frac{dT}{dX})} + \frac{\rho_{v,b}}{\rho_{v,sat}} \right] \quad (14)$$

### 3. Results and discussion

The new method (based on equation (14)) is implemented to generate the relative activation energy of a mixture of polyvinyl alcohol (PVA) during drying at 35 and 55 °C [4-5]. The experimental details are presented previously [4-5] and reviewed briefly here in order to better understand the modeling framework. Materials used in this experiment were a mixture of equal proportion of partially hydrolyzed polyvinyl alcohol (80 wt%) and glycerol which has 88 wt% of water. 8 mL of the mixture was poured into a 90 mm diameter of Petri dish so that the initial thickness of sample was 1.3 mm. The velocity of the drying medium was set to 1 m.s<sup>-1</sup>. The experiments were undertaken at drying air temperature of 35°C and 55°C.

Figure 1 indicates the relative activation energy of polyvinyl alcohol (PVA) during drying at drying air temperature of 55 °C. By using the new method (combined heat and mass balance, equation (14)), the relative activation energy of drying at drying air velocity of 1 and 2.8 m s<sup>-1</sup> collapses to the similar profiles. As expected, similar profiles are also produced based on the calculation using the mass balance only (equation (6)). Comparing the relative activation energy retrieved using the heat and mass balance with the mass balance only indicates that the profiles are very similar. The results suggest that the new method can produce well the relative activation energy of polyvinyl alcohol at drying air temperature of 55 °C.

Figure 2 shows the relative activation energy of polyvinyl alcohol (PVA) during drying at drying air temperature of 35 °C. The new method generates the very similar profiles of the relative activation energy for drying at drying air velocity of 1 and 2.8 m s<sup>-1</sup>. In addition, the profiles of relative activation energy generated using the combined heat and mass balance collapse to those retrieved using the mass balance only.

The relative activation energy generated by the new method can be represented as:

$$\frac{\Delta E_v}{\Delta E_{v,b}} = \exp[-1.0794(X - X_b)^{1.6874}]$$

The similar expression is also shown for the relative activation energy retrieved by the mass balance only [6]. This is also supported by the profiles of relative activation energy generated by both methods as show in Figures 1 and 2. Therefore, the expression of the relative activation energy is independent on the retrieving method.

Figure 1. The relative activation energy of PVA mixture during drying at 55 °C

Figure 2. The relative activation energy of PVA mixture during drying at 35 °C

Based on the generated relative activation energy, the new method can also be used to evaluate the change of surface area of materials during drying. Measurements of areas of materials (such as dairy droplets, fruits and leafy vegetables) can sometimes be difficult due to highly deformation during drying and irregularity of the materials. The accuracy of the measurements is needed in order to project the drying kinetics accurately. This new approach offers advantage of ability to measure the surface area during drying by combining the generated relative activation energy of specific materials with the mass balance or heat balance. Nevertheless, it is still uncertain whether the new approach can be implemented to generate the relative activation energy for spherical or cylindrical materials where the heat and mass transfer correlations are more complex.

#### 4. Conclusions

In this study, the new approach to generate the relative activation energy of the reaction engineering approach (REA) is proposed and implemented. In the new approach, the heat

and mass balance is combined to yield the activation energy. Only a set of experimental data of moisture content and temperature during drying time is required to generate the relative activation energy. The results indicate that the new approach is applicable to retrieve the relative activation energy of flat materials. Different drying conditions result in the similar profiles of the relative activation energy. It is independent on external drying conditions which has also been highlighted for the relative activation energy retrieved using the mass balance only. The relative activation energy retrieved using combined both heat and mass balance gives the similar profiles of that evaluated based on mass balance only. Implemented in the REA, the relative activation energy evaluated by the new approach projects well the drying kinetics of flat materials.

### **Abstract**

*Dryers are used for removal of moisture from an raw materials (such as effluent) to form a dried solids as per the requirements. For removal of the moisture, energy requirement is huge. Therefore, in this paper, methodology for heat recovery in one of the type of dryers as spray dryers is developed, which is simple and easy to apply. The proposed methodology is illustrated with the help of an example taken from literature. It is observed that the indirect heat recovery method could save energy maximum up to 82 % as compared to literature and 41 % higher than without heat recovery.*

**Keywords:** *Spray dryer, pinch analysis, heat recovery, effluent drying, energy saving.*

---

## **1. Introduction**

Spray dryer has been used for the removal of liquids by evaporation from concentrated solid solutions giving product out in the form of powder with various grain sizes. In recent years, it also become part of waste management treatment employed for removal of water part from effluent getting dried solid waste. Industrial effluents (dissolved liquid wastes) are produced as a waste from industrial and commercial activities from diversified field such as food, textile, oil, chemicals, pesticides etc. [1]. Effluents production in India will rise per capita rate of around 1 to 1.33 % annually from 2021 to 2031 [2]. In spray dryers, fluid atomized through the atomizer in the form of fine droplets, which instantly comes into contact with a flow of hot air, results in vaporization of liquid part of it. Spray dryers consume substantial thermal energy around 10 - 20 % of total industrial energy usage in most of the developed countries [3]. It is observed that a significant heat energy is wasted in the form of gases, exhaust from industrial effluent dryers. Many researchers have studied recovery of waste heat by different methods such as partial recirculation of exhaust gases as direct heat recovery, heating inlet fresh air by exhaust gases as indirect heat recovery, etc. Kilkovsky et al. [4] studied indirect heat recovery from flue gases of waste and biomass incinerator plant. Ogulata [5] investigated the potential of heat recovery in textile drying by using heat exchangers such as recuperators, regenerators and heat pumps. The methodology proposed for the determination of Performance characteristics and efficiency of heat exchanger, heat pump and combined system (heat exchanger and heat pump) are described in details [6]. Johnson et al. [7] discussed various techniques of thermal system analysis to optimize drying process for spray dryer of air and superheated steam types and illustrated with case study of milk powder plant. Golman and Julklang [8] reported exhaust gas heat recovery through partial recirculation of exhaust air in spray dryer of alumina slurry plant. In this plant, alumina slurry is atomized and dried in spray dryer, recovering value added product from it. Bade and Bandyopadhyay [9] proposed methodology for targeting the thermal oil required for process heating using pinch analysis and extended it for integration of other thermal systems. There is a paucity of information in literature for heat recovery and energy analysis of industrial effluents spray dryer. The purpose of the current work is to develop mathematical model of spray dryer based on mass and energy balance equations and to propose simple methodology for indirect heat recovery of spray dryers depends on pinch analysis.

Feed supplied to dryer contains moisture in range of 30-40 % reduced from as high as 99 % [1] present in effluent by concentration in mechanical vapour recompression (MVR) and/or thermal vapour recompression (TVR). To analyze the energy performance of the dryers and to have simplicity for individual mass balance of solids in waste feed and dried powder as well as water in waste feed and moisture in exhaust and fresh air, each stream is shown

with mass of individual constituent content in it as shown in Fig. 1. Further, complete spray dryer is considered as control volume boundary with inlet and outlet streams and energy interaction with surrounding systems. The mathematical model is formulated on the basis of overall mass and energy balance equations applied to control volumes of dryer.

Fig. 1 Illustrative diagram of spray dryer.

## 2. Model of spray dryer without heat recovery

One of the approach to improve energy efficiency of spray dryers is by recovering waste heat in exhaust either by indirectly or directly and recirculation of this thermal energy in to dryer. This energy recovery will be best analysed by developing the model of spray dryers. Model developed here is simple based on mass and energy balance equations. Overall mass and energy balance equations for the spray dryer is denoted as:

$$(m_{w,wf} + m_{s,wf}) + (m_{wv,ha} + m_{da,ha}) = (m_{wv,ea} + m_{da,ea}) + (m_{s,dp} + m_{w,dp}) \quad (1)$$

$$Q_{in} = m_{da,ha} * C_{p,da,ha} * (T_{da,ha} - T_{ref}) + m_{wv,ha} * C_{p,wv,ha} * (T_{wv,ha} - T_{ref}) \quad (2)$$

Energy content in various streams of total control volume of spray dryer and energy transfer for spray drying system are summarized as follows:

$$\text{Heat input; } Q_{in} = Q_{s,wf} + Q_{w,wf} + Q_{da,ha} + Q_{wv,ha} \quad (3)$$

$$\text{Heat Output; } Q_{out} = Q_{da,ea} + Q_{wv,ea} + Q_{s,dp} + Q_{w,dp} \quad (4)$$

Where,

$$Q_{s,wf} = m_{s,wf} * C_{p,s,wf} * (T_{s,wf} - T_{ref}); \quad (3a) \quad Q_{w,wf} = m_{w,wf} * C_{p,w,wf} * (T_{w,wf} - T_{ref}) \quad (3b)$$

$$Q_{da,ha} = m_{da,ha} * C_{p,da,ha} * (T_{da,ha} - T_{ref}); \quad (3c) \quad Q_{wv,ha} = m_{wv,ha} * C_{p,wv,ha} * (T_{wv,ha} - T_{sat@dpt}) +$$

$$Q_{da,ea} = m_{da,ea} * C_{p,da,ea} * (T_{da,ea} - T_{ref}) \quad (4a) \quad m_{wv,ha} * L_{vap@dpt} + m_{wv,ha} * C_{p,wl} * (T_{dpt} - T_{ref}) \quad (4b)$$

$$Q_{s,dp} = m_{s,dp} * C_{p,s,dp} * (T_{s,dp} - T_{ref}) \quad (4c) \quad Q_{wv,ea} = m_{wv,ea} * C_{p,wv,ea} * (T_{wv,ea} - T_{sat@dpt}) +$$

$$Q_{w,dp} = m_{w,dp} * C_{p,w,dp} * (T_{s,dp} - T_{ref}) \quad (4d)$$

The difference between the quantity of water in the waste feed and water in the dry product is termed as water evaporated from the dryer. Mass of dry air is constant at inlet and outlet shown in Eq. (6a), only mass of water vapour are changing in air stream. Relations of humidity and dry air at various locations in the dryer are given by Equations (6b, c) and (7).

$$m_{da,ha} = m_{da,ea} \quad (6a) \quad m_{wv,ha} = \omega_{ha} * m_{da,ha} \quad (6b) \quad m_{wv,ea} = m_{wevap.} + \omega_{ha} * m_{da,ha} \quad (6c)$$

The humidity ratio at exhaust is given as:  $\omega_{ea} = (m_{wevap.} + m_{wv,ha}) / m_{da,ha}$  (7)

However, the minimum mass flow rate of dry hot air at inlet to drying chamber can be determined by simplifying mass and energy balance equations as:

$$m_{da,ha} = \frac{\left( m_{wevap.} * C_{p_{wv,ea}} * (T_{da,ca} - T_{sat@dpt}) + m_{wevap.} * (L_{vap@dpt})_{ea} + m_{wevap.} * C_{p_{wl}} * (T_{dpt} - T_{ref})_{ca} + m_{s,dp} \right)}{\left( C_{p_{da,ha}} * (T_{swf} - T_{ref}) + \omega_{ha} * C_{p_{wv,ha}} * (T_{da,ha} - T_{sat@dpt}) + \omega_{ha} * L_{vap@dpt,ha} + \omega_{ha} * C_{p_{wl}} * (T_{dpt} - T_{ref})_{ha} - (C_{p_{da,ca}} * (T_{da,ca} - T_{ref})) \right)} \quad (8)$$

$$- \left( \omega_{ha} * C_{p_{wv,ca}} * (T_{da,ca} - T_{sat@dpt}) - \omega_{ha} * (L_{vap@dpt})_{ca} - \omega_{ha} * C_{p_{wl}} * (T_{dpt} - T_{ref})_{ca} \right)$$

The proposed methodology for evaluating the mass flow rate of hot air ( $m_{ha}$ ) and humidity ratio at exhaust air ( $\omega_{ea}$ ) are summarized in the form of flowchart in Fig. 2. This methodology is validated by illustrative example 1 [8] for without heat recovery (base case) taken from literature in following sub-section 2.1.

### 2.1. Illustrative example 1: Without heat recovery [8]

An illustrative example 1 taken from literature [8] to explain and validate proposed methodology. Process parameters in Table 1 are reproduced from [8]. Problem is to determine minimum mass flow rate of drying air keeping moisture removal constant. In this calculation, the exhaust gas temperature is assumed to be constant.

As hot air inlet temperature increases, the mass flow rate of hot air and total heat supplied to the dryer reduces resulting in increasing efficiency of drying process as shown in Fig. 3.

Fig. 2 Flow chart of spray drying computation.

Table 1. Process parameters [8].

Parameters	Data	Parameters	Data
Drying air temperature	230 °C	Temperature of slurry	20 °C
Slurry feed rate	50 kg/h	Reference temperature	20 °C
Slurry water content	40 %	Relative humidity	70 %
Ambient temperature	30 °C	Moisture content in dried prod.	3 %
Vol. flow rate of drying air	3200 m <sup>3</sup> /h		

Fig. 3 Effect of temperature on mass flow rate of hot air, heat load and efficiency of the dryer.

### 3. Model of spray dryer with indirect heat recovery

Indirect heat recovery (IHR) is applicable when mixing of exhaust air is not permitted with feed or direct mixing of exhaust air is not possible. Heat exchanger is assumed as counter flow with suitable minimum approach temperature between exhaust air and inlet fresh air. The schematic diagram of IHR is shown in Fig. 4. Heat energy is transferred from hot fluid to cold fluid. Subsequently, temperature of preheated air is raised up to required by heater. In this case, heat is recovered from entire exhaust air with minimum approach temperature. The main drawback of IHR is deposition of agglomerates on the surface of the tubes, which is high mainly when the mass flow rate and moisture content of exhaust air is higher causing increased operating and maintenance cost of the heat exchanger.

#### 3.1. Methodology for indirect heat recovery

The proposed methodology for determination of total heat supplied by heater and drying efficiency are summarized in Fig. 5. In this methodology, to determine maximum possible heat recovery from exhaust air, pinch analysis a well known heat recovery tool is applied [10]. Property data such as specific heat of water vapour and dry air is taken from property table, which is used to calculate enthalpy change for water vapours and dry air as:

$$\Delta H = \omega [m_{wv,ea} * C_{p,wv,ea} * (T_{wv,ea} - T_{sat.}) + m_{wv,ea} * L_{vap@dpt} + m_{wv,ea} * C_{p,wl} * (T_{dpt} - T_{ref})] \quad (9)$$

$$\Delta H = m_{da,ea} * C_{p,da,ea} * (T_{da,ea} - T_{ref}) \quad (10)$$

With the help of Illustrative example 1 applicability of proposed methodology given in Section 3.1 is demonstrate as following section.

Fig. 4 Schematic diagram of indirect heat recovery through heat exchanger.

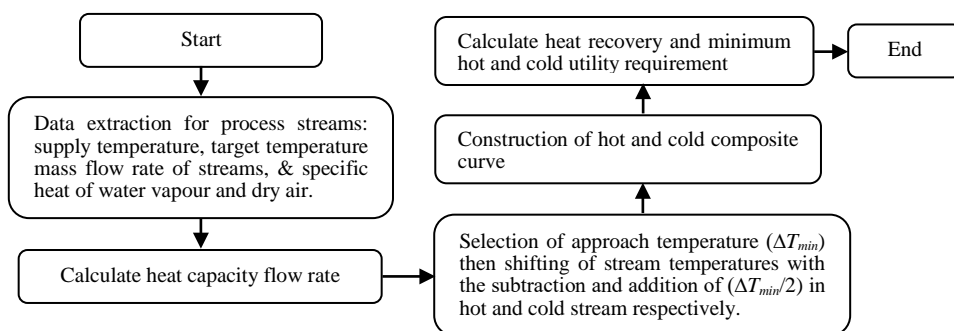

Fig. 5 Flowchart for indirect heat recovery through pinch analysis.

### 3.2. Illustrative example 1 revisited: Indirect heat recovery [8]

Input process data is same as given in Section 2.1. As outlet temperature of exhaust gas is higher than the dew point temperature, only sensible heat will be recovered from exhaust. Using pinch analysis hot composite curve (HCC) and cold composite curve (CCC) are plotted [3] as shown Fig. 6. After matching of the HCC and CCC for minimum approach temperature of  $50\text{ }^\circ\text{C}$ , the overlapping between the composite curves represents the maximum heat recovery  $27.372\text{ kJ/s}$  between hot exhaust air and incoming fresh air and the uncovered upper section of the cold composite curve shows external heating requirement of  $10.38\text{ kJ/s}$  for the fresh air. It is observed that the indirect heat recovery method could save energy maximum up to 82 % as compared to literature (for same without heat recovery configuration) and 41 % as compared to without heat recovery (base case) as shown in Table 3 for spray dryer with inlet hot air temperature of  $240\text{ }^\circ\text{C}$ .

Table 2. Illustrative example 1 revisited for indirect heat recovery.

Streams	Actual temp. (°C)		Shifted temp. (°C)		Mass flow rate (kg/s)	Humidity ratio (kg/kg dry air)
	T <sub>s</sub>	T <sub>t</sub>	T <sub>s</sub>	T <sub>t</sub>		
Exhaust air, dry	186	70	161	45	0.2225	0.037
Water vap.,ea	186	70	161	45	0.00834	
Fresh air, dry	20	180	45	205	0.2225	0.019

Table 3. Comparative results for drying air temperature of 240 °C

S.N.	Methods Parameters	Without heat recovery (Literature)	Without heat recovery (Base case)	Indirect heat recovery (pinch analysis)
1	Heat load (kJ/s)	60	35.29	10.38
2	Mass flow rate of hot air at inlet (kg/h)	2100	813	813
3	Energy saving (%)	--	41	82

Fig. 6 Hot and cold composite curve for illustrative example 1 revisited.

#### 4. Conclusions

In the present work, fundamental approach of mass and energy balance equations is applied to develop the mathematical model of spray dryer. Proposed methodology for indirect heat recovery of spray dryers is based on pinch analysis. Each process stream is divided into separate stream for constituents content in, which is helpful to apply pinch analysis and to consider variation in heat capacities mainly of moisture and dry air. It is observed that heat recovery could reach up to maximum of 82 % as compared to literature results for same case. Additionally, this approach helps to reduce the operating cost of dryers by reducing the flow rate of air and the capital cost by reducing heat transfer area. Further, compared to base case (without heat recovery), 41 % energy saving is possible with reduction in mass flow rate of hot air.

### Abstract

*A thermodynamic model employing the UNIFAC (Dortmund) method was developed to determine the currently unavailable partial vapor pressures of the binary gas mixture of water and tert-butyl alcohol (TBA) in equilibrium with their frozen solid mixtures. The results agree satisfactorily with the experimental data and indicate that TBA has higher vapor pressures which lead to higher total pressures at the moving interface that could result in larger total pressure gradients and convective mass transfer rates in the dried layer during primary drying. But the higher total pressures reduce the magnitude of the bulk diffusivity of the gas mixture and combined with the smaller Knudsen diffusivity of TBA could significantly impact the competing mass transfer mechanisms during freeze drying.*

## 1. Introduction

The presence of organic solvents as co-solvents with water in pharmaceutical and biological solutions could reduce the degradation rate of the pharmaceutical/biological product in water and/or increase its solubility. It has been shown experimentally [1] to affect the freezing characteristics of the solution during the freezing stage as well as during the primary and secondary stages of the freeze drying process. In the production of a number of anti-cancer drugs, the tertiary butyl alcohol (TBA, or 2-methyl-2-propanol) represents the organic co-solvent in the water solutions with varying concentrations dependent on the biotechnology method of production and the nature of the anti-cancer drug. Currently due to strict quality and toxicity standards required by the Food and Drug Administration (FDA), most of TBA is removed prior to the freeze drying of the drug solution. In order to ascertain if this is the only or best strategy, it is of paramount importance to acquire both physical and quantitative knowledge of the unsteady state variations and their interactions that occur during the freeze drying process in the (i) temperature and heat transfer rates in the frozen and porous dried layers of the product, (ii) mass transfer mechanisms and rates in the porous dried layer, (iii) relative residual amounts of frozen water and TBA in the frozen solid layer which affect the partial pressures of the vapors of water and TBA at the moving interface separating the frozen and porous dried layers during the primary drying stage, and (iv) the amounts of sorbed (bound) water and TBA on the surface of the pores of the dried layer during the primary and secondary drying stages. Because these data cannot be measured experimentally during the freeze drying process, it becomes necessary to construct and solve an unsteady-state and multi-dimensional in space mathematical model of the freeze drying process in order to determine, evaluate, and analyze the dynamic behavior of items (i) – (iv) for ascertaining whether or not the presence of TBA in the drug solution could reduce the drying times of the primary and secondary drying stages of the freeze drying process and, furthermore, whether the presence and distribution of the residual TBA in the three-dimensional space of the product being freeze dried could result in the violation of the strict quality and toxicity standards required by the FDA for the freeze drying of pharmaceuticals.

The mathematical model required to be constructed and solved for the freeze drying process of frozen solutions of pharmaceuticals involving water and an organic co-solvent like TBA has now to consider the vapor pressures and mass transfer rates of a ternary gas mixture (inert gas, water, and TBA) in the porous dried layer of the product, which is more complex than the models [2-6] for a binary mixture (inert gas and water) system. The off-diagonal terms of the diffusivity tensor for the three species will require careful examination of the relative concentrations of water and TBA vapors in the pore structure of the dried layer at different temperatures, in order to ascertain whether or not these off-diagonal terms and their effects on the heat and mass transfer processes need to be included in the structure of the mathematical model. The construction and solution of this new class of freeze drying models and the achievement of its aforementioned purposes require the following two pieces of fundamental physical information: (a) the thermodynamic model whose expressions provide the partial pressures of water and TBA vapors in equilibrium with the binary frozen mixtures of water and TBA as a function of temperature and of the mole

fractions of water and TBA in the frozen solid phase, and this necessary information also provides the important partial pressures of the vapors of water and TBA at the moving interface separating the frozen and dried layers of the product being freeze dried during the primary drying stage of the freeze drying process, and (b) the equilibrium adsorption/desorption isotherms of the sorbed (bound) binary mixtures of water and TBA on the surface of the pores of the dried layer which provide the concentrations of water and TBA in the binary sorbed (bound) mixture as a function of the temperature and of the partial vapor pressures of water and TBA in the gas phase in the pores of the dried layer, and this provides in the mathematical model the quantitative expressions needed to represent binary competitive adsorption/desorption through which the residual amounts of sorbed water and TBA as well as their distributions in the three-dimensional space of the dried layer of the product at any given time and especially at the end of the secondary drying of the freeze drying process could be calculated, so that we can determine whether the strict quality and toxicity criteria of the FDA are properly satisfied.

In this work the UNIFAC method coupled with the Dortmund parameter values for the subgroups of the binary mixture comprised of the species of water and TBA is employed and a thermodynamic equilibrium model is constructed. This model can provide the partial pressures of the vapors of water and TBA in equilibrium with the frozen solid phase of the binary mixture of frozen water and TBA, as a function of the temperature and of the mole fractions of water and TBA in the binary mixture of the frozen solid phase. The results obtained from the thermodynamic equilibrium model constructed and solved in this work are compared with the experimental results of Kasraian and DeLuca [7] and the agreement between the theoretical and the experimental results is found to be good. Therefore, this work considered the necessary and very important research problem stated in item (a) above and provides a satisfactory solution to this important research problem.

## 2. Thermodynamic Models and Methods

The thermodynamic equilibrium of a species between its pure liquid phase and its frozen mixture can be represented by

$$\ln(x_i \gamma_i) \approx \frac{\Delta H_{\text{tri}}^{\text{fus}}}{RT_{\text{tri}}} \left(1 - \frac{T_{\text{tri}}}{T}\right) - \frac{\Delta C_P^{sl*}}{R} \left[1 - \frac{T_{\text{tri}}}{T} + \ln\left(\frac{T_{\text{tri}}}{T}\right)\right], \quad (1)$$

where  $x_i$  and  $\gamma_i$  are the mole fraction and activity coefficient of species  $i$ , respectively, and  $l^*$  represents its subcooled liquid state at a temperature below its triple point ( $T_{\text{tri}}$ ). Equation (1) has also been used as a means to predict solid-liquid equilibrium for mixture systems. For the binary frozen mixture of water and TBA, its experimental solid-liquid equilibrium phase diagram as demonstrated by Kasraian and DeLuca [7] is quite complex and has two eutectic points. The water-rich region forming pure solid ice and the TBA-rich region forming pure solid TBA were first read from the phase diagram [7] to estimate  $\gamma_i$  based on Eq. (1) and compared with those estimated by the modified UNIFAC (Dortmund) group contribution method [8]. For this purpose, the needed triple point and molar heat of fusion at  $T_{\text{tri}}$  ( $\Delta H_{\text{tri}}$ ) are 273.16 K and 6004 J/mol for water and 298.96 K and 6700 J/mol for TBA (National Institute of Standards and Technology, NIST WebBook), respectively. Within the

temperature ranges, the heat capacity difference,  $\Delta C_p^{s/l*} = C_p^{l*} - C_p^s$ , for water is correlated into  $\left(\frac{234.784}{T - 229.760} + 69.924\right) - (0.1051T + 8.323)$  J/mol-K,  $T$  in K, while for TBA it is based on  $C_p^{l*} = C_p^l = 2125.37$  J/mol-K (NIST WebBook) and  $C_p^s$  interpolated from the reported experimental data [9]. The activity coefficients are shown in Fig. 1 where the levels of agreement could be considered practically satisfactory, especially for the water-rich region, when there is a lack of both experimental data and an alternative theoretical approach.

Despite their importance to the freeze drying operation as well as to the intended mathematical modeling, the partial pressures of the water and TBA vapors above their frozen binary mixtures appear not to have been measured experimentally or reported in the literature. Instead, only the total pressures of the eutectic mixtures at 90 wt% TBA ( $x_{TBA} = 0.6863$ ) have been measured and correlated [10]. In order to further verify the practical usefulness of the thermodynamic methods and models employed and presented in this work, the UNIFAC (Dortmund) method was applied in the following approach to estimate the total eutectic pressures,

$$P_{tot} = P_W + P_{TBA} = \gamma_W x_W P_W^{l*} + \gamma_{TBA} (1 - x_W) P_{TBA}^{l*} \quad (2a)$$

$$P_W^{l*} \text{ (Pa)} = 612 \exp \left[ -\frac{45054}{R} \left( \frac{1}{T} - \frac{1}{273.16} \right) \right], \quad T \text{ in K} \quad (2b)$$

$$P_{TBA}^{l*} \text{ (Pa)} = \exp \left( -\frac{5583.5}{T} + 27.925 \right), \quad T \text{ in K} \quad (2c)$$

It is clear from the results presented in Fig. 2 that the thermodynamic approach presented here is able to produce the eutectic pressures satisfactorily within the ranges measured by experiments. The approach presented here could thus be considered a useful and reasonable one, especially in the absence of experimental thermodynamic data as currently is the case, for estimating the partial pressures of water and TBA vapors at other compositions in equilibrium with their binary frozen solid mixtures.

Fig. 1 Activity coefficient as a function of the TBA concentration

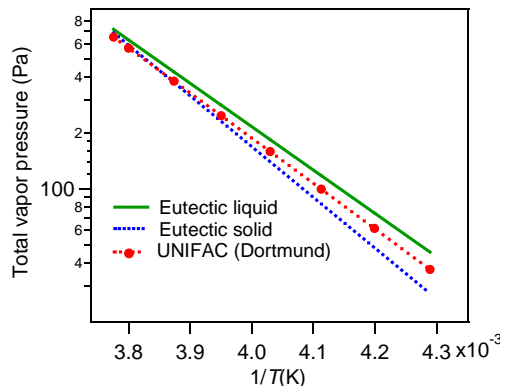

Fig. 2 Total pressure of eutectic mixtures at  $x_{TBA} = 0.6863$

The partial pressures of water and TBA vapors resulting from the approach presented here at different temperatures and water mole fractions in the binary frozen solid phase are plotted in Fig. 3, while the total pressure resulting from adding the two partial pressures together is plotted in Fig. 4. It should be noted that the highest temperature selected to be considered here is  $-8.3\text{ }^{\circ}\text{C}$  because this is the lower eutectic temperature below which the binary mixtures are frozen solids over the entire compositional range [7,10]. To incorporate the results of the partial vapor pressures into a future mathematical modeling study of the freeze drying process, well-correlated analytical expressions are much more desirable. For this purpose, only the activity coefficients, as indicated by Eqs. (2a)-(2c), need to be correlated. The functional form of the Non-Random Two-Liquid (NRTL) activity model was found to provide excellent correlations for the partial pressures with the following temperature-dependent parameters where  $R$  is the ideal gas constant and  $T$  is in K,

$$\ln \gamma_{\text{W}} = \ln \left( \frac{P_{\text{W}}}{x_{\text{W}}} \right) = x_{\text{TBA}}^2 \left[ \frac{b_{21}}{RT} \left( \frac{G_{21}}{x_{\text{W}} + x_{\text{TBA}} G_{21}} \right)^2 + \frac{G_{12} b_{12} / RT}{(x_{\text{TBA}} + x_{\text{W}} G_{12})^2} \right], \quad (3a)$$

$$\ln \gamma_{\text{TBA}} = \ln \left( \frac{P_{\text{TBA}}}{1 - x_{\text{W}}} \right) = x_{\text{W}}^2 \left[ \frac{b_{12}}{RT} \left( \frac{G_{12}}{x_{\text{TBA}} + x_{\text{W}} G_{12}} \right)^2 + \frac{G_{21} b_{21} / RT}{(x_{\text{W}} + x_{\text{TBA}} G_{21})^2} \right], \quad (3b)$$

$$\begin{cases} G_{12} = \exp \left( -\alpha \frac{b_{12}}{RT} \right) \\ G_{21} = \exp \left( -\alpha \frac{b_{21}}{RT} \right) \end{cases}; \begin{cases} \alpha = 1.628 - 0.00992T + 1.860 \times 10^{-5} T^2 \\ b_{12} \text{ (J/mol-K)} = -11874.652 + 101.182T - 0.120T^2 \\ b_{21} \text{ (J/mol-K)} = -7429.529 + 58.534T - 0.108T^2 \end{cases} \quad (3c)$$

It is worth noting here that, as pure species or as components with the same mole fractions in the frozen solid mixtures, water has noticeably lower sublimation partial pressures (see Fig. 3) than those of TBA vapor and the resulting total pressure in the porous dried layer of

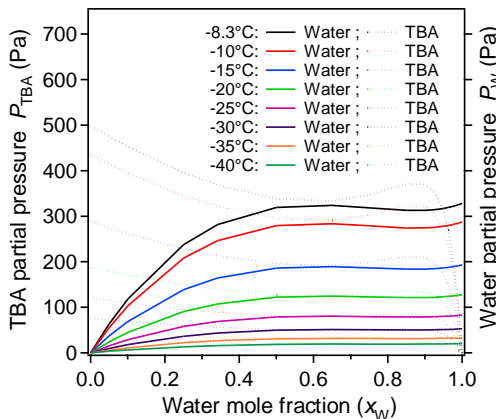

Fig. 3 Partial vapor pressure as a function of temperature and water mole fraction in the binary frozen solid mixture

Fig. 4 Total vapor pressure as a function of temperature and water mole fraction in the binary frozen solid mixture

the product being freeze dried is significantly higher than in the case where water was the only solvent and, thus, the resulting total pressure gradient between the moving interface and the drying chamber pressure could be larger and provide an increase in the total convective mass transfer rate of the water and TBA gas mixture due to the presence of TBA. Therefore, TBA could sublime faster during primary drying and facilitate the mass transfer of water vapor from the frozen product and possibly reduce the primary drying time. But there are additionally two diffusion mass transfer mechanisms occurring simultaneously with convective mass transfer in the porous dried layer of the product, namely Knudsen and bulk diffusion. The Knudsen diffusivity is independent of total pressure, but it has dependencies on temperature and molecular mass. Taking a representative pore radius of 1000 Å, the Knudsen diffusivities [11] of water and TBA vapors in the porous dried layer were calculated and plotted in Fig. 5. As expected, water being lighter than TBA by a factor of approximately 4, has a Knudsen diffusivity about two times larger than that of TBA. The binary bulk diffusivity [11] is affected by both temperature and total pressure, which are both varying during freeze drying. Given the low total pressure condition (see Fig. 4) and considering the effective collision diameters of water and TBA being 2.64 Å [12] and 5.40 Å [13], respectively, the binary bulk diffusivities were calculated [11] and are represented by solid curves in Fig. 6 where the total vapor pressures are also included (dashed curves) for reference. Even the lowest bulk diffusivity in the range occurring at -8.3 °C and  $x_{TBA} \approx 0.85$  is still 50-100 times greater than the Knudsen diffusivities of water and TBA vapors.

Enthalpically, water and TBA have very similar heats of sublimation, both around 51 kJ/mol [10,14], so their frozen binary mixtures also require a similar heat of sublimation [10]. This fact likely reduces the number of variables to control when devising an optimal heating strategy for the freeze drying process. In this respect, the system temperature cannot exceed -8.3 °C as it is the lowest melting temperature of the frozen water-TBA mixtures over the entire compositional range, which is also an eutectic point [7] occurring at 17.8 wt%

Fig. 5 Knudsen diffusivity of water and TBA as a function of temperature

Fig. 6 Binary bulk diffusivity and total vapor pressure as a function of temperature and water mole fraction in the binary frozen solid mixture

TBA ( $x_{\text{TBA}} = 0.05$ ). Similar heats of sublimation also attest, from the viewpoint of the Clausius–Clapeyron equation, the constantly higher pressures of TBA vapor over those of water vapor, and hence faster removal of TBA than water could occur during the primary drying stage of the freeze drying process. But the above data still point to water being a major process controlling species with respect to system constraints that have to be satisfied in the freeze drying process of pharmaceutical water solutions with TBA as a co-solvent.

### 3. Conclusions

Due to the limitations of current experimental techniques, a new class of physicochemical mathematical models is needed in order to enable rational physical and quantitative evaluation of the freeze drying process of pharmaceutical water solutions involving tertiary butyl alcohol (TBA) as a co-solvent. The construction and solution of such models require knowledge of the vapor pressures of water and TBA in equilibrium with their binary frozen solid mixtures, but these pressure data were not available to date. A thermodynamic approach based on the UNIFAC method coupled with the Dortmund parameters was developed to provide the needed pressure data as a function of temperature and of the mole fraction of the binary frozen solid mixture of water and TBA. The results have further been correlated into analytical expressions using a NRTL type model function. The results indicate the TBA vapor pressures to be constantly higher than those of water vapor and this leads to higher total pressure gradients in the porous dried layer of the product that could increase the convective mass transfer rates and support the experimental observation that TBA is removed relatively faster than water during the primary drying stage. When the bulk and Knudsen diffusion coefficients were evaluated under the temperatures and total vapor pressures that could be encountered in freeze drying, the former was found to be at least 50-100 times higher in magnitude than the latter. But the higher in magnitude total pressures of the binary gas mixtures of water and TBA which are due to the significantly larger vapor pressures of TBA, reduce the magnitude of the bulk diffusion coefficient. Furthermore, the Knudsen diffusion coefficient of TBA vapor is significantly smaller than that of water vapor. These effects on the magnitudes of the diffusivities could affect the mass transfer rates due to bulk and Knudsen diffusion during the primary and secondary drying stages. To ascertain the relative importance of the competing mass transport mechanisms of convection and bulk and Knudsen diffusion on the drying rates, one has to construct and solve an unsteady-state and spatially multi-dimensional freeze drying model that accounts for the effects of TBA presented here, while the thermodynamic expressions developed and presented in this work are a necessary component of the mathematical physics structure of such a model.

### **Abstract**

*Most of the CFD simulations of spray dryers reported in the literature utilizes a fixed air inlet temperature numerical framework. In this paper, a numerical framework was introduced to model spray drying as an outlet air temperature controlled process. A P-controller numerical framework was introduced which allows the inlet temperature to be automatically adjusted based on the required outlet temperature set point. This numerical framework was evaluated with a simulation of a two-stage pilot scale spray drying system at the Davis Dairy Plant (South Dakota State University) which is used for commercial contract spray drying operation.*

**Keywords:** CFD simulation; Multi-Stage Spray Drying; P-Controller

## **1. Introduction**

Spray drying is a popular unit operation in drying industry in which dry powder can be produced by removing moisture from a liquid material using a hot gas. This is a preferred method where heat sensitive material are used in food and dairy industries. The spray drying involves multiphase flow with heat, mass and momentum transfer between drying gas flow and the discrete phase. Therefore, controlling and designing spray dryers is time-consuming and complicated task particularly where the intent is large-scale production volume [1].

The use of CFD simulations for the design and analysis of spray dryers have been widely reported in the literature [2-5]. A survey of the simulation reported so far revealed that all the simulations employed a fixed inlet conditions (temperature) from which the outlet conditions (temperature) will be predicted. In actual commercial operations, the spray dryer is mainly outlet temperature controlled where the inlet temperature is adjusted (by the control system or sometimes manually), accounting for the evaporation within the chamber, to meet the desired outlet temperature. Such backward computation of the inlet temperature is not trivial in a CFD simulation. Therefore, there is a need for the development of a numerical framework to capture the outlet controlled operation of spray dryers.

In this work, to address this gap in knowledge, a numerical P-Controller was developed for implementation in a CFD simulation of a spray drying system. An industrial scale two-stage spray drying system at Davis Dairy Plant located at South Dakota State University (SDSU) with an external vibrating fluidized bed was modelled where the operation was outlet temperature controlled. In the operation of the SDSU dryer, spraying micellar casein concentrate, the desired temperature of side outlet was set at 82.2°C. Numerical challenges in the development of the P-Controller framework will be further discussed in this paper.

## **2. Description of the SDSU spray dryer system**

Fig. 1 shows the dimensions of the spray drying unit modelled in this paper. The bottom outlet from the chamber leads to the external vibrating fluidized bed as the second stage dryer. The actual mass flow rate of the drying air entering the chamber was not measured or monitored as part of the control system. From the manufacturer's blower performance curve and the measured average pressure at the chamber inlet, the air mass flow rate was determined to be 1.1 kg/s.

The combined operation of the inlet air blower and the main outlet suction blower was used to maintain a negative pressure of approximately 677 Pa (gauge) within the chamber. This negative pressure was measured at approximately the middle elevation of the top conical region of the drying chamber. The bottom outlet pressure was unknown. Simulation of

airflow and particles trajectories ratios between two outlets revealed that the -250 Pa pressure would be a reliable prediction for the bottom outlet [6].

In the startup of the spray dryer, the dryer is firstly heated up with the inlet hot air without spray. At this stage, the automatic system will be manually overridden and a higher temperature, typically at around 161.1-214.4°C to achieve an outlet temperature of 82.2°C, will be used depending on the intended spray rate. Once the dryer reaches the desired outlet temperature, feed spray will be initiated and the automated inlet temperature control will be activated. By intuition, evaporation would have provided cooling to the hot air stream and this would have led to the need for a higher temperature to compensate in maintaining the outlet air temperature. The automatic control system will then increase the inlet air temperature to maintain the outlet temperature at the set point.

### **3. Modelling approach**

The 3D simulations (Fig. 1) of spray dryer with a mesh size of 275764 elements were undertaken using ANSYS Fluent V17.1. [7]. The details of mesh dependency is described in [6]. Boundary condition for air inlet was mass flow inlet that was entered according to the manufacturer's blower air flow specifications (mass flow rate=1.1 kg/s). The walls of the chamber were specified as non-slip insulated wall boundaries. The side outlet (-677 Pa) and the bottom outlet (-250 Pa) were specified as pressure outlets. This approach allowed numerical capturing of the negative pressure within the drying chamber. The pseudo tracer analysis and how to predict the bottom outlet pressure is explained in [6]. Convergence criteria was  $1 \times 10^{-3}$  for all scaled residuals.

Transient simulations were undertaken. The Reynolds-time averaged Navier–Stokes conservation equations were used to describe the airflow field. The turbulence in the air was modelled using the standard  $k-\epsilon$  model. It has been demonstrated that  $k-\epsilon$  model performs much better in transient simulations than steady-state simulations particularly in spray drying systems [8]. For pressure–velocity coupling, the coupled algorithm was used. The transport, turbulence and species equations were discretized using a second-order upwind scheme. Pressure equation was discretized using the PRESTO scheme. A time step size of 0.05s with 10 iterations per time step was sufficient to capture the transient self-sustained central jet flapping behavior of the flow field. This time step size was also adopted by past reports simulating industrial scale spray dryers with inlet air flow of the same magnitude in velocity [9,10]. Particle injection time step sizes were set 0.05s. The “escaping wall” boundary condition was employed at the dryer walls, which assumes that all the particles deposit at the wall upon collision with the wall.

Fig. 1 Dimensions of spray drying chamber

### 3.1. Equations

Continuity equation is described in Equation (1):

$$\frac{\partial(\alpha_q \rho_q)}{\partial t} + \nabla \cdot (\alpha_q \rho_q \vec{v}_q) = 0 \quad (1)$$

where q is either gas or solid.

Gas phase-momentum is described in Equation (2):

$$\frac{\partial}{\partial t} (\alpha_g \rho_g \vec{v}_g) + \nabla \cdot (\alpha_g \rho_g \vec{v}_g \vec{v}_g) = \nabla \cdot \bar{\tau}_g - \alpha_g \nabla P + \alpha_g \rho_g \vec{g} + \beta (\vec{v}_s - \vec{v}_g) \quad (2)$$

Droplet trajectories were captured by the Lagrangian framework. This formulation (Equations (3) to (5)) tracks each discrete droplet individually within the air flow by integrating the motion equations governed by Newton's second law and including the influence of the relevant drag force interaction with the air.

$$\frac{dv_s}{dt} = C_D \frac{18\mu}{\rho_s d} \times \frac{Re}{24} (v_g - v_s) + g \left( \frac{\rho_s - \rho_g}{\rho_s} \right) \quad (3)$$

$$C_D = \frac{24}{Re} [1 + 0.15(Re)^{0.687}] \quad (4)$$

where

$$Re = \frac{\rho_g d (v_g - v_s)}{\mu_g} \quad (5)$$

The heat transfer model is explained in Equation (6):

$$mC_p \frac{dT_s}{dt} = hA(T_g - T_s) - \nabla \cdot H_{evap} m_s \frac{dT_s}{dt} \quad (6)$$

The heat transfer coefficient was calculated using Ranz-Marshall equation:

$$Nu = 2 + 0.6Re^{0.5} Pr^{0.33} \quad (7)$$

The distribution of droplet diameters in the spray is assumed to obey the Rosin-Rammler distribution function [11]. The Rosin-Rammler model is given by Equations 8-9:

$$Y_s = e^{-(d/\bar{d})^n} \quad (8)$$

$$n = \frac{\ln(-\ln Y_s)}{\ln(d/\bar{d})} \quad (9)$$

where  $Y_s$  is retained mass fraction of particle,  $d$  is the particle diameter,  $\bar{d}$  is the mean particle diameter and is  $394 \times 10^{-7} \mu\text{m}$ ,  $n$  is the size distribution parameter and is 2.4. The corresponding maximum and minimum droplet size are taken as  $200 \times 10^{-8} \mu\text{m}$  and  $672 \times 10^{-8} \mu\text{m}$ . User-defined functions (UDFs) in Fluent were developed to describe the shrinkage behavior of particles and Reaction Engineering Approach (REA) models. The particle mixture density was modified using linear shrinkage model [12, 13] (see Equation 10):

$$\frac{d}{d_0} = b + (1 + b) \frac{X}{X_0} \quad (10)$$

where  $d_0$  is the initial diameter of the particle/droplet,  $X_0$  is the particle/droplet initial moisture ( $\text{kg kg}^{-1}$ ) on dry basis, and for MCC particles,  $b$  is 0.59 [14]. The Reaction Engineering Approach (REA) [15] model for 20 wt% solid content MCC is presented in Equation (11):

$$\frac{\Delta E_v}{\Delta E_{v,e}} = 0.012(X - X_e)^6 - 0.142(X - X_e)^5 + 0.6142(X - X_e)^4 - 1.2944(X - X_e)^3 + 1.483(X - X_e)^2 - 1.0771(X - X_e) + 1.0023 \quad (11)$$

This equation was determined from single droplet measurements in SDSU. The equilibrium moisture content ( $X_e$ ) for MCC was calculated using Guggenheim-Anderson-de Boer (GAB) model. The constants were taken from [16], and described in Equation 12:

$$X_e = \frac{(0.564 \times RH)}{1 + 6.01RH - 5RH^2} \quad (12)$$

## 4. Results and Discussion

### 4.1. Development of the P-Controller numerical scheme

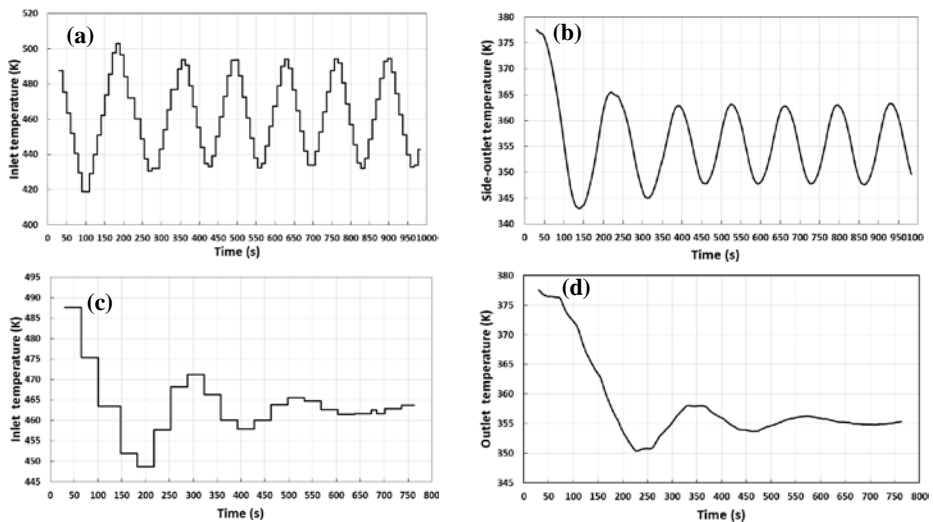

As mentioned in Section 2, the essence of the P-Controller is the continuous adjustment of the inlet temperature based on the outlet temperature relative to the desired outlet temperature set point. In this study, the desired outlet temperature was  $82.2^\circ\text{C}$ . In the Fluent framework, the UDF is implemented (hooked) to provide input to the air inlet temperature. The first key aspect of the numerical implementation is that there is a proportional gain parameter embedded into the code which subsequently translates to the step adjustment to the inlet temperature. From trial and error, there was a need to implement an arbitrary maximum possible change to the inlet temperature to ensure stable numerical computation. This limiter to certain extent will be affected by how the simulation is initialized prior to the activation of the P-controller (in case the initial outlet temperature difference relative to the set point is large). The second key aspect to the

numerical implementation is that a response time of the controller was embedded into the framework.

A ‘counter’ approach was used in the current code corresponding to the enforced number of flow field iterations per time step in the simulation. Both parameters, proportional gain (and the arbitrary limiter) and the response time will affect the simulation time required to achieve a stable air flow outlet temperature. In this work, only the response time was evaluated while keeping the proportional gain parameter constant.

#### 4.2. Evaluation on the effect of different controller response time

Preliminary transient simulations with a fix inlet temperature (without P-controller) showed that characteristic response time of the simulation was approximately 10 seconds. In other words, it takes 10 seconds until the outlet temperature reaches 82.2°C. Therefore the number of time steps to receive a feedback from P-Controller, between the initial inlet temperature and the calculated outlet temperature was 200, as each time step size was set 0.05 second. The time-step response of 10 seconds was taken as the base study, and the 25s and 35s time-step responses were also investigated. For the brevity, the 25s time-step results were not presented here. Fig. 3 (a-d) shows the inlet and side outlet temperature profiles where time responses are 10s and 35s respectively.

**Fig. 3** Temperature profiles (a) inlet temperature: 10s time-step response (b) side-outlet temperature: 10s time-step response (c) inlet temperature: 35s time-step response (d) side outlet temperature: 35s time-step response

As can be seen from Fig. 3(a,b), the temperature profiles kept fluctuating where the time-step response is 10s and the final inlet temperature is not predictable. However, at 35s time-step responses (Fig.3(c,d)) the temperature profiles were stabilized after approximately

750seconds. The temperature profiles were stabilized after 970 seconds where time-step responses were 25s (For the brevity the figures are not shown here). The measured experimental inlet temperature was 447K, and the predicted CFD inlet temperature was 463K (Fig. 3(c)). The corresponding error is 3.5%, and it could be due to the uncertainties in other parameters of the simulation such as the atomization parameters or the estimation of the bottom outlet pressure. Nevertheless, this is the first reported attempt in the implementation of the P-Controller for a CFD simulation of spray dryers.

### 3. Conclusions

CFD simulations of two-stage spray dryer were performed where the inlet temperature was estimated using a P-Controller. The crucial step to estimate the inlet temperature was to predict the proper time-step responses between the inlet and the side-outlet. Comparison of three different time-step responses showed that the longer the time-step responses are the shorter the time required to achieve stabilized temperature profiles. It was found that the time-step response of 35s is adequate to achieve the stabilized temperature profiles. It was proved that the presented P-Controller approach was reasonably able to predict the inlet temperature, however the corresponding error can be due to the uncertainties in obtaining operating parameters from the semi-commercial plant. Future applications of this approach, for faster computation, may require an initial overall black-box mass and energy balance to provide the initial inputs to the dryer from which the P-Controller can then be used for further refinement to the CFD analysis.

### **Abstract**

*A new Process Analytical Technology (PAT) has been developed and tested for on-line process monitoring of a vacuum freeze-drying process. The sensor uses an infrared camera to obtain thermal images of the ongoing process and multivariate image analysis (MIA) to extract the information after automatic detection and segmentation of the region corresponding to the product in every vial. A reference model was built, using the information of six batches, and different kind of anomalous events, involving either single vials in the batch or the whole batch, were simulated to test the capacity of the MIA-based monitoring system to promptly identify them.*

**Keywords:** freeze-drying; process monitoring; infrared image; multivariate image analysis.

## **1. Introduction**

Vacuum freeze drying (VFD) is a highly attractive process for the water removal in thermal sensitive products, mainly pharmaceutical ones, since water is removed at low temperature by sublimation. Monitoring of critical quality attributes of the product, e.g. its temperature, is required to guarantee that the desired characteristics are obtained in the final product. Besides, it is required that the monitoring system does not interfere with product dynamics.

In the past, many approaches to this problem, based on the measurement of product temperature, sublimation rate, heat flux to the product, among the others, were proposed and tested [1], in particular at lab-scale. The measurement of the temperature of the product, possibly in a well-defined position (e.g. the bottom of the vial), was studied in detail and successfully applied for process monitoring and control [2]. The main drawback, up to this moment, of this approach is that the temperature measurement has to be performed using a thermocouple stuck into the product and this does not guarantee neither the sterility requirements nor that the sensor is not interfering with the ongoing process.

In this work we used an infrared camera, instead of a thermocouple, for temperature measurement. Differently from the system proposed in the literature, we placed the camera inside the chamber, thus being able to monitor the vials in several positions, and not only on the top shelf of the freeze-dryer [3], thus extending the monitoring capacity of the system. Unfortunately, thermal images include a lot of useless (i.e. everything that is outside the vial) information and also the one directly related with the process is highly noisy, redundant and correlated. The first problem is a matter of gray-scale image segmentation, and traditional image analysis, as well as computer vision, supply a lot of tools for working out this kind of matters; the second is a frequent problem when dealing with real industrial data, and latent based multivariate statistical techniques can easily deal with this kind of problems.

The idea underlying the development of a latent variable multivariate monitoring system is that only a few underlying events are driving the process, and all the measurements we obtain are just a different sight on this underlying driving force. Multivariate statistical methods allow us to obtain a model of the process by projecting the information into a low dimensional space defined by latent variables and, in this reduced space, we can build control charts able to detect any deviation from the normal operating conditions [4]. Principal component analysis (PCA) has been widely studied and applied for this purpose being also able to successfully deal with the highly auto-correlated and cross-correlated data typical of batch processes [5] such as VFD intrinsically is. Multivariate control charts for batch process monitoring have been proposed by Nomikos and MacGregor [6].

## 2. Materials and Methods

### 2.1. Experimental

Drying experiments were carried out using a lab scale equipment LyoBeta 25<sup>TM</sup> freeze-dryer (Telstar, Spain). In all tests ten vials (ISO 8362-1 8R) were placed at 30 cm from the camera, and a new image was acquired every five minutes. Each vial in the batches has been assigned with a number referring to the position in the shelf as Figure 1 shows.

The normal operating conditions (NOC) set was obtained processing a solution of 10% b.w. sucrose (Sigma Aldrich, 99.5%), 5 ml per vial, at -20°C and 20 Pa. Six batches were processed in the same operating conditions, thus obtaining 60 observations, corresponding to the 10 vials monitored in the 6 tests. The detection ability of the system was evaluated in four additional batches (i.e. observations from 61 to 100). In batch 7, after 5 hours of drying, chamber pressure was raised to 50 Pa; in batch 8 the shelf temperature was set to -10°C while in batch 10 a solution 5% b.w. of sucrose was used. Batch 9 aimed to prove the ability of the model to detect faults affecting the single vials and, while shelf temperature and chamber pressure were set to the NOC values, only four vials (corresponding to observations 81, 88, 89 and 90) were filled with the 10% solution. A piece of glass was inserted into two vials, one was filled with pure water, one with the same 5% b.w. solution used for batch 10 and the remaining two with respectively 2.5 and 7.5 ml of solution.

Due to the vibrations of the equipment, during batch three, vial 7 fell down and was considered as a fault, while the remaining nine vials were considered successfully dried.

### 2.2. Image segmentation and data acquisition

The thermal images are 256x320 pixels. The camera is equipped with a 63°x50° lens which leads to a slight optical distortion, known as barrel effect. This second order deviation from the ideal rectilinear projection can be compensated remapping the pixels according to the following equation:

$$r_{new} = r_{old} + f \cdot r_{old}^2 \quad (1)$$

where  $r$  is the distance from the center of the image of a generical pixel and  $f$  a correction factor (negative in this kind of optical aberration) depending on the distance between the camera and the object [7]. In all our tests the same distance was used this factor is approximately constant and equal to -1.5.

After optical correction, the Hough transform [8] was used to detect the position of the vials in the images, as shown in Figure 1. Being known the diameter of the vials bottom and the length of the line detected by the Hough transform we were able to infer the width of a single pixel and thus, as we know also the height of the vial, the height of the mask.

The whole portion of the image corresponding to the product into every vial was segmented and, to study the evolution over time of the temperature distribution, mean, standard deviation (std), skewness and kurtosis of the temperature in this region were measured. The results were collected into a three-dimensional data structure  $\mathbf{X}$  ( $I \times J \times K$ ) where  $I$  is the number of observation, being each vial intended as a single observation,  $J$  is the number of variables measured, and  $K$  is the number of time instants.

### 2.3. Batch process monitoring

The data structure was batch-wise unfolded obtaining a matrix  $\mathbf{X}(I \times JK)$  [5]. After mean centering and scaling  $\mathbf{X}$ , a PCA model with  $A$  principal component was built using the available observations, obtained in batch 1 to 6.

$$\mathbf{X} = \mathbf{T} \cdot \mathbf{P}' + \mathbf{E} \quad (2)$$

where  $\mathbf{T}$  is the  $I \times A$  score matrix,  $\mathbf{P}$  is the  $A \times JK$  loading matrix and  $\mathbf{E}$  is the  $I \times JK$  residual matrix. The number of principal components that maximizes the classification skills of the model was determined as that who maximizes the following function:

$$f_A = (1 - \alpha) \cdot (1 - \beta) \quad (3)$$

where  $\alpha$  is the overall type I error rate (i.e. false positive rate) and  $\beta$  is the overall type II error rate (i.e. false negative rate). Once the latent variable sub-space is known, unusual behaviors can be detected using two multivariate control charts: Hotelling  $T^2$  ( $T^2$ ) and the squared prediction error ( $SPE$ ) defined by equations 4 and 5 for each observation:

$$T^2 = \sum_{a=1}^A \frac{t_a^2}{\lambda_a} \quad (4) \quad SPE = \sum_{c=1}^{KJ} e_c^2 \quad (5)$$

where  $t_a$  is the  $a$ -th score and  $e_c$  is the error obtained after predicting the measurement of variable  $c$  for a certain observation. Upper control limits (UCL) for these charts were computed both empirically, that is taking the percentile of the actual values measured for the same NOC observations, and using their theoretical statistical distributions [6]. Once the number of principal components has been fixed, the possible outliers that would contribute to raise the control limits have been detected and purged. Due to the reduced number of batches available, a *one-batch-out cross-validation* approach was used: each batch is in turn removed from the NOC data set used to build the PCA, all the observations are projected, and those observations that prove to be outliers are removed.

The main issue when dealing with on-line multivariate SPC is the imputation of the missing information [6], a good approach being regression on the available NOC data used to build the PCA model [9]. In this work the *Trimmed Score Regression (TSR)* method has been used [10]. In on-line monitoring the  $SPE$  is computed only on the information measured at instant  $k$ , and for this reason is called *instant SPE (SPEI)*:

$$SPEI_c = \sum_{c=1+(k-1)J}^{KJ} e_c^2 \quad (6)$$

Nomikos and MacGregor proposed to use the errors on a moving window of five instant measurements to compute the UCL limits for this statistic [6]. The percentage of time instants that *SPEI* overtake the UCL in in-control batches, also called Overall type I (OTI) risk, should be lower than the imposed significance level (ISL = 0.5%) and for this reason the UCL have been manually tuned [11]. *N<sub>f</sub>* is the number of instantaneous faults for the overall trial set.

$$OTI = 100 \cdot \frac{N_f}{I \cdot K} \% \quad (7)$$

### 3. Results

Figure 2 reports an example of the 10 trajectories, one for each vial, described by the four variables measured during the drying process in one of the reference batch. Average temperature shows an asymptotic behavior up to the thermal equilibrium. The standard deviation (std), after a sudden decrease, grows up until a maximum is reached at almost 9 h; then, it slowly decreases again until reaching an almost constant value at 36 h. Both skewness and kurtosis show a maximum, followed by a local minimum around 9 hours. An almost constant value is kept from 36 h to the end. The local maxima (or minima) seems to correspond to the first slope change of the Pirani/Baratron pressure ratio. The constant values at the end indicates that the thermal equilibrium has been reached and the primary drying is over. Significant differences in these thermal trajectories may reveal an abnormal heat transfer, that is an anomalous drying kinetic and a lower product quality.

From the analysis of the scree plot and the cumulative variances plot (not reported) we decided to evaluate  $f_A$  for a number of components going from 5 to 13, that is from 83.9% to 95.4% of the whole variance. Figure 3 shows that  $f_A$  clearly shows a maximum when 10 PC are used (93.6% variance explained). Observation 21 appeared as the only outlier during the one-batch-out cross-validation step, and for this reason has been removed from the final data set. The UCL for  $T^2$ , depending only on the number of PC extracted and the number of observations, are constant but there is a remarkable difference between the theoretical and the empirical value; being the former (20.9) always lower than the latter (36.3). On the other hand, the UCL for *SPEI* computed with the theoretical distribution and the one obtained taking the percentile of 99.5% are always very similar. After tuning the control limits, the obtained OTIs were 0.496% for *SPEI* and zero for  $T^2$ .

The classification performance of this monitoring system has been evaluated by projecting all the batches (one hundred vials/observations) on the obtained model. Tuned empirical limits performed slightly better than the theoretical ones and have been used. Figure 4 shows an example of the resulting control chart for three observations: number 5, a vial of the NOC set, always below the UCL; number 21 that was removed as an outlier and has been detected as a fault by the *SPEI* control chart only; and number 75 dried at a higher shelf temperature

and lies over the control limits of both statistics almost all the time. The control charts for *SPEI* detected 10 false positives observations in the trial set (6, 9, 10, 15, 16, 19, 25, 31, 40, 50). Observations 21 and 27 (the one that felt down in batch 3) have been detected as faults as well as all the observations of the anomalous batches 7, 8 and 10. In batch 9 six vials were tampered and all of them have been correctly discriminated, while all the remaining good vials resulted into false positives. The  $T^2$  control chart reported thirteen false negatives. Only two of the four vials of batch 9 dried with the original 10% sucrose solution (observations 81 and 90) have been correctly found to be successful drying tests. Observations 88 and 89 have been highlighted as faults.

Looking at the observations that appeared as false positives in *SPEI* (they are 6, 9, 10, 15, 16, 19, 25, 31, 40, 50) we can notice a certain periodicity in the results. Position 1 and 10 in every batch corresponds to the external vials, directly radiated by the chamber walls. Observation 21, as well as 81 and 90, appear to support this hypothesis. In the first three batches a thermocouple was located inside the vials in position 5 and 6, see Figure 2. This slight difference into the data structure of observation 6, 15, 16 and 25 might be due to the influence of the thermocouple on the drying kinetics.

These observations overtake the control limits on a limited number of time instants. If we accept these spurious errors as part of the unavoidable statistical error rate, that is, we consider the phenomena responsible for these instantaneous faults cannot jeopardize the quality of the resulting product, the fault detection performance could be further optimized. This new relaxation of the control limits was achieved by considering faults only the observations that cross the control limits in more than 5% of the time instants. In this way all the false positives in *SPEI* were properly classified as successful tests except observations 81 and 90. No further improvement was possible for Hotelling  $T^2$  control charts since lowering the UCL to include the false negatives raises new false positives. This lower detection ability of  $T^2$  control charts, when dealing with data from batch processes, has already been reported in the literature and is basically due to the strong auto-correlation in the data [11].

#### **4. Conclusions**

In this work MIA techniques have been applied to thermal images of the VFD process and a PAT for real time monitoring have been developed and successfully tested. The sensor, using an infrared camera, is completely non-invasive and have no side-effects on the process kinetics. This technology proved to be quite sensitive being able to discriminate the slight effect on the product of either a thermocouple inserted into some vials or chamber walls radiation. Future works will aim to prove the possibility to use this PAT and the infrared imaging technology for process control and optimization purposes.

### **Abstract**

*Drying is a complex, dynamic, unsteady and nonlinear process that, when not optimized on a system level, may be responsible for (1) significant quality degradation and (2) energy wastage. Consequently, new drying technologies must be designed combining non-invasive at/on/in-line advanced measurement and control systems with models cross-linking all relevant aspects of product quality changes and heat and mass transfer phenomena.*

*This paper presents preliminary results on the use of RGB imaging, NIR spectroscopy and Vis-NIR hyperspectral imaging for real-time monitoring of physicochemical changes of apples and carrots during drying.*

**Keywords:** *chemometrics, artificial intelligence, deep learning*

---

## **1. Introduction**

Commercial drying of apple and carrot produce is generally conducted according to drying strategies developed decades ago. These strategies operate to a large degree based on strict control of the characteristics of raw material at the input stage. This strict sorting, however, results in a significant proportion of produce being wasted prior to any processing. This coarse sorting at the input stage, however, does not guarantee that, after the set drying process, the entire produce will be of the same quality or will even fulfill the minimum quality required by consumers. In recent years, the organic sector has put significant efforts into the development of clear definitions for gentle and quality oriented ways of processing plant based foodstuffs to supplement existing regulations and guarantee premium quality of the product whilst reducing resource depletion [1].

The use of non-invasive measurement and control systems have shown a great potential for improvement of the product quality [2]. Simple solutions can readily be implemented into existing processes (e.g. dynamic control of product temperature [3]), while integration of advanced solutions is not possible nor financially viable in practice. Thus, there is a need for smart processing systems which allow for simultaneous multi-factor control (i.e. air temperature, velocity, humidity) to guarantee high-value end products, while enhancing energy demand and resource efficiency, by implementing innovative and reliable microcontrollers, sensors, resources, tools and practices at low cost and embracing various R&D areas (e.g. computer vision, hyper-/multispectral imaging, deep learning, etc.) [4].

Aim of this study was, therefore, the development of non-invasive measurement systems based on RGB imaging, Vis/NIR Hyperspectral imaging and NIR spectroscopy in combination with analysis algorithms to determine colour development, water content and chemical components throughout the drying process. These technologies and techniques are essential to provide inputs for the development of product quality driven adaptive control systems for drying. Eventually, these systems are intended to be transferred to simpler solutions and integrated into smart control systems for product quality oriented drying.

## **2. Materials and Methods**

### **2.1 RGB imaging study on apples**

Organic apples var. Red Delicious with the origine Italy were sourced from a local supplier (Trondheim, Norway) and stored at 8°C until processing. For the trials slices of 5 mm were cut. Core and skin were not removed.

Drying experiments were conducted at 20 and 40 °C with relative air humidities of 25, 40 and 60 % using an experimental drying chamber built at SINTEF. The chamber was equipped with a camera system, including an LED barlight for illumination. Details on the experimental set-up and conduction of trials are presented by Bantle [5].

Analysis of optical alterations was conducted using the OpenCV libraries for image processing, using images taken every 5 minutes during the drying tests. RGB values were transformed into CIE-XYZ color space according to the ISO Standard 13655 and then further processed to receive the CIE-L\*a\*b values. A detailed procedure is given by Bantle et al. [5].

## 2.2 Vis/NIR Hyperspectral imaging study on apples

Apples var. Golden Delicious were sourced from a local retailer (Witzenhausen) and stored at room temperature until use. The apples were de-cored and sliced to 5mm thickness and cut to a uniform outer diameter of 65mm. Drying was conducted in a hot air convection oven at 50°C.

Drying tests were conducted using a convective air cabinet dryer (HT-Mini, Innotech Ingenieurgesellschaft mbH, Altdorf, Germany) at 50 and 70°C. Measurement protocols followed those described by Crichton et al. [6].

Samples were imaged using a Specim V10E PFD hyperspectral camera (Schneider Optics Xenoplan 1.9/35) in conjunction with a linear translation stage (Specim Spectral Imaging Ltd., Finland). Three 60W halogen GU10 bulbs were used for illumination. A detailed description of the image processing moisture content prediction protocols followed is given by Crichton et al. [6].

## 2.3 Near infrared spectroscopy study on carrots and apples

Organic carrots (*Daucus carota L.*, var. Romance) and apples (*Malus domestica B.* var. Gala) were purchased and immediately stored at  $4 \pm 1$  °C until processing. Carrot slices and apple wedges were prepared by washing and cutting samples using a sharp ceramic knife. The slices and wedges were subjected to 8-h hot-air drying and batch sampling was performed at every hour of drying. The dehydration process was conducted at 40°C (carrot) and 60°C (apple). Samples were divided into two groups, one of which was subjected to a blanching pre-treatment before hot-air drying and one that was dried without pre-treatment (i.e. hot-water blanching at 95°C for 1.45 min for carrots and microwave blanching at 850W for 45 sec for apples). Each batch was subjected to both NIR spectral data acquisition and determination of CIELab colour, moisture content (wet basis), water activity ( $a_w$ ), soluble solids content and total carotenoid content (carrot only).

Absorbance spectra were acquired using a spectrophotometer mod. Luminar 5030 (Brimrose Corp., Baltimore, USA) (range 1100-2300 nm, 2-nm resolution). Each sample was measured in duplicate on two opposite sides of each slice/wedge (i.e. 4 spectra per sample).

Chemometric analysis was performed following spectral pre-treatments including Standard Normal Variate, Multiplicative Scatter Correction, Savitzky-Golay first and second

derivatives with a second or third order polynomial fitted over a window of five, seven, nine or eleven features, as well as Mean Centering [7, 8].

Regression models were computed using the partial least squares (PLS) regression through the SIMPLS algorithm [9]. The samples were randomly split as calibration set (C) and the prediction set (P). The venetian blinds cross-validation with 10 data splits was performed. Root Mean Square Error (RMSE), BIAS and coefficient of determination ( $R^2$ ) were employed as model performance metrics [10]. PLS models were computed to predict changes in chemical and physicochemical attributes during 8-h dehydration process.

### 3. Results

#### 3.1 RGB imaging-based analysis of color changes in apples

The employed camera system and associated developed codes allowed for the reliable real-time measurement of changes in product quality at the set measurement intervals. Fig. 1 shows the impact of drying conditions on the resulting changes in the  $a^*$  and  $b^*$  values. It is evident that all settings led to an increase of both  $a^*$  and  $b^*$  values, signifying the change of visual appearance of the samples. The most beneficial drying conditions for maintenance of the appearance were at 20 °C (T) and 25 % RH.

The developed real-time monitoring system for color (and shape) changes will make it possible to include information of the current color changes in the control consideration of a smart drying system. This is of particular importance as consumers tend to judge a product's quality by its visual appearance.

Fig 1: Development of CIE-a\* as a function of CIE-b\* for different drying conditions, temperatures are given as T and relative humidity as RH in the graph

### Vis/NIR hyperspectral water content determination in apples

PLSR analyses with the full reflectance spectra were carried out across the complete data set. For both conditions PLSR was performed for models varying from 1-20 components with 10-fold creation and testing. The 3-component [540 nm, 817 nm, 977 nm] PLSR model satisfied the minimal RMSE criterion. Table 1 gives an overview of the results for full and reduced spectra.

**Table 1: Performance of moisture content PLSR models**

Setting (°C)	Full Spectrum		Reduced (3-wavelength set)					
	Calibration	Test	Calibration		Test			
	$r^2$	RMSE (g/g)	$r^2$	RMSE (g/g)	$r^2$	RMSE (g/g)	$r^2$	RMSE (g/g)
		[M.C. %]		[M.C. %]		[M.C. %]		[M.C. %]
50	1.00	0.01 [0.12]	1.00	0.11 [1.32]	0.99	0.18 [2.16]	1.00	0.09 [1.08]
70	1.00	0.03 [0.36]	1.00	0.07 [0.84]	1.00	0.18 [2.16]	0.98	0.05 [0.60]

For the deeper understanding of the drying behavior of foodstuffs in terms of heat and mass transfer, and the performance analysis of the applied drying devices, a spatial and temporal evaluation of moisture content development during the drying process is intrinsic. Thus, the spatial variation of reflectance spectra at different times of the drying process was used to visualize the development of moisture content throughout the drying process as well as the spatial difference of said moisture content (Fig. 2).

**Fig 2: Normalised moisture distribution for apple slices before (left), during (middle) and at the end of the drying process.**

Further studies using hyperspectral imaging on apples [11], meat [12] and potatoes [13, 14] show similarly promising results. A reduction of the wavelengths needed for detection of product features will allow for the transfer to simpler systems, e.g. colour or black and white cameras in combination with either selective lighting or band pass filters. This could then also be combined with full color detection described above, as well as physical feature detection, as described by Bantle et al. [5] if sequential feature detection is implemented. This method will in turn open new possibilities for deeper analysis of the drying process and consequently the integration of feature analysis into smart drying process control.

## 3.2 Near infrared spectroscopy study on carrots and apples

### 3.2.1 Regression models (carrots)

Poor results ( $R^2 < 0.70$ ) were obtained for the prediction of soluble solids content for the unblanched treatment. Conversely, regression models with good ( $R^2 \geq 0.80$ ), very good ( $R^2 \geq 0.90$ ) or excellent ( $R^2 \geq 0.95$ ) predictability were obtained to monitor changes in soluble solids content (only for blanched carrots),  $a_w$  (Fig. 3a), moisture content (Fig. 3b), total carotenoids content (Fig. 3c) and color changes (Fig. 3d) of carrot slices during drying, regardless of thermal treatment. Except for the calibration model for color changes, the coefficient of determination ( $R^2$ ) was higher than 0.90 for the parameters. Thus, for the test set validation with one quarter of the data (randomly selected) RMSEPs ranging from 0.03-0.04 for  $a_w$ , 0.03-0.04 for moisture content and 22.62-29.51 for total carotenoids content were obtained.

**Fig 3:** PLS regression plots of Y-measured (reference) and Y-predicted (NIR) values for water activity (column a), moisture (column b), total carotenoids content (column c) and colour changes (column d) monitored during 8-h drying in both unblanched (row 1) and blanched (row 2) carrots.

PLS regression plots refer to models based obtained from the full spectrum.

### 3.2.2 Regression models (apples)

PLS regression models with good or excellent predictability were obtained to monitor changes in  $a_w$  (Fig. 4a), moisture content (Fig. 4b), chroma (Fig. 4c) and SSC (Fig. 4d) of apples wedges during drying, regardless of type of thermal treatment. Except for the calibration model for chroma, the coefficient of determination ( $R^2$ ) was higher than 0.96 for all the aforementioned quality parameters. Thus, for the test set validation with one quarter of the data (randomly selected) RMSEPs ranging from 0.03-0.04 for  $a_w$ , 0.04-0.05 for moisture content and 4.54-4.99 for SSC were obtained. The latter performance parameter was comparable with both calibration and cross-validation results.

**Fig 4:** PLS regression plots of Y-measured (reference) and Y-predicted (NIR) values for water activity (column a), moisture (column b), chroma (column c) soluble solids content (column d) monitored during 8-h drying in both control (row 1) and microwave (row 2) treated apples. PLS regression plots refer to models based obtained from the full spectrum.

## 4 Conclusions

In this study, the potential of single-point NIR spectroscopy, Vis/NIR hyperspectral imaging and RGB imaging was evaluated to proactively and non-destructively detect and monitor changes in quality parameters (i.e. water activity, moisture content, total carotenoids content, colours and SSC) of both apples and carrots. For this purpose, regression and classification models were successfully developed obtaining either very good or excellent results in terms of R<sup>2</sup> and RMSE. These promising results encourage additional research to develop low-cost dynamic multi factorial process control strategies (based on a Quality by Design approach) using machine learning architectures to produce quality dried products while reducing the environmental impact of the drying processes. Future research should include features not covered by the instrumentation used for this study, increasing the light-beam intensity, and/or combining other chemometric methods, as these could improve the performance of the measurement systems and, thus, the robustness of the smart-drying system under development.

### **Abstract**

*A mathematical model that simulates atmospheric freeze-drying for apple slices was developed based on the classical mass and heat balance equations. When operated above the glass transition temperature, product shrinkage and micro-collapse due to the glass-rubber transition occurred. So, instead of assuming formation of dried and frozen zones, a glassy matrix with particular vapor pressure was assumed. Apparent vapor pressure of apple slices in the glassy state was experimentally measured and summarized in a diagram, and the values in this diagram were employed for the simulation. This approach well predicted drying kinetics with reasonable accuracy with simplified equations.*

**Keywords:** *atmospheric freeze-drying; food; mathematical model; glassy state*

## 1. Introduction

Freeze-drying is known as one of the best drying methods in terms of preservation of product qualities. Vacuum freeze-drying (VFD) process is widely implemented in food and pharmaceutical industries, and variations of products are commercialized. Atmospheric freeze-drying (AFD) is basically equivalent to vacuum freeze-drying, where the ice sublimation is the major dehydration mechanism. The water vapor pressure difference between the frozen zone and the ambient gas is the driving force of the mass transfer. In order to operate drying at below sub-zero temperature, the air humidity must be low at appropriate level. A heat-pump system is commonly used to make low humidity air. The condenser temperature of the heat-pump unit is necessarily set lower than the product temperature during drying, and the dehumidified air must properly be heated up to realize appropriate drying rate. Numbers of studies on AFD process were motivated to optimize this heat-pump drying system in terms of the energy consumption and drying rate.<sup>[1-4]</sup>

Drying temperature (air temperature) applied for AFD is usually at around  $-10$  to  $0^{\circ}\text{C}$ . So, the product temperature during drying, that could be several degrees lower than the drying temperature depending on the drying rate, is much higher than the case of VFD. When drying agricultural products, a typical AFD run places the products above their glass transition temperatures ( $T_g$ ). For example, the  $T_g$  value of strawberry ranges from  $-33$  to  $-41^{\circ}\text{C}$ , that of apple is at around  $-42^{\circ}\text{C}$ , and peach at around  $-36^{\circ}\text{C}$ .<sup>[5]</sup> Considering that the drying rate is not rapid as the case of a hot air drying, product temperature could be several degree below the air temperature that is far above the glass transition temperature. At this temperature, the product deformation such as shrinkage and/or micro-collapse occur as a consequence of the glass-rubber/ glass-liquid transitions. In such cases, the dried cake layer, that commonly forms during a typical freeze-drying run, does not clearly separate from the frozen zone. In order to simulate this drying system, it is necessary to develop a model that is different from commonly employed two zone models consisted with frozen and dry zones.

In this study, mathematical model that simulates atmospheric freeze-drying for apple slices was developed. This study was targeted for an atmospheric freeze-drying process operated far over the glass transition temperature of the products, where we must admit the product deformation such as shrinkage and micro-collapse due to glass-rubber transition.

## 2. Mathematical Model

A product placed in the atmospheric freeze-dryer is dried by convective air. A product (i.e. a slice of apple) has porous structures derived from cellular microstructures. The external and some parts of the inner pore surfaces contact to the external air flow. Whereas, the other parts of the surfaces contribute to the convection with the internal air flow (Fig. 1). The surface that contributes to the internal convection is written with the total product surface, namely:

$$A_{in} = \gamma A_{total} \quad (1)$$

Here,  $\gamma$  is the coefficient that gives the surface that is not influenced by the convective air. The surface that effectively contributes to the external convection can be written as:

$$A_{eff} = (1 - \gamma)A_{total} \quad (2)$$

The mass transfer equation of the vaporized water vapor can be written with the mass transfer coefficients of the external and internal boundary layers, namely:

$$\frac{dm}{dt} = \frac{P_i/T_i - P_{air}/T_{air}}{1/(1-\gamma)A_{total}k_{gex} + 1/\gamma A_{total}k_{gin}} \frac{M}{R} \quad (3)$$

The heat transfer equation can be written with the heat transfer coefficients of the external and internal boundary layers:

$$Q = \frac{T_i - T_{air}}{1/(1-\gamma)A_{total}h_{ex} + 1/\gamma A_{total}h_{in}} \quad (4)$$

Assuming that the system is at a quasi-steady state, the heat flow is balanced with the mass flow.

$$Q/\Delta H = \frac{dm}{dt} = \frac{P_i/T_i - P_{air}/T_{air}}{1/(1-\gamma)A_{total}k_{gex} + 1/\gamma A_{total}k_{gin}} \frac{M}{R} = \frac{T_i - T_{air}}{1/(1-\gamma)A_{total}h_{ex} + 1/\gamma A_{total}h_{in}} \frac{1}{\Delta H} \quad (5)$$

The solution of this equation provides the value of  $T_i$ . The calculation was performed with spreadsheet software (Microsoft Excel®) by non-linear regression using solver add-in. It should be noted that the water vapor pressure  $P_i$  at the temperature  $T_i$  was given as a function of the moisture content of product as the detail explained in the later section.

Fig. 1 Schematic illustration of AFD model.

### 3. Materials and Methods

#### 3.1. Atmospheric freeze-drying

The atmospheric freeze-dryer that composed with a condenser and heating devise was set-up as schematized in Fig. 2. The condenser temperature was set at around  $-30^{\circ}\text{C}$ , and the out-gas temperature could be controlled by the heating devise in the range of  $-20$  to  $5^{\circ}\text{C}$ . The air flow rate in the drying room was controlled by an electric fan in the range of 0.1 to 0.5 m/s. Four slices of apple ( $15\times 15\times 5$  mm) were set in a plastic tray and suspended from a load-cell (A&D, Japan). The weight loss during drying was monitored with the load-cell. Apple slices were first frozen with the convective air at  $-30^{\circ}\text{C}$ , and then the air temperature was increased at a selected heating rate from  $-10$  to  $5^{\circ}\text{C}$  and the weight loss was recorded with data logging system.

Fig. 2 Drying apparatus.

#### 3.2. Ice sublimation test

The ice sublimation test was conducted in order to determine mass and heat transfer coefficients. Distilled water was filled in a plastic tray and frozen in the devise. Weight losses were monitored at selected temperature and air velocity settings. The temperature of the sublimating ice ( $T_p$ ) and the sublimation rate ( $dm/dt$ ) were collected with the selected operating conditions. The obtained values were applied to Equation 5 to estimate  $k_{\text{ges}}$  and  $h_{\text{ex}}$  values by applying  $A_{\text{in}}=0$ ,  $A_{\text{ex}}=A_{\text{total}}$ .

#### 3.3. Measurement of apparent water vapor pressure of apple slice

The use of apparent water vapor pressure as a function of the temperature and moisture content was a key part of this study. The relationship among these parameters were determined by the pressure rise test with a specially designed experimental set as illustrated

in Fig. 3. An apple slice was first vacuum freeze-dried, and then placed in a desiccator with a solution saturated with various salts ( $\text{LiCl}$ ,  $\text{MgCl}_2$ ,  $\text{KNO}_3$  and  $\text{Mg}(\text{NO}_3)_2$ ) in order to humidify the dried product. The moisture content of the humidified sample was measured by a moisture meter (A&D, Japan), and the other portion was set in the sample room and the measurement device was immersed in a cooling bath of which temperature was set at a selected temperature in the range of  $-30$  to  $0^\circ\text{C}$ . The external room that was separated with a bellows valves was first evacuated with a rotary type vacuum pump. After stabilizing the temperature and pressure, the bellows valve was rapidly opened for 2–3 seconds and immediately closed. The pressure rise due to the vaporization was monitored for 1 hour with a pirani gauge that was set in the sample room.

*Fig. 3 Pressure rise measurement set-up.*

## 4. Results and Discussions

### 4.1. Apparent water vapor pressure of apple slices

Some selected results of the pressure rise test were shown in Fig. 4. One can clearly see that the pressure rose just after opening the bellows and stabilized at a certain pressure level. Fig. 4A shows the dependency of the vapor pressure on the temperature; the pressure, as expected, was higher at higher temperature. However, the absolute values of the pressure were significantly lower than the equilibrium vapor pressure value of pure water. It means that several hours was not enough for the system to reach at an equilibrium state. Fig. 4B suggested that the time required for reaching at an equilibrium state was greatly affected by the moisture content of the apple slice; the apparent vapor pressure was higher for the sample with higher moisture content. The effective vapor pressure that a product shows during drying could be the pressure that was measured by the pressure rise test. We thus employed the value of the pressure from the pressure rise test at the point of 1 hour, and the values were plotted as a function of temperature and solid content (converted from the moisture content value). As summarized in a diagram in Fig. 5, this is a key characteristic of the present apple that is distinguished from the other products showing different drying kinetics. The solid line in the diagram correspond to the glass transition line; the closer the glass transition line, the apparent vapor pressure significantly decreases.

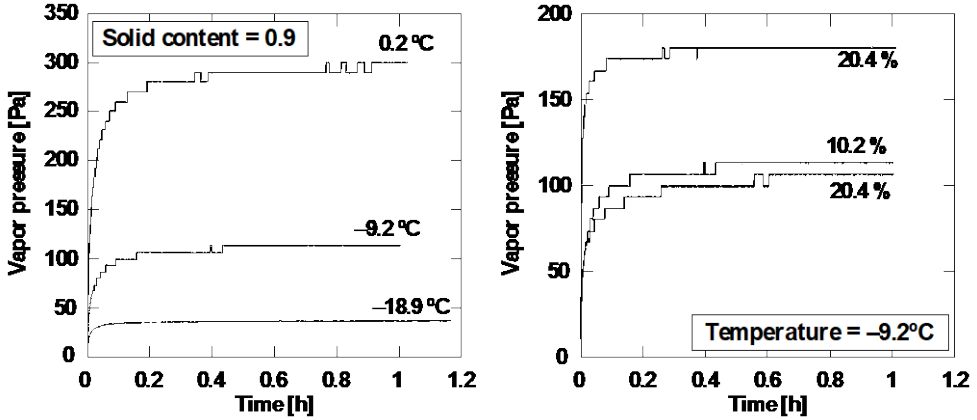

Fig. 4 Pressure rise of apple slice under sub-zero temperature.

Fig. 5 Apparent water vapor pressure contour lines as a function of temperature and solid content.

### 4.2. Freeze-drying run

A result of the atmospheric freeze-drying run is shown in Fig. 6. The air flow temperature was operated as shown in this figure by the present drying apparatus, and the consequence of the weight loss was plotted in the same figure. Air temperature was programmed to increase as the progress of drying in order to reduce total drying time. A simulation was carried out based on the mathematical model by applying the experimentally obtained air flow temperature. The water vapor pressure value, that is dependent on the temperature and

moisture content, was estimated from the surface plots shown in Fig. 5 by applying a simulated product temperature and moisture content values. The parameters applied for the simulation were listed in Table 1. The simulated drying curve is compared in Fig. 6 with the experimental curve. It was obvious that the simulation well predicts the experimental drying kinetics. The present simulation is based on a mechanistic mathematical model, so it simultaneously gives the other important values such as product temperature, mass and heat flow rates, etc. The simulated product temperature during drying plotted in Fig. 6 suggested that the drying progressed far above the glass transition temperature of apple, so some phenomena that may occur in a rubbery system (e.g. shrinkage, micro-collapse) are not avoidable in this drying system. The simulation could thus be more accurate by introducing a variable drying surface area instead of mean total surface area ( $A_{total}$ ) and mass transfer coefficient values ( $k_{gin}$ ). The air temperature was well programmed to realize the driving force for heat transfer until the final stage of the drying. This simulation approach would be useful to design favorable drying protocol.

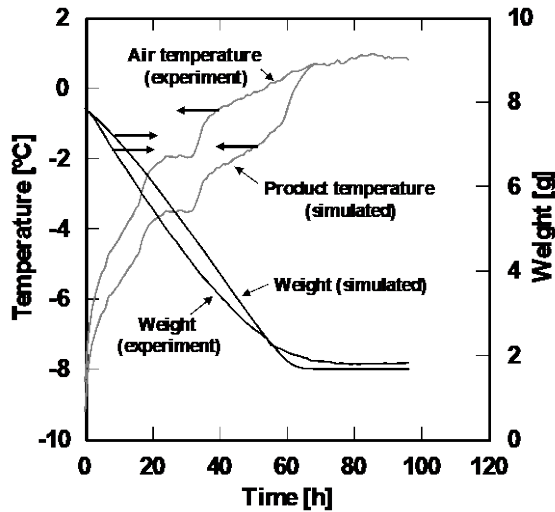

Fig. 6 Drying curves; comparison between experimental and simulated curves

Table 1. Parameters for simulation

Parameter	Value	Parameter	Value
$A_{total}$ [m <sup>2</sup> ]	$9.7 \times 10^{-2}$	$h_{gex}$ [Wm <sup>-2</sup> K <sup>-1</sup> ]	49.2
$\gamma$ [-]	0.99	$h_{gin}$ [Wm <sup>-2</sup> K <sup>-1</sup> ]	13.7
$k_{gex}$ [ms <sup>-1</sup> ]	$1.01 \times 10^{-2}$	$P_{air}$ [Pa]	104.9
$k_{gin}$ [ms <sup>-1</sup> ]	$1.47 \times 10^{-2}$	$R$ [J mol <sup>-1</sup> K <sup>-1</sup> ]	8.314
$\Delta H$ [J kg <sup>-1</sup> ]	$2.4 \times 10^6$	$T_{air}$ [K]	253
$M$ [kg mol <sup>-1</sup> ]	$1.8 \times 10^{-2}$		

## 5. Conclusions

A mathematical model that simulates atmospheric freeze-drying for sliced fruits was developed and applied to apple slice drying. Apparent vapor pressure of the apple slice was measured by the pressure rise test and the obtained values were summarized in a diagram. The pressure values were dependent on the temperature and moisture content; the closer the glass transition line, the apparent vapor pressure significantly decrease. Simulations carried out with this diagram well predict drying kinetics with reasonable accuracy with simplified equations.

## 6. Nomenclature

$A_{\text{total}}$	total surface area	$\text{m}^2$
$\gamma$ [-]	inner surface ratio	-
$k_{\text{gex}}$	mass transfer coefficient	$\text{ms}^{-1}$
$k_{\text{gin}}$	mass transfer coefficient	$\text{ms}^{-1}$
$\Delta H$	latent heat of vaporization	$\text{J kg}^{-1}$
$h_{\text{gex}}$	heat transfer coefficient	$\text{Wm}^{-2}\text{K}^{-1}$
$h_{\text{gin}}$	heat transfer coefficient	$\text{Wm}^{-2}\text{K}^{-1}$
$M$	molar mass of water	$\text{kg mol}^{-1}$
$m$	mass of product	$\text{kg}$
$P_{\text{air}}$	water vapor pressure in the air flow	$\text{Pa}$
$P_i$	water vapor pressure at the drying interface	$\text{Pa}$
$Q$	heat flow	$\text{J s}^{-1}$
$R$	ideal gas constant	$\text{J mol}^{-1}\text{K}^{-1}$
$T_{\text{air}}$	temperature of the air flow	$\text{K}$
$T_i$	temperature at the drying interface	$\text{K}$
$t$	time	$\text{s}$

### **Abstract**

*Food dehydration is one of a main process to preserve meal. In order to optimize a freeze-drying operation a physic model is needed to well describe the thermodynamic behaviors involved in this process. In this work, a thermographic camera and different physico-chemical determinations are used to monitor many phenomena that occur during the lyophilization of poultry breast. Finally, a non-continuous irreversible thermodynamic model, based on thermal infrared measures and in shrinkage/swelling mechanism, has been developed, wich explains the behaviours produced throughout the meat freeze-drying process.*

**Keywords:** *freeze-drying, thermodynamic model, infrared thermography, poultry.*

---

## 1. Introduction

Lyophilization is a drying process that consists in sublimate ice into vapour, producing water desorption, and one possibility can be to bring the product below the triple point (273.16 K and 611.73 Pa) of the water state diagram. This process gets very low water activities and does not heat the product, which is an advantage when thermolabile compounds are present<sup>[1,2,3]</sup>. Once the product has frozen below its eutectic point and generated vacuum, the product begins the elimination of water in two consecutive phases: sublimation and evaporation. When the frozen product reaches the vapor pressure, the freezing water fraction of the product is sublimated starting from the surface, creating a sublimation front that advances towards the center. With the advance of the front, there is a zone that has sublimated the freezing water, but still has water adsorbed as liquid phase<sup>[4,5]</sup>. The steam, coming from the front, causes a mechanical drag of the adsorbed water, which removes it and causes its desorption by evaporation.

Considering the importance of dehydration processes to conserve food, it is necessary to study them closely. For this, the process can be modeled with equations such as the Gibbs free energy, which can describe the thermodynamic behavior of the food throughout the process. These equations have been used previously in orange peel<sup>[6]</sup> and pork meat<sup>[7]</sup>. The water transport is also modeled in pork meat<sup>[8]</sup> and tomato<sup>[9]</sup>. Also, another freeze-dried product has been modeled like Strawberries<sup>[10]</sup> or black currant juice<sup>[11]</sup> as well as generic mathematical models<sup>[12]</sup>.

Infrared thermography is a technique that allows to predict the temperature along a surface by receiving the flow of photons emitted by a body. Therefore, the possibility of monitoring the process with this technology gives us the ability to develop kinetic models of drying, thanks to the possibility of follow the temperature distribution over a surface, over a period of time<sup>[13]</sup>.

The aim of this research is the development of a thermodynamic model of freeze-drying process of poultry meat using infrared thermography.

## 2. Materials and Methods

### 2.1. Experimental procedure

For the experimental phase, poultry breast samples (*Pectoralis major*) were used. Cylinders of 2 cm in diameter and 2 cm in height were obtained by a punch. The cutting of the cylinders was perpendicular to the fibers. Two cylinders were used for each lyophilization and this operation was carried out in triplicate. The samples were frozen at -40 °C and introduced into the dry chamber of the lyophilizer, at a distance of 1.5 cm between them. During the

lyophilization, the temperature of the surface in one of the two chicken cylinders, as well as the reference material and the environment was controlled by type K thermocouples. In addition, the thermographic camera was introduced inside the lyophilizer for a continuous recording of the process.

In order to characterize the samples, these determinations were made before and after the lyophilization: mass, water activity, humidity and volume. In addition, the density of frozen and lyophilized product was determined.

## **2.2. Physico-chemical measurements**

The mass of the samples was determined with a Mettler Toledo AB304-S balance, with an accuracy of  $\pm 0.001$  g. The humidity of the sample was obtained following the ISO 1442 (1997) standard for meat products, drying the samples at 110 °C and atmospheric pressure for 48 hours until reach a constant mass. The water activity was determined with a dew point hygrometer Aqualab®, series 3 TE, with an accuracy of  $\pm 0.003$ . The volume was determined by image analysis, using Adobe © Photoshop © CS6 software. The density of frozen and lyophilized sample was determined by the pycnometer method. All measurements were made in triplicate.

## **2.3. Freeze drying operation**

The thermographic camera was placed at 15 cm from the samples, with an angle of 0° and focusing the flat surface of the cylindrical samples. A reference material of known emissivity ( $\epsilon = 0.95$ ) (Optris GmbH, Berlin, Germany) was placed between both samples.

The control of the temperature during the lyophilization, the inside, the reference material and the sample, was carried out with three K-type thermocouples, all of them connected to an Agilent 34901A multiplexer (Agilent Technologies, Malaysia); for the automatic recording of the measurements, the Agilent data acquisition equipment 34972A (Agilent Technologies, Malaysia) was used. The internal pressure control was carried out with the lyophilizer's own pressure sensor.

The lyophilizer used for the experimental was the Lioalfa-6 from Telstar, Germany. With a working pressure of 35 to 50 Pa and a cooling circuit at -45 °C. All the cables and sensors necessary for the data collection were introduced in the dry chamber replacing the original stopper of the lyophilizer with one of rubber, and filled in with silicone to achieve the necessary vacuum.

## **2.4. Medida de infrarrojos**

The thermal images were acquired using the Optris PI 160 thermographic camera (Optris GmbH, Berlin, Germany). It uses a two-dimensional focal plane array with 160x120 pixels, a spectral range of 7.5 to 13  $\mu\text{m}$ , a resolution of 0.05 °C and an accuracy of  $\pm 2\%$ . The camera

covers a temperature range of -20 to 900 °C. It has a field of vision of 23°x17° with a minimum distance of 2 cm. The camera uses Optris PI Connect software (Optris GmbH, Berlin, Germany).

### 3. Results and discussion

The temperature values obtained from the thermographic camera are not real, therefore, the correction developed by Traffano-Schiffo et al., 2014<sup>[7]</sup> was applied.

When the sublimation front advances, it alters the composition of the sample. The areas that have already been sublimated reduce their heat transmission because a loss of water, which causes a change in trend in the evolution of temperature with respect to time. Figure 1 shows this change in trend. So, the sublimation temperature and the process time can be extracted for each point of the sample's profile.

*Fig. 1 Evolution of the temperature for different points of the profile over time.*

With the sublimation temperature it is possible to calculate the water activity ( $a_w$ ) using the Fontan and Chirife equation (1981) (Eq. 1).

$$-\ln(a_w) = 9.6934 \cdot 10^{-3} \cdot \Delta T_f + 4.761 \cdot 10^{-6} \cdot \Delta T_f^2 \quad (1)$$

Where:  $\Delta T_f$  = difference between the initial freezing temperature and the the sample (K).

From this  $a_w$  and the poultry sorption isotherm at low temperatures, it is possible to obtain the non-freezeable water fraction ( $x_w^{NF}$ ) of the product at the sublimation time. The isotherm parameters modeled by GAB are  $x_{w0} = 11.009 - 0.4589T + 0.0116T^2$ ;  $C = -3423.2 + 1144T - 77.248T^2 + 1.4357T^3$ ;  $K = 0.9419 - 0.0034T + 0.0006T^2 - 0.00001T^3$ . Subtracting to the overall water fraction, the non-freezeable water, it is possible to obtain the ice fraction.

Once the lyophilization process has begun, sample can be divided in two volumetric areas: the sublimated zone (partially dehydrated) and frozen zone, separated by the sublimation front (Fig. 2). When the frozen water sublimates, appears a vapour flux from the sublimation front to the surface, crossing the sublimated zone and evaporating a part of adsorbed water by mechanical dragging. Mass of each zone throughout the process has been estimated using the volume difference between cylinders and the density of freeze-dried and frozen product.

**Fig. 2** Diagram of the different zones and phenomena. ■ Sublimated area; ■ Sublimation front; ■ Frozen zone. The limits of the system are highlighted in red, enlarged to the right with the molar and energy balances.

In order to obtain the different mechanism involved in the freeze-dry process, it is necessary to estimate the water flux, using a molar water balance in the sublimated zone (Eq. 2).

$$J_v^T \cdot S_{ext} = J_v^{sub} \cdot S_{sub} + \frac{\partial M_w^{des}}{\partial t \cdot M_{rw}} \quad (2)$$

When the vapor flux comes from the sublimation can be calculated as follows (Eq. 3):

$$J_v^{sub} = \frac{x_w^f \cdot \rho_{wf} \cdot \Delta r}{\Delta t \cdot M_{rw}} \quad (3)$$

Where:  $J_v^T$  = overall vapour flux leaving the system ( $\text{mol} \cdot \text{s}^{-1} \cdot \text{m}^{-2}$ );  $S_{ext}$  = external surface of the cylinder ( $\text{m}^2$ );  $J_v^{sub}$  = sublimated vapour flux ( $\text{mol} \cdot \text{s}^{-1} \cdot \text{m}^{-2}$ );  $S_{sub}$  = surface of the sublimation front ( $\text{m}^2$ );  $M_w^{des}$  = evaporated water mass (kg);  $t$  = process time (s);  $x_w^f$  = frozen water mass fraction ( $\text{kg} \cdot \text{kg}^{-1}$ );  $\rho_{wf}$  = density of frozen water ( $\text{kg} \cdot \text{m}^{-3}$ );  $M_{rw}$  = Molecular water mass ( $18 \text{ g} \cdot \text{mol}^{-1}$ ). The last term of mass balance represents the negative accumulation of adsorbed water molecules induced by mechanical drag of these molecules by the strong vapour streams produced in the sublimation front.

In order to continue determine the mechanism of water dehydration, the equation 4 that describes the free energy variation was applied<sup>[14]</sup>.

$$dG = -SdT + VdP + Fdl + \psi de + \sum_i \mu_i dn_i \quad (4)$$

Where:  $SdT$  = entropic term related to heat flux;  $VdP$  = mechanical energies related to the variation of pressure;  $Fdl$  = mechanical energies related to the elongation force (resistance of the tissue to expand);  $\psi de$  = effect of the electric field induced by ions;  $\sum_i \mu_i dn_i$  = sumatory of the chemical potentials of the species "i", with the rest of the variables state are constant.

When the variation of free energy is represented per mole of water, the extended water chemical potential is obtained (Eq. 5).

$$\Delta\mu_w = \frac{\Delta G}{\Delta n_w} \quad (5)$$

Where:  $\Delta\mu_w$  = water chemical potential ( $J \cdot mol^{-1}$ );  $\Delta G$  = Gibbs free energy variation (J);  $\Delta n_w$  = water moles (mol).

Combining the equations 4 and 5, the equation 6 is obtained, which describes the water chemical potential in the system described in figure 2 (sublimated zone) . In this equation, the last term is not included, because the desorption caused by the difference between water activities in the sample is negligible compared with the entropic term and those of mechanical energies. Moreover,  $\psi de$  term also is negligible since the sample only presents native ions.

$$\Delta\mu_w^{des} = s_w \Delta T + v_w \Delta P + F_w dl \quad (6)$$

Where:  $s_w$  = partial water molar entropy ( $J \cdot K^{-1} \cdot mol^{-1}$ );  $\Delta T$  = gradient of temperature between surface and sublimation front (K);  $v_w$  = partial water molar volume ( $m^3 \cdot mol^{-1}$ );  $\Delta P$  = pressure variation (Pa);  $F_w dl$  = elongation force (J). It is possible to estimate the entropic and the pressure term by using the sublimation temperature and its corresponded sublimation pressure obtained from Fig. 2.

Applying the Onsager relations<sup>[14]</sup>, the water molar flux is related to the water chemical potential, working as a driving force for water transport, through the phenomenological coefficient (Eq. 7).

$$J_w^T = L_w \cdot \Delta\mu_w \quad (7)$$

Where:  $J_w$  = water molar flux ( $mol \cdot s^{-1} \cdot m^{-2}$ );  $L_w$  = phenomenological coefficient ( $mol^2 \cdot J^{-1} \cdot s^{-1} \cdot m^{-2}$ );  $\Delta\mu_w$  = water chemical potential ( $J \cdot mol^{-1}$ ).

From the equation 7 it is possible to calculate the phenomenological coefficient after 200 min, where value remains constant because the sublimation front is reaching the center and the swelling resistance of the tissue is negligible ( $L_w = 1.14 \cdot 10^{-5} mol^2 J^{-1} s^{-1} m^{-2}$ ). Therefore, applying this value along the treatment it is possible to estimate the elongation term (Fig 3a). Using the expansion of the sublimated area, and estimating the ice space loosed in the sublimation it is possible to calculate the increment of the porosity ( $\Delta\epsilon$ ). Fig. 3b shows the relation between the elongation term and the increment of the porosity, where it is possible to observe that the swelling process of tissue is proportional to the reduction of the elongation

term, reducing the swelling resistance of the tissue reaching its maximum expansion in its minimum resistance.

Fig. 3a Elongation term vs process time; 3b Elongation term vs increment of the porosity.

#### 4. Conclusions

Has been developed a non-continuous irreversible thermodynamic model based in thermal infrared measures and in shrinkage/swelling mechanism that explains the behaviours produced throughout the meat freeze-drying process.

### **Abstract**

*This study models the internal fluid flow from the center to the edge of a rotary atomizer wheel, the flow out of the atomizer, including the film, rivulet and ligament formation, as well as the subsequent atomization process associated with the atomizer outflow using computational fluid dynamics with a volume of fluid approach.*

*The model shows how fluid exits through the overflow and not through the bushing at high inlet fluxes and can reproduce experimental results of power consumption. Furthermore, the drop-size distribution at a given distance from the bushing exit is in good agreement with experimental results.*

**Keywords:** *Spray drying; Rotary Atomizer; CFD; Droplet size; Volume of Fluid.*

## **1. Introduction**

Feed atomization is one of the most important process steps in spray drying. In the chemical industry, rotary atomizers are often used because they are flexible, can handle abrasive materials and operate at very large capacities. Although development of atomizer wheels is usually based on a trial and error approach current designs are very advanced. New tools, like tailored computer simulations, are therefore needed to design a new and significantly improved generation of atomization wheels. These wheels will reduce atomizer power consumption, suffer less wear and can operate at higher capacity while avoiding overflow as described below. All this while improving the droplet size distribution which is the most important output from the atomizer. The size distribution influences every downstream aspect of the powder production process, ranging from drying chamber depositions to cyclone and bag filter efficiency and further on to packing, and of course, final powder characteristics and properties [1,2].

The fluid flows into the rotary wheel nearly at the center, from here the fluid enters narrow channels or bushings. From the entrance into the bushings to the exit of the atomizer the fluid and the air is accelerated towards the exit due to the centrifugal force and is at the same subject to a substantial Coriolis force. In addition, there are internal forces within the fluids e.g., surface tension and viscous forces. The combination of these forces and the complex geometry makes understanding of the fluid flow within a rotary atomizer extremely difficult.

Computational Fluid Dynamics (CFD) as a numerical method for solving the equations of motion gives an opportunity to directly simulate the flow under various operating conditions and various geometries. This will be the focus of this paper and will be thoroughly elaborated in the next section. Previous studies where CFD is used to model various aspects of spray drying includes [3,4,5,6].

The results obtained from this study is then compared to existing in-house atomization experiments where the power usage and droplet size distribution are measured. Furthermore, it should be noted that this study is a continuation of previous studies [7,8,9,10]. Here information about the method used in the experiments, that are referred to in this study, can be found.

## **2. Materials and Methods**

Albeit, several different wheels have been modelled, and results will be presented accordingly. We will, in this paper, only present the CFD-model for one geometry. We will, however, present results for other geometries since these have been simulated in a similar way. The differences in geometry for the rotary atomizer wheels presented in this paper consists of different diameters of the rotary wheel, different number of bushings in the rotary wheel, as well as slight deviations in the geometry of the cavity of the wheel.

One of the wheels modelled consists of eight bushings equally distributed over the circumference of the wheel. Hence, symmetry considerations allow us to model a subdomain of the wheel, i.e.,  $\theta \in [-\pi/8; \pi/8]$  with a bushing at the center of the domain, i.e.,  $\theta=0$ , where  $\theta$  represents an angle (rad).

**Fig. 1** Illustration of the geometry of the simulated part of a wheel. Indicated by numbers and arrows are 1) inlet, 2) overflow, 3) cavity, 4) bushing 5) exit. Notice, how water enters through the inlet and exits through the overflow and the bushing.

In Fig. 1 the geometry of the modelled domain is shown. The modelled domain consists of the inlet, the wheels cavity of the wheel, the bushing, the ‘overflow area’ and the outside of the bushing, i.e., the drying chamber.

To give realistic flow distributions to the inlet, the flow in the liquid distributor prior to the inlet has, although not shown in this paper, been modelled for different feed rates. The solution to these prior investigations have been used as boundary conditions for the inlet flow.

Under normal operating conditions the fluid will move from the inlet through the cavity of the wheel, through the bushing and out into the drying chamber. Under abnormal operating conditions, i.e., very high values of the feed rate, part of the fluid will exit the wheel through the overflow. In the small part of the drying chamber included in this model, the breakup of the exiting jet and thin film annulus is modelled. Here the resulting drops are accounted for and the size distribution a size distribution is calculated.

All simulations presented in this study have been performed using ANSYS Fluent with a volume of fluid (VOF) approach.

## 2.1 Governing equations

The governing equations for fluid and the air are the Navier-Stokes equation and continuity equation of fluid and air where subscript  $j$  represents one of the fluid phases air (a) or water

(w) and  $\varepsilon_j$ , is the fraction of component j. Note that there are only two phases – hence,  $\varepsilon_a + \varepsilon_w = 1$ .

$$\frac{\partial}{\partial t}(\varepsilon_j \rho_j) + \nabla \cdot (\varepsilon_j \rho_j \mathbf{u}) = 0 \quad (1)$$

$$\frac{\partial}{\partial t}(\varepsilon_j \rho_j \mathbf{u}) + \nabla \cdot (\varepsilon_j \rho_j \mathbf{u} \mathbf{u}) = -\varepsilon_j \nabla p + \nabla \cdot (\varepsilon_j \boldsymbol{\tau}_j) + \varepsilon_j \rho_j \mathbf{g} + \mathbf{f}. \quad (2)$$

Here,  $\mathbf{u}$ , is the velocity field (m/s),  $\rho$ , is the density (kg/m<sup>3</sup>),  $\varepsilon_j$ , is the volume,  $p$  is the pressure (Pa) and  $\mathbf{g}$ , is the gravitational acceleration (m/s<sup>2</sup>) and  $\mathbf{f}$  (N/m<sup>3</sup>) represents forces per unit volume, not accounted for by the motion of the fluid, i.e., centrifugal force, surface tension and the Coriolis force. Here, the stress tensor,  $\boldsymbol{\tau}_j$ , is given by

$$\boldsymbol{\tau}_j = \mu_j \left( [\nabla \mathbf{u} + \nabla \mathbf{u}^T] - \frac{2}{3} (\nabla \cdot \mathbf{u}) \mathbf{I} \right), \quad (3)$$

where,  $\mu_j$ , is the viscosity (Pa·s) and  $\mathbf{I}$  represents the unit matrix. Note that the water is modelled as incompressible whereas the air is compressible. Turbulence is modelled with a RANS (k,  $\omega$ ) model.

## 2.2 Boundary conditions

### 2.2.1 Walls

On the walls we impose a no flux condition in direction of the normal vector and a no-slip condition in tangential direction. I.e., there is no transport of fluid through solid walls and the relative velocity between the fluid and a solid wall is zero.

### 2.2.2 Outlet

At the surface of the domain where the fluid exits into the drying chamber a zero gauge pressure boundary condition is imposed.

### 2.2.3 Periodic boundary conditions

At all boundaries normal in the direction of the rotation has a periodic boundary, i.e., what exits on one side enters on the other. Hence,

$$\alpha \left( r, -\frac{\theta}{8}, z \right) = \alpha \left( r, \frac{\theta}{8}, z \right). \quad (4)$$

Here  $\alpha$  represents conserved properties, i.e., velocity field,  $\mathbf{u}$ , the pressure,  $p$ , the volume of fluid fractions,  $\varepsilon_f$ , as well as the turbulence parameters  $k$  and  $\omega$ .

### 2.2.4 Inlet

As mentioned the velocity field at the inlet for different volumetric inlet fluxes,  $\dot{V}$  ( $\text{m}^3/\text{s}$ ) and different geometries,  $\Omega$ , has been determined in a previous study. The velocity field,  $\mathbf{v}$  ( $\text{m/s}$ ) at the inlet for different feed flows are used as a boundary condition at the inlet. Hence,

$$\mathbf{u}_i = \mathbf{v}_i(\dot{V}, \Omega). \quad (5)$$

### 2.3 Mesh

The mesh used is a swept mesh with the special ability of adapting size according to the gradient of volume of fluid, i.e., the mesh has small elements in the interface between fluid and air. This adaptive mesh ensures that the resolution of the air-water interface improved without compromising the simulation time. An illustration of the mesh and the size adaption is shown in Fig. 2.

*Fig. 2 Illustration of the mesh as well as how the mesh is refined depending on the VOF-gradient. The red part of the figure represents water and the blue is air.*

### 2.4 Drop size calculations

To estimate the drop size in the simulations, a virtual surface is included at a given distance from the bushing exit. The volume of fluid droplets that passes through this virtual surface is then directly related to the volume of a sphere and the radius is calculated accordingly. The observation of droplets passing through the virtual surface is collected for enough time to give a reasonable size distribution.

## 3. Results and discussions

As mentioned in the introduction the results from the CFD-simulations are compared to experimental results. Firstly, we shall relate the findings from the simulations to experimental power consumptions. Secondly, we shall relate the droplet size distribution from the simulations to experimental results.

### 3.1 Power consumption and wheel capacity

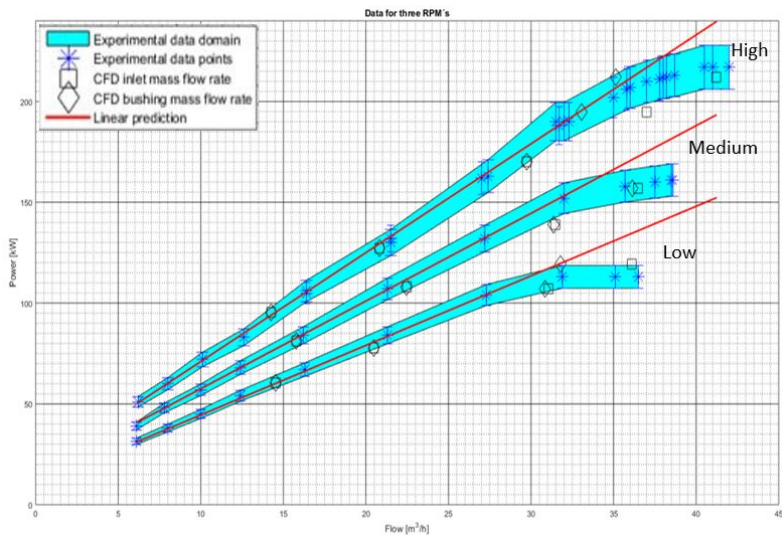

The equation governing the power consumption is given by,

$$P = \dot{m}_b(\omega R_b)^2 = (\dot{m}_f - \dot{m}_o)(\omega R_b)^2. \quad (6)$$

Here,  $P$  is the power (W),  $\dot{m}_b$  is the liquid mass-flux (kg/s) through the bushing,  $\omega$  is the angular velocity (rad/s),  $R_b$  (m) is the radius at the bushing exit,  $\dot{m}_f$  is the mass-flux of feed (kg/s) and,  $\dot{m}_o$  is the mass-flux of liquid through the overflow (kg/s). Hence, a linear dependency of power versus inlet flux is expected if no fluid passes through the overflow, i.e.,  $\dot{m}_o = 0$ . Furthermore, a larger power consumption is needed for larger angular velocities of the rotary atomizer. Trivially, the linear dependence between power and feed flow ceases to exist when fluid passes through the overflow – which will happen at a sufficiently high inlet-fluxes.

It is, however, not trivial that simulations from CFD and experiments performed on the wheels simulated are able to produce overflow for the same values of the influx.

The power distribution is a function of inlet flux, both experimental and from simulations, are presented in Fig. 3 for three different angular velocities. As seen there is a good agreement between experiment and simulations. For small values of the inlet flux there is a linear tendency between power consumption and inlet flux. Increasing the inlet flux even further causes a higher fraction of the fluid to pass through the ‘overflow’ inducing a larger deviation from the straight line.

**Fig. 3 Power consumption as a function of feed-rate for CFD simulations and experimental data for three different RPM – increasing from bottom to top.**

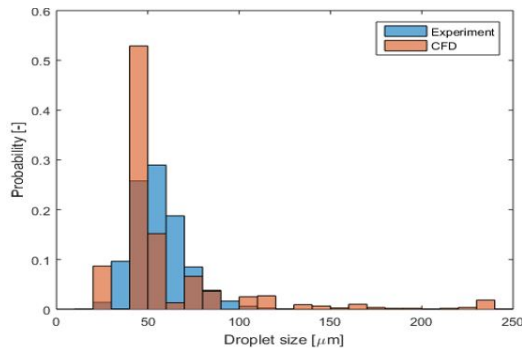

It can also be seen from Fig. 3 that the critical inlet flux is increasing for increasing angular velocity of the wheel. This is expected due to the larger acceleration of the fluid in radial direction due to an increase in centrifugal force. As seen from the figure there is an excellent agreement between the CFD simulations and experiments made on the wheel simulated at

corresponding angular velocities. In figure Fig. 1 it is illustrated how fluid passes through the overflow during simulations.

### 3.2 Prediction of atomization and droplet size distribution

Experimental results of the drop-size distribution as well as measured drop-size distribution from the simulations are shown in Fig. 4. As seen there is a good qualitative agreement between the two. The droplet-size depends among other things on the exiting jet from the bushing. The exiting jet and breakup from a simulation and experiment are shown in Fig. 5.

**Fig. 4 Droplet size distribution from CFD simulations and experimental results measured at 110 mm from the bushing exit at an angular velocity of 29000 RPM.**

**Fig. 5 Snapshot from the CFD-simulations (left) and experiment (right) of the breakup of the thin film and exiting jet into droplets.**

The ability to reproduce experimental results serves as a validation of the model. This validation is a first step for future research, where extraction of valuable information, e.g., total wall shear stress, mixing, rivulet height, film thickness for different fluids and different operating conditions. This in return allows for topology optimization, power consumption and essentially optimized conditions for drying and end-product.

The inclusion of CFD in our production line allow us to design new geometries for rotary wheels, and operate them at optimal feed rates and angular velocities in terms of power

consumption. Furthermore, the ability to estimate the droplet size distribution for any given fluid makes it possible to give optimal conditions for the final product. Hence, enables us to produce tailor made solutions for a given product and increasing value for industry.

#### **4. Conclusions**

The CFD model presented in this study gives valuable insight in the fluid flow and interaction between fluid and air in a rotary atomizer. The model can reproduce experimental results for power consumption and droplet size-distribution.

### Abstract

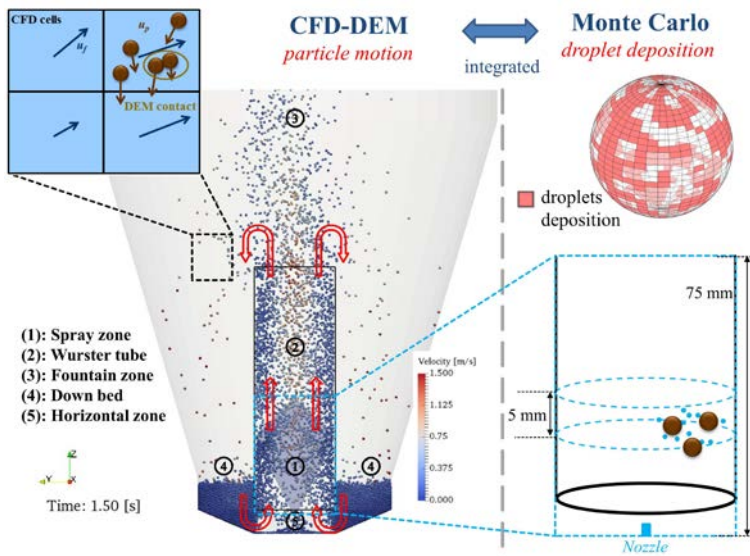

*CFD-DEM approach is applied to investigate circulation motion of particles in a mono-disperse system under both dry and wetting conditions. Good agreement between simulation results and measurement data is observed, in terms of cycle time and residence time in dry condition. The deposition of droplets on the particle surface is modeled by a Monte Carlo approach. The influence of cohesion forces on the macroscopic particle circulation is discussed. In addition, information about coating coverage, the layer thickness and particle size distribution can be predicted by this integrating approach.*

**Keywords:** *CFD-DEM; Wurster coater; Monte Carlo; cohesion force; residence time.*

---

## 1. Introduction

Particle coating is widely applied in pharmaceutical, food and fertilizer industry. The Wurster coater can be used as a batch or a continuous fluidized bed to precisely control the quality of the coated product [1]. The entire coating process is considerably complex, caused by a large number of sub-processes, including wetting, drying and film formation; and by the presence of different zones with different controlling parameters (such as gas velocity, gas temperature, and spray rate), as shown in Fig. 1. The enhanced understanding of particle dynamics in different zones is significant to optimize drying kinetics that governs particle formation in coating.

**Fig. 1** Modeling of particle behavior by CFD-DEM for particle motion integrating Monte Carlo for droplet deposition (The Wurster coater is divided into 5 process zones; and the droplet deposition takes place in the region marked by the light blue rectangle).

The circulation motion of particles under dry conditions has been investigated in experiments and simulations [2, 3]. However, published studies of the influence of cohesion forces existing in spray zone on the circulation motion are very limited. In this study, computational fluid dynamics-discrete element method (CFD-DEM) was used to investigate the particle motion in the Wurster coater, under both dry and wetting conditions. The influence of cohesion forces, relating to wetting properties and process parameters, on the residence time and the cycle time are discussed based on the analysis of all individual particle trajectories. For the prediction of particle size, a two-zone population balance modeling is usually used to predict the growth of particles during the coating process. In this work, the event of droplet deposition modeled by a Monte Carlo approach [4] was integrated with the particle motion predicted by the CFD-DEM approach, which creates a relatively cost-effective multiscale

numerical method to predict particle size distribution and coating coverage during the coating process. The effect of cohesion forces in the Wurster tube on particle size distributions for different process times is discussed.

## 2. Methodology

### 2.1 CFD-DEM approach

The CFD-DEM approach has been widely applied to investigate the complex granular flow in chemical applications. The CFD-DEM approach can capture the macroscopic particle dynamics in the multiphase flow, simultaneously providing an insight into behavior of individual particle scale including particle-particle interactions, as shown in Fig. 1. The open source code OpenFoam+LiGGGHTS (CFDEM@project) was used for this study. The detailed governing equations of solid and gas phase, Gidaspow drag model, Hertz soft sphere contact model and rolling model can be found in our previous works [3, 5].

Fig. 2 Flow chart of the Monte Carlo integrated with CFD-DEM including required random numbers ( $N_{p,m}$  is the number of particles in the Monte Carlo domain).

### 2.2 Cohesion model

The capillary force and viscosity force have been implemented into the DEM code [6]. The equation for calculating the capillary force  $F_c$  (N) of a specific particle-pair geometry was obtained by fitting the set of discrete solutions of the Laplace equation, expressed as:

$$F_c = \pi\sigma\sqrt{R_i R_j} \left[ C + \exp\left( A \frac{d_{inter}}{\max(R_i, R_j)} + B \right) \right], \quad (1)$$

where  $R_i$  and  $R_j$  are radii of two particles (m),  $d_{inter}$  is the inter-particle distance (m), and  $\sigma$  is the surface tension of liquid (N/m). The coefficients  $A$ ,  $B$  and  $C$  are functions of liquid volume  $V_l$  (m<sup>3</sup>), contact angle  $\theta$  (radians) and larger particle radius  $R_{max} = \max(R_i, R_j)$  [6]. The liquid volume between two particles is assumed to be evenly distributed when the inter-particle distance is larger than the rupture distance  $D_r = (1 + 0.5\theta) \cdot V_l^{1/3}$  (m).

The viscosity force  $F_v$  (N) can be calculated as:

$$F_{v,n} = 6\pi\mu R^* v_n \frac{R^*}{d_{inter}}, \quad F_{v,t} = 6\pi\mu R^* v_t \left[ \frac{8}{15} \ln \frac{R^*}{d_{inter}} + 0.9588 \right], \quad (2)$$

where  $\mu$  is the fluid dynamic viscosity (Pa·s),  $R^* = R_i R_j / (R_i + R_j)$  is the equivalent radius; and  $v_n$  and  $v_t$  are relative velocity of two particles in normal and tangential directions (m/s), respectively. The capillary force and viscosity force are included into Newton's law of motion for individual particle. Note that these two forces only exist in the Wurster tube and wall boundaries are assumed in dry condition.

### 2.3 Monte Carlo approach

According to the geometry of spray zone, the simulation domain for Monte Carlo is the cylinder with the height of 75 mm and the radius of the Wurster tube, and the bottom of the domain is aligned with the tip of the spray nozzle, as shown in Fig. 1. The particles in the Monte Carlo domain were determined by the CFD-DEM data. The overview of the Monte Carlo integrated with CFD-DEM is given in Fig. 2. In each Monte Carlo time step  $\Delta t_m$ , one droplet deposition event is guaranteed to happen in the Monte Carlo domain. The time step can be calculated from the number flow rate of droplets injecting into the system, expressed as:

$$\Delta t_m = -\left(\frac{6\dot{M}}{\pi\rho_a d_a^3}\right)^{-1} \ln r_1, \quad (3)$$

where  $\dot{M}$  is the mass flow rate of solution and  $r_1$  is a uniformly distributed random number for the interval (0,1). The droplet diameter is constant. Once the total Monte Carlo process time  $t_m$  exceeds 0.01 s, CFD-DEM simulation was advanced for 0.01 s and number of particles in the Monte Carlo domain  $N_{p,m}$  was updated based on new CFD-DEM data.

To evaluate the individual droplet deposition, two more random numbers are required:  $r_2$  to pick up the particle from the domain and  $r_3$  to choose deposition position on the single particle surface. In current work, each particle in the domain has the same possibility to receive the droplets. Based on the work of Rieck et al. [4], the number of positions (with same size) per particle  $N_{pos}$  is calculated by  $N_{pos} = d_p^2 / d_{contact}^2$ . The diameter  $d_{contact}$  is the diameter of contact area, which depends on the contact angle and droplet volume.  $N_{pos}$  was rounded to an integer value in the code. Each position can have four statuses labeled by four numbers in the model: 1) no droplet (initial), 2) with wetting droplet, 3) with dry droplet and 4) no droplet (new). In cases of label 1, 3 and 4, the droplet deposition event can occur. If a wetted position (2) is selected, a new random number  $r_3$  is generated until the requirement of deposition is satisfied.

The criterion for determining dry or wet position is related to the drying process of the deposited droplet, expressed as:

**Table 1. Summary of the setup for CFD-DEM integrating with Monte Carlo**

Parameters	Value	Unit
<i>Particle phase (DEM)</i>		
Particle diameter $d_{p,0}$	1.75	mm
Particle density $\rho_d$	1420	kg/m <sup>3</sup>
Particle number	50 000	-

Integrate time Monte Carlo and CFD-DEM	0.01	s
Simulation time	20	min

$$t_m \geq t_{deposition} + \Delta t_{drying}, \quad (4)$$

where  $t_{deposition}$  is the moment the droplet deposition happens, and  $\Delta t_{drying}$  is the drying time of the deposited droplet. Considering the first drying period only, the  $\Delta t_{drying}$  can be calculated by [4]:

$$\Delta t_{drying} = \frac{\left(\frac{1}{6}\pi d_d^3\right) \cdot \rho_d \cdot (1 - \epsilon_s)}{\beta_m A_{dep} \rho_g (Y_{sat} - Y)}, \quad (5)$$

where  $\beta$  is the mass transfer coefficient (m/s),  $Y_{sat}$  is the adiabatic saturation moisture content of fluidization gas (g liquid/kg dry gas), and  $Y = Y_{inlet} + \dot{M} \cdot (1 - \epsilon_s) / (\dot{V}_g \cdot \rho_g)$  is the moisture content of bulk gas.  $A_{dep}$  is the curved area of deposit droplet in contact with the gas (m<sup>2</sup>), which can be calculated by:

$$A_{dep} = \frac{1}{2} \frac{\pi \cdot d_{contact}^2}{1 + \cos \theta} \quad (6)$$

The thickness of solid layer in single position on particle surface  $h_i$  can be calculated as:

$$h_i = \left( \frac{d_{core}^3}{8} + \frac{3}{4} \frac{N_{pos} \cdot \left( \frac{1}{6} \pi d_d^3 \right) \cdot \frac{\rho_d \cdot \epsilon_s}{\rho_s \cdot \phi_s}}{\pi} \right)^{1/3} - d_{core}, \quad (7)$$

where  $d_{core}$  is the diameter of core particle. The coating coverage  $\Psi$  can be evaluated by:

$$\Psi = \frac{N_{pos,tot} - N_{pos,free}}{N_{pos,tot}}, \quad (8)$$

where  $N_{pos,tot}$  and  $N_{pos,free}$  are total number of positions and number of positions without droplet, respectively. With the average coating thickness  $h_m$ , the particle diameter can be expressed as:  $d_p = d_{core} + 2h_m$ .

## 2.4 Simulation setups

The mesh of Wurster coater was built by O-grid method [3], according to the configuration used in PEPT experiments [2]. The initial particle diameter  $d_{p,0}$  is 1.75 mm. All important simulation parameters in the sub-models of CFD-DEM integrating with Monte Carlo are summarized in Table 1. The coupling interval between DEM and CFD is 100 time steps of DEM; and the integrating interval with Monte Carlo is 0.01 s, which is approximately  $2d_{p,0}/v_m$  (mean particle velocity in the Wurster tube).

## 3. Results and discussion

### 3.1 Particle circulation motion

As shown in Fig. 3, the global circulation of particle from simulation with cohesion forces (0.1 %) is very similar to that in dry condition; however, the particles tend to be clustered in the Wurster tube. The detailed value of mean cycle time and mean residence time are listed in Table 2. The ideal cycle time and residence time in the Wurster tube were found to be in good agreement with PEPT measurement data in dry condition. However, the non-ideal cycle was underestimated in the simulation. With the effect of cohesion forces, the ideal cycle time and the fractions of ideal cycle are decreased, resulting in the increase of total cycle time. The decrease of the fractions of ideal cycle may cause by upwards and downwards motion of particle clustering in the Wurster zone.

### 3.2 Particle coating

Figure 4 left) shows the coating coverage of a sample particle after 70 s and the spherical particle was mapped into 2D space based on number of deposition positions. The gray level

Fig. 3 Influence of cohesion forces on particle motion in the Wurster coater.

Table 2. Comparison of ideal cycle time, overall cycle time, residence time

Variable	CFD-DEM simulation		Measurement [2]
	dry	$\alpha_l = 0.1\%$	dry
$\bar{t}_{ic}$ [s]	4.98 (52.8)	4.25 (33.5)	4.84 (99.0)
$\bar{t}_c$ [s]	5.82 (61.5)	6.42 (73.3)	6.14 (89.8)
$r_n$ [%]	78.3	60.2	55.3
$\bar{t}_{r,t}$ [s]	0.96 (33.7)	0.90 (44.6)	1.00 (-)
$\bar{t}_{r,s}$ [s]	0.15 (22.1)	0.14(28.3)	-

\*  $\bar{t}_{ic}$  is mean ideal cycle time,  $\bar{t}_c$  is mean total cycle time,  $r_n$  is number ratio of ideal cycle,  $\bar{t}_{r,t}$  and  $\bar{t}_{r,s}$  are mean residence times in Wurster tube and spray zone; the coefficient of variation (CV) is in the brackets.

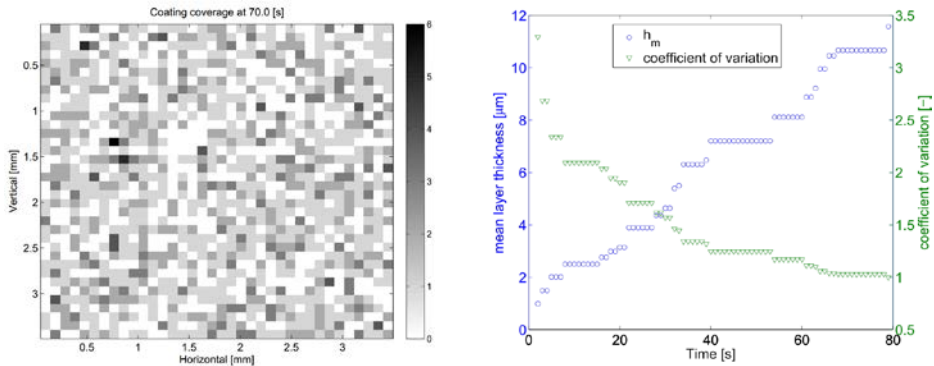

Fig. 4 Coating coverage and layer thickness of sample particle from wetting simulation: left) droplet deposition on single particle, right) layer thickness and CV with respect to time.

represents the number of deposition droplets in each pixel. According to Eq. (8), the coating coverage at this moment is 67 %. However, the coating coverage cannot roundly measure the uniformity of coating layer. The coefficient of variation (the ratio of standard deviation to mean) of the layer thickness is 1.05 at this moment. Figure 4 right) shows that the mean layer thickness increases and the coefficient of variation decreases. The variation only happens when the particle passes through the Wurster tube. Figure 5 show the size distributions under dry and wetting conditions. There are wider distributions of particle diameter  $d_p$  for simulations with cohesion forces for different process times.

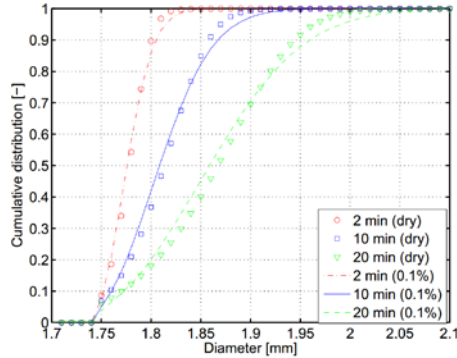

Fig. 5 Particle size distributions of 50000 particles in different process time (both dry and wetting).

#### 4. Conclusion

Cohesion forces scatter distributions of cycle time, residence time and particle size. It is important to provide enough drying capacity in fluidization gas to prevent the appearance of particle agglomeration and achieve high product quality in the Wurster coating process.

### **Abstract**

*In this study the operation of spray drying chambers fitted by the multi-stream monodisperse atomizer was simulated by the previously developed CFD model of skim milk spray drying. A series of CFD simulations of skim milk monodisperse spray drying were performed. The influence of different nozzle positions, initial droplet diameters (180  $\mu\text{m}$  and 167  $\mu\text{m}$ ) and the way of air introduction (vertical or swirling with 30° or 60° angle) on the drying process were checked. Parameters like drying air and particle residence time, wall deposition, inter-particle collisions, protein thermal deactivation, air velocity and temperature profiles were compared for each case.*

**Keywords:** *CFD, spray drying, skim milk, monodisperse atomizers, optimization.*

## 1. Introduction

Spray drying process for powder production and dehydration is widely used in many sectors of industry. Low content of solids in the liquid feed sprayed inside the drying chamber results in a large amount of energy required for particle solidification and evaporation of moisture. Therefore, the spray drying process consumes much energy used for preparation of the drying agent. Continuous growth in the demand for spray dried products makes improvements in the spray drying process necessary, not only in regard of energy and substrates consumption but also of product quality.

Modern technologies of computational simulation allow to design or optimize the production process of powders with properties directly specified by the customers. Spray drying process optimization performed by CFD techniques can also be used to solve production problems in certain regions of the drying chamber. An example has been given by a series of CFD simulations of a detergent counter current spray drying tower performed by Wawrzyniak [1]. In this work a theoretical solution of problems related to powder baking near the hot air inlet area was proposed. Particle deposition on the wall and its effect on spray drying tower operation has been widely studied in the literature [2]. Especially, the effects of flow hydrodynamics and air flow direction on the trajectories of particles, residence time and deposition inside of the drying chamber has been studied [3]. In CFD studies of air hydrodynamics in spray drying towers mostly the effect of different ways of air introduction on flow stability inside of the chamber has been checked [4]. Simulations with swirl air distribution were verified on the basis of experimental investigations [5]. Not only airflow and drying efficiency can be simulated by the CFD models. More advanced studies on particle morphology allow to include into the CFD simulations models of agglomeration, particle formation or material degradation during the spray drying.

Particle agglomeration occurs mostly in counter current and mixed flow spray dryers, having significant influence on particle size distribution in the final product. In some production processes full control of the size of particles in the dried powder is required. For this reason CFD simulations are used to identify theoretically regions where agglomeration can take place [6] or to predict final particle size distribution in the product [7]. In food industry, like skimmed milk powder production, it is also necessary to take into account influence of process parameters on product quality. CFD simulations of the influence of drying parameters on lysine loss were performed for example by Schmitz-Schug [8].

In the presented article the influence of drying conditions, swirl flow, monodisperse multi-stream atomizer configurations and droplet diameter on the drying efficiency, product quality, agglomeration probability and wall deposition will be predicted by the developed CFD skimmed milk spray drying model. All simulation results are compared to show the impact of each parameter on the drying process and to show which configuration and

parameters can give optimal results in spray drying of skimmed milk when using novel monodisperse multi-stream atomizers.

## 2. Materials and Methods

The presented manuscript is a summary of the European project ENTHALPY whose task is to optimize skim milk powder production via spray drying. Design of new spray dryer can be supported by the CFD simulations and for this reason mathematical model of skim milk drying and thermal inactivation of the proteins need to be developed.

### 2.1. CFD model of skim milk spray drying

Development of the CFD model of skim milk spray drying process starts with the series of single droplet drying (SDD) experiments performed for milk and milk components in wide range of operating conditions [10]. Based on obtained data advanced model of single droplet drying was developed. This model takes into account internal circulation of liquid in droplet, spatial gradient of solid concentration, temperature and moisture distribution and calculation of inflation and deflection of particle in elevated temperatures [11]. Next developed model was simplified and implemented into the CFD solver. To verify correctness of performed simulations calculation results were compared with experimentally obtained data from the test spray drying installation constructed on Otto von Guericke University in Magdeburg [12]. The test installation will later be called OVGU dryer. Additionally, evaporation model was combined with the protein inactivation model to calculate degradation of the skim milk powder during the spray drying process [13]. A full mathematical description of the models and details of the dryer geometry and settings of the CFD solver can be found in the quoted articles. Here only brief description of CFD simulations is presented.

### 2.2. Geometry and nozzle configurations

Tested spray drying tower is a co-current installation with narrow drying chamber: total height is 6.5 m with 0.4 m inner diameter [12]. Instead of a standard two-fluid spray nozzle the newly designed monodisperse multi-stream droplet atomizer was used [14]. It was assumed that dryer will be fed by four monodisperse atomizers. Each printing head has a base plate with 150 outlets placed in one line. Each outlet generates a single stream of droplets with constant initial diameter which depends on the size of the outlet and on the frequency of the piezo element inside the printing head. In CFD simulations special arrangements of the heads, which lead to a variation in the shape and dimensions of their supporting plates, were tested. Each configuration of the printing heads has a different denotation which will be used further in the description of results:

- **CI\_1** – four printing heads arranged one next to the other. Heads are mounted on the round base (diameter 214 mm) plate used in the OVGU dryer.

- **SQ\_2** – four printing heads arranged one beside the other. Heads are mounted on the rectangular (188 mm x 188 mm) base plate.
- **RI\_3** – four printing heads arranged on a ring support plate (internal diameter = 150 mm, external diameter = 290 mm, distance of printing head from the axis = 80 mm)
- **CR\_4** – four printing heads mounted on an equal-armed cross with arms of length 133 mm and breadth 42 mm.

To distinguish different air inlet directions additional markings were added to the name of the geometry:

- **Ax** – axial flow of air (example Cl\_Ax).
- **30** – airflow with 30° swirl (example Cl\_30).
- **60** – airflow with 60° swirl (example Cl\_60).

ANSYS Meshing software was used for grid generation. Near the wall area, where the highest gradients of velocity are predicted, a five-step boundary layer was generated. Finally, a fine mesh with 385k tetrahedral elements was generated. For every case, with different printing head configurations, a new mesh was generated with different computational elements on the atomizer support plate and air inlet surface. Those differences change the mesh structure near the air inlet area. However, all mesh quality parameters and number of mesh element were kept constant.

### 2.3. Operating parameters

Skimmed milk with initial solid mass fraction equal to 45% was used as the feed in the simulations. Initial diameter of the droplets injected into the drying chamber depends on the frequency of the piezo element inside of the printing head. In this report two frequencies were tested, 12 kHz and 15 kHz which generate droplets with diameters of 180 microns and 167 microns respectively. The mass flow rate of skimmed milk solution was equal to 0.018 kg/s, with an inlet temperature of 55°C. Initial velocity of the droplets was 18.7 m/s.

Air inlet on top of the dryer was set up as mass flow inlet boundary condition. In every simulated case the mass flow rate of air was constant and equal to 0.1 kg/s. Air was assumed as dry ideal gas with initial temperature of 200°C. In simulations with vertical airflow direction, inlet air vectors were set as normal to the boundary. In simulations with swirl airflow, air direction vectors were inclined to the inlet surface by an angle of 30° or 60°. Centre of rotation was the tower axis.

To calculate the number of inter-particle collisions it was necessary to perform all calculations in transient state. The number of time steps maintained for every simulation was 400 with time step size of 0.1 s. In simulations with axial flow of air the realizable  $k-\varepsilon$  turbulence model was used. However, in simulations with rotary movement of air the turbulence model was changed to the RNG  $k-\varepsilon$  turbulence model with switched on option of swirl dominated flow, which is recommended for calculations with rotary airflow.

## 2.4. Simulations results

Simulations results were summarized in Table 1. Swirling air distribution has a significant impact on particle flow trajectories. Particles rotation increases their residence time inside the drying chamber.

*Table 1. Summary of the CFD simulations results*

Based on the evaporation model, temperature distribution inside the spray dryer was obtained. The temperature of the continuous phase decreases along the tower because the

heat is transferred to the discrete phase for moisture evaporation. Swirling flow of the air and particles shows an interesting relationship with the temperature drop due to moisture evaporation. Comparison of time average outlet air temperature shows that in cases with higher swirl air movement the final air temperature is higher. This phenomenon can be explained as follows: In cases of axial flow of air particles are falling in the whole volume of the dryer, which results in a low temperature region near to the tower axis. With increasing swirl angle particles are moving to the dryer wall and the low temperature region is also moved from the dryer centre near to the dryer wall. For 60° swirl angle all particles are flowing near the wall where due to evaporation and heat losses to the environment air temperature is lowest. Due to this, in cases with swirl movement of air the evaporation rate of particle moisture is lower and the overall consumption of energy decreases. From the analysis of changes in evaporation rate of particles following conclusions can be drawn:

For vertical flow in cases CI\_1 and SQ\_2 where particle injections are concentrated near to the tower axis, the highest concentration of water source terms can be observed in the middle of the drying tower. In RI\_3 and CR\_4 nozzle configurations particles are better distributed in the volume of the dryer.

Swirling introduction of air significantly changes the pattern of evaporation regions inside the dryer. With axial air flow evaporation takes place in the middle of the dryer. With an increase in the angle of air rotation the centrifugal force that pushes the particle toward the walls of the dryer also increases. Near to the wall evaporation rate is lower due to lower air temperature. However the drying process is much longer, due to longer residence time of particles inside the drying chamber. Analysis of drying efficiency shows that 30° swirl increases the residence time and this improves drying efficiency. However too strong rotation pushes particles into the low temperature region and decreases drying efficiency.

From the CFD simulations we determined regions, in which inter-particle collisions can take place. With axial air flow particle collision regions are distributed in the whole volume of the drying chamber. With increasing angle of air rotation collision regions are moved to the dryer wall. With small swirl angles (30°) when particles are not reaching the dryer wall, rotary movement decreases the inter-particle collision probability.

Powder deposition on the dryer walls is an undesirable process during spray drying. This phenomenon can reduce the product quality or, in extreme case, stop the drying process by clogging the drying chamber. Analysis of contours where powder can be deposited and overall percentage of feed storage on the dryer wall shows that in such a narrow spray dryer swirling movement of air is not recommended and strongly increases powder deposition on the dryer walls. According to the deactivation model, the two parameters that control the activity of the protein in skimmed milk are moisture content and temperature of particles. From the point of view of protein deactivation analysis, strong swirling movement of air decreases deactivation rate despite the longer residence time of particles inside the drying

chamber. Near to the wall particles are dried slower in low temperature region which results in lower protein deactivation.

### 3. Conclusions

Series of CFD skimmed milk drying simulations of the co-current spray dryer fitted by multi-stream monodisperse atomizer were performed. Comparison of obtained simulations results shows:

- The use of monodisperse atomizer allows to obtain a more orderly flow of particles inside the drying chamber than in the simulations with standard polydisperse nozzle.
- Greater spacing between atomizer heads (like in the suggested ring or cross configuration) increases drying efficiency.
- In co-current spray towers with narrow diameter of chamber swirling air flow is not recommended due to:
  - Creating centrifugal forces which increase wall deposition and particle collision rate.
  - Much energy from the air is not used for the evaporation process. Dryer has lower efficiency.
  - Less uniform radial distribution of air velocities and temperatures.
- Dryers with axial movement of air fitted by monodisperse atomizer have lower probability of powder agglomeration and wall deposition than dryer with standard two-fluid spray nozzles.
- Powders obtained from dryers with monodisperse atomizers have higher protein activity level than products obtained from standard production.
- Produced powder will have uniform particle size.

Simulation of OVGU dryer shows that for the new monodisperse atomizer the best construction is a high and narrow co-current spray dryer. Axial air flow without recirculation prevents agglomeration, wall deposition and overheating of particles. Co-current spray drying allows for better control by changing flow the rate and temperature of the drying agent. The optimal diameter of the tower depends on the number of installed printing heads. However it is recommended that each printing head should be separated by an air inlet to increase drying efficiency and prevent collisions between the particle streams.

CFD simulations of skimmed milk spray drying fed by monodisperse atomizer show big advantages over other drying processes performed by standard nozzles. Produced powder is expected to have high quality and uniform particle size which can be of crucial in pharmaceutical, cosmetic and food powders production.

### **Abstract**

*The pore scale progression of the sublimation front during primary freeze drying depends on the local vapor transport and the local heat transfer as well. If the pore space is size distributed, vapor and heat transfer may spatially vary. Beyond that, the pore size distribution can substantially affect the physics of the transport mechanisms if they occur in a transitional regime. Exemplarily, if the critical mean free path is locally exceeded, the vapor transport regime passes from viscous flow to Knudsen diffusion. At the same time, the heat transfer is affected by the local ratio of pore space to the solid skeleton. The impact of the pore size distribution on the transitional vapor and heat transfer can be studied by pore scale models such as the pore network model. As a first approach, we present a pore network model with vapor transport in the transitional regime between Knudsen diffusion and viscous flow at constant temperature in the dry region. We demonstrate the impact of pore size distribution, temperature and pressure on the vapor transport regimes. Then we study on the example of a 2D square lattice, how the presence of micro and macro pores affects the macroscopic progression of the sublimation front.*

**Keywords:** pore size distribution; transitional vapor transport; pore network model; fractured sublimation front.

## 1. Introduction

Primary lyophilization, or freeze drying, is a coupled process of heat and mass transfer through frozen matter, which is usually a block of a frozen solution or a packing of frozen particles, e.g. [1]. The heat of sublimation is usually provided by contact of the frozen material to a shelf with higher temperature and by radiation. The heat transfer from the shelf to the sublimation front, at lower temperature (usually saturation temperature is anticipated at the sublimation front), occurs mainly by heat conduction through the ice phase, if the thermal conductivity of the solid is assumed to be low (usually  $\lambda_{ice} \ll \lambda_{solid}$ ). It is thus plausible that the local distribution of solid and ice phase significantly affects the transport of heat. Especially in case of a strongly heterogeneous distribution of solid and ice, the heat transfer rate can vary locally and affect the structure of the sublimation front. Similarly, vapor transport from the sublimation front to the surface of the frozen material is affected by the distribution of solid and pores, which emerge from sublimation of the ice phase. It is basically expected that more vapor can be transported through larger pores while the occurrence of smaller pores results in the deceleration of drying, e.g. [2]. From this it can be concluded that the drying process might be optimized in terms of drying time and capacity of the dryer based on the control of the distribution of ice crystal sizes (in regard of heat transfer through the ice saturated region of the frozen material) and the distribution of pore sizes (in regard of vapor transfer through already dry regions). For this reason, frozen solutions are foamed to obtain a heterogeneous distribution of pores [3]. Foamed frozen matter is characterized by smaller pores which are saturated with ice at the start of drying and larger unsaturated pores which result from the admixion of gas to the liquid solution before and during the first stage of freezing. As shown in [3] by experiments with a frozen aqueous solution of mannitol stabilized by a mixture of skim milk and sodium carboxymethylcellulose, drying can be much faster using this method, because the transport of vapor is positively affected in presence of the large pores.

It will be discussed in this paper that the simulation of vapor transport through a heterogeneous porous medium of interconnecting and interpenetrating large and small pores, such as in the experiment of [3], represents a special situation in which traditional model approaches or empirical models might rather be substituted by pore network models. The motivation behind that, is the assumption of a transitional vapor transport regime between Knudsen diffusion (in smaller pores) and viscous flow (in larger pores), which cannot be captured by the traditional continuous models or empirical approaches, which essentially blur the different transport properties into effective parameters. Basically, different flow regimes, i.e. either based on a gradient in total pressure (viscous flow) [4] or based on a gradient in vapor pressure (Knudsen diffusion) [5-9] underly the classical models of freeze drying. The distinction between the different flow regimes is generally based on the Knudsen-number,

$$Kn = \frac{\Lambda}{d}, \quad (1)$$

with pore diameter  $d$  and the mean free path of the diffusing molecules

$$\Lambda = \frac{\mu}{P} \sqrt{\frac{\pi \tilde{R} T}{2}}. \quad (2)$$

In Eq. (2)  $\mu$  denotes the dynamic vapor viscosity in  $\text{Pa s}^{-1}$ ,  $P$  the pressure in Pa,  $\tilde{R}$  the ideal gas constant in  $\text{J kmol}^{-1} \text{K}^{-1}$  and  $T$  the temperature in K.

Continuum flow (i.e. Darcy flow with no-slip conditions) is expected for  $Kn < 0.001$ , while slip flow is expected for  $0.001 < Kn < 0.1$ . Molecular (Knudsen) flow, based on a concentration gradient of the diffusing substance, occurs for  $Kn > 10$ , e.g. [10]. In the transitional range between  $Kn > 0.1$  and  $Kn < 10$ , neither the Darcy equation of viscous flow ( $\dot{m}_v = -(\rho k/\mu)\nabla P$ ) nor the molecular flow equation ( $\dot{m}_v = -D_{Kn}(\tilde{M}/\tilde{R}T)\nabla P_v$ ) can provide an exact approach. However, in many situations this range is relevant for freeze drying because of the occurrence of very low pressures, i.e. highly diluted gases. In this range, the approach e.g. presented in [10] can be applied. This is further elaborated in the following section in conjunction with the pore network model.

## 2. Pore network model

The pore network model is based on the concepts e.g. given in [11]. In the simplest case, the porous medium can be represented by a square lattice of pores and throats of varying width and length. Here, we present the results from drying of a pore network with  $50 \times 51$  pores (4949 throats) of length  $L = 100 \mu\text{m}$  and with the pore size distribution given in Fig. 1. Note the bimodal distribution of pore sizes, i.e. the presence of pores with smaller radius (peak in Fig. 1) and the tailing of the curve to throats with greater radius (similar as in experiments discussed in [2]). The pores are arranged in a way, that the radii of vertical throats and the pores in every fifth vertical column (i.e. columns [1, 6 11, 16, 21, 26, 31, 36, 41, 46, 51] as indicated by the inlet of the figure) are three times larger than the remaining throats and pores.

**Fig.1 Pore size distribution of the investigated 2D pore network. Note the tailing of the curve towards greater radii (i.e bimodal pore size distribution).**

The simulation is realized with constant temperature  $T^* = T = -38^\circ\text{C}$  and pressure inside the drying chamber  $P_v^\infty = P = 10$  Pa. The parameters of water are  $\tilde{M}_v = 18.02$  kg kmol<sup>-1</sup> (molar mass), ice density  $\rho_{ice} = 918$  kg m<sup>-3</sup> and dynamic viscosity of the vapor phase  $\mu_v = 2.5 \cdot 10^{-6}$  Pa s<sup>-1</sup>. The equilibrium vapor pressure is computed from

$$\log_{10} P_v^* (\text{mbar}) = a \cdot (T_0 / T (K) - 1) + b \cdot \log_{10} (T_0 / T (K)) + c \cdot (1 - T_0 / T (K)) + \log_{10} (P_{v,0}^*) \quad (3)$$

with  $T_0 = 273.15$  K,  $P_{v,0}^* = 6.1071$  mbar and  $a = -9.09718$ ,  $b = -3.56654$ ,  $c = 0.876793$ . [12]. It is  $P_v^* (T^* = -38^\circ\text{C}) = 16.0580$  Pa.

Computation of vapor transport through the dry zone of the pore network (white throats and pores in Fig. 3 below) follows the semi-empirical approach proposed e.g. in [10] based on the works of Knudsen. The mass flow rate is given by

$$\dot{M}_v (kg \text{ s}^{-1}) = -KA \frac{\tilde{M}_v \Delta P}{\tilde{R}T L} \quad (4)$$

with cross sectional area  $A$  in m<sup>2</sup>, pressure gradient between two neighbor pores  $\Delta P$  in Pa and throat length  $L$  in m. The transport coefficient  $K$  is computed from

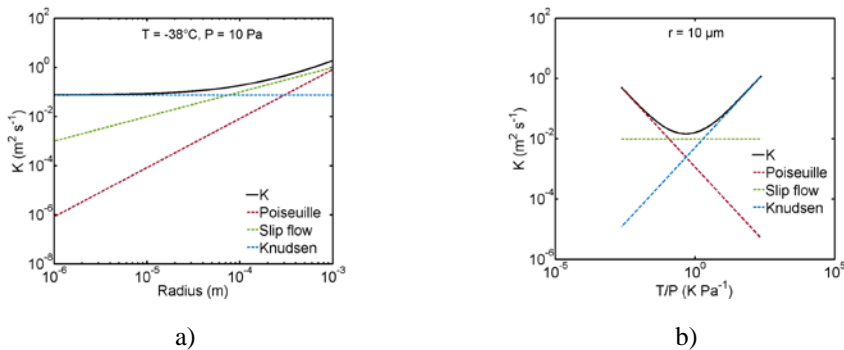

$$K (m^2 s^{-1}) = \frac{d^2 P}{32 \mu} (1 + 8.88 Kn + 4.96 Kn^2) \quad (5)$$

[10] and  $Kn$  from Eq. (1). Each term in Eq. (5) can be related to the contribution of the different flow regimes: the first term of Eq. (5) represents the contribution of Poisseuille flow, the second term of slip flow and the third term of Knudsen flow. Note that the

calculation of  $K$  is an iterative problem if it is assumed that  $P = P_v$ , i.e. the total pressure gradient is equal to the vapor pressure gradient. Then pressure varies with position  $x$  (also refer to Fig. 3) and  $K$  varies accordingly (Eq. (5)).

Figure 2 shows the dependency of  $K$  on pore sizes in the range between  $r = 1 \mu\text{m}$  and  $r = 1 \text{mm}$  with pressure and temperature as in the pore network simulation (Fig. 2a) and for constant pore radii  $r = 10 \mu\text{m}$  and varying ratio  $T/P$  (Fig. 2b). As can be seen, Knudsen flow dominates as long as pore radii are smaller than approximately  $10 \mu\text{m}$ ; however for radii  $r > 10 \mu\text{m}$  slip flow and Poiseuille flow become increasingly important (Fig. 2a). In the range between  $r = 1 \mu\text{m}$  and  $r = 25 \mu\text{m}$  (Fig. 1),  $K$  increases almost linearly by about 32 %. A similar picture is drawn for constant radius,  $r = 10 \mu\text{m}$ : In the range  $0.01 < T/P < 100 \text{ K Pa}^{-1}$  transitional flow occurs if pressure varies between  $\sim 2 \text{ Pa}$  and  $\sim 235 \text{ hPa}$ , leading to a global minimum at  $T/P \cong 0.48 \text{ K Pa}^{-1}$  (given  $T = -38^\circ\text{C}$ ).

**Fig. 2 Contribution of flow regimes to vapor transport a) for constant temperature and pressure and b) for constant radius.**

The pore network simulation is started from an initially fully saturated network. The vapor pressure field is computed from the boundary conditions of each pore [11] and the vapor flow rate between two pores is computed from Eq. (4). The sublimation rate from ice saturated pores and throats at the sublimation front is then calculated from

$$\dot{M}_{sub} = -\dot{M}_v \quad (6)$$

The vapor pressure field as well as the transport parameters (essentially  $K$ ) are updated after the complete emptying of either a throat or a pore.

### 3. Simulation Results

Figure 3 shows the distribution of ice phase and dry solid phase resulting from a pore network simulation realized with the parameters specified above. Most striking is the structure of the sublimation front evolving in the pore network with bimodal pore size distribution (Fig. 1). Obviously, in the transitional regime vapor flow through larger pores (in every 5th column) is accelerated compared to the flow through smaller pores (in the neighbourhood). This leads to the erosion of the sublimation front and faster progression of the gas phase in pores with greater diameter.

**Fig. 3** Freeze drying of a 2D pore network. The ice phase appears in blue, empty pores in white and the solid in gray. Vapor escapes from the top edge.

Figure 4a shows the least advanced position of the sublimation front (measured from the open side of the pore network) as a function of the total ice saturation, i.e. the sublimation front velocity. As can be seen, the macroscopic velocity of the sublimation front is approximately constant in this representation. However, the saturation profiles in Fig. 4b indicate that the front is significantly broadening with progressive invasion of the pore network. This is a result of the assumption of transitional flow in a pore network with bimodal pore structure (Fig. 1) and the higher vapor transport rates in pores with greater radius which allow for higher sublimation rates according to Eq. (6). This is in agreement with experimental results reported in [2]. Furthermore, as indicated by the dashed lines in Fig. 4b, the slice averaged relative humidity,  $\phi = P_v/P_v^*(T^*)$ , is approximately  $\phi = 1$  in the region of the fractured front and decreases only slightly towards the network surface due to the low spread of vapor pressures ( $\Delta P = P_v^* - P_v^\infty$ ). This shall further be elucidated in future research related to collapse phenomena, e.g. [13].

**Fig. 4** Analysis of drying kinetics and sublimation front structure: a) sublimation front velocity in terms of  $\Delta x/\Delta S$ , b) slice average saturation profiles (solid lines) and relative humidity (dashed lines) for different overall network saturations  $S$  with ice phase.

#### 4. Summary and outlook

We have presented the results of a pore network simulation of freeze drying applying a bimodal structure of the pore space. It could be shown that in the transitional regime between molecular diffusion and viscous flow, drying can be accelerated due to the presence of macro pores. The interpretation of this outcome is twofold: on the one hand, drying performance can be positively affected by pore design (i.e. in terms of drying time and capacity), on the other hand, higher demands are imposed on process control if the occurrence of material collapse is associated with the local drying rate or rather the spatial variation of the velocity of the sublimation front. We thus aim to study in more detail in a future work freeze drying in the transitional regime by 2D and 3D pore network models with different structures of the pore space.

### **Abstract**

*The aim of the present work is to determine the moisture diffusion coefficient in peas applying, in a first step, a methodology previously published in the literature by Uddin et al.<sup>[1]</sup> for determining constant diffusion coefficients taking in account the volume reduction associated to the drying process. Then, in a second step, refine it by means of an optimization step. The optimization step is justified because the methodology of Uddin et al. is based in a solution of the diffusion equation that is not mathematically valid for the drying-shrinking problem.*

**Keywords:** : moisture diffusivity; drying-shrinking; peas drying.

---

## 1. Introduction

Usually bio-products such as fruits and vegetables have high initial moisture content and present appreciable volume shrinkage during the drying process. Shrinkage of biological materials takes place simultaneously with moisture diffusion during drying and thus may affect the drying rate. It is important to take into account the shrinking phenomena when determining the moisture diffusion coefficients. When this phenomenon is not negligible there are not analytical solutions available for the equations describing this moisture diffusion process. In these cases changes in radius should be taken into consideration when predicting moisture profiles and, also when estimating diffusion coefficients. Not taking into account volume shrinkage leads to over-estimated diffusion coefficients (Xianxi et al.<sup>[2]</sup>; Guohong et al.<sup>[3]</sup>).

A simple method for determining diffusion coefficients taking into account the variation in radius was proposed by Uddin et al.<sup>[1]</sup>. It is based on a modification to the one term truncated infinity series solution that takes into account the reduction in radius. Examples of its application to drying can be found in Hawlader et al.<sup>[4]</sup>, Giovanelli et al.<sup>[5]</sup>, García et al.<sup>[6]</sup>, Martínez et al.<sup>[7, 8]</sup>.

The aim of the present work is to determine the moisture diffusion coefficient in peas applying, in a first step, the methodology previously published in the literature by Uddin et al.<sup>[1]</sup> for determining constant diffusion coefficients taking into account the volume reduction associated to the drying process. Then, in a second step, the diffusivity values are adjusted in order to satisfy a more rigorous model of the drying-shrinking problema by means of an optimization procedure. The optimization step is justified because the methodology of Uddin et al. is based on a solution of the diffusion equation that is not valid for drying-shrinking problems. Finally, in a third step, by means of another optimization step, the model of the shrinking phenomena is improved.

## 2. Materials and Methods

### 2.1. Uddin methodology

Mass transfer processes are commonly described by the second Fick's law, the phenomenological parameter in this equation is the mass diffusion coefficient. Analytical solutions to the diffusion equation for mass transfer in solids are available for some cases under certain assumptions among which could be mentioned constant volume and constant diffusivity. In particular, for unidirectional mass transfer in slabs or spheres with a symmetry boundary condition at the centre and a Dirichlet boundary condition at the external border, with uniform initial diffusant content, these solutions are given in the form of infinite Fourier series and are the departing point for the determination of constant moisture diffusion coefficients at a constant temperature from the truncated to just one term or at most to a few terms of the series when volume shrinkage is not relevant. A method presented in the literature for determining diffusion coefficients taking into account the radius variation was proposed by Uddin et al.<sup>[1]</sup>. It is based on a modification of the one term truncated infinity series solution to take into account the reduction in radius.

In the Uddin et al. methodology the moving boundary condition is introduced a posteriori in the solution for the fixed boundary condition. As signalled properly by Hawlader et al.<sup>[4]</sup> this approach is a simplified one and the diffusivity coefficient determined by his method can be considered an effective diffusivity. However, the methodology provides an effective diffusion coefficient of the specimen under given drying conditions which is valid for the assumed model.

The Uddin et al. approach departs from an approximated solution to the moisture transfer in the solid when the shrinkage is neglected. The analogous equations for spherical coordinates analogous to those presented by Uddin et al. for a slab are :

$$\text{Ln}\left(\frac{c}{c_0}\right) = \text{Ln}\left(\frac{6}{\pi^2}\right) - \frac{\pi^2 D t}{R^2} \quad (1)$$

Where  $c$  indicates de volumetric moisture concentration ( $\text{kg/m}^3$ ),  $c_{eq}$  the equilibrium moisture content,  $c_0$  the initial moisture content,  $R$  the particle radius (m) Then  $D$ , the moisture diffusion coefficient, could be obtained from the slope of a plot of  $\text{Ln}(\omega/\omega_0)$  versus  $t$  or  $t/R^2$  for those cases in which the shrinkage is negligible. For those cases for which this condition is not sustainable the proposed methodology proceeds as follows. The reduced radius  $R'$  at time  $t$  was related to the moisture content at each time instant by the following equation:

$$\frac{R'}{R} = \left(\frac{\omega_t}{\omega_0}\right)^n \quad (2)$$

Where  $R_0$  is the radius at the initial time,  $R'$  is the reduced radius,  $\omega_0$  is the initial moisture content ( $\text{kg water/kg dry mass}$ ) and  $\omega_t$  is the moisture content at time  $t$ .  $n$  is an exponent to be found which makes that the plot of  $\text{Ln}(\omega/\omega_0)$  versus  $t/R'^2$  results in almost a straight line. A value of  $n$  equal 0 means there is not shrinkage and a value of  $n=1$  would indicate that the reduction in volume is equal to the volume of the water transferred to the air.

In the present work we start with the diffusion coefficients obtained with the Uddin et al. approach. In the second step the drying process is posed, as a direct moving boundary problem in which the diffusion coefficient is assumed as known and with experimental radius-time data. The model (given below) is numerically solved, the average moisture concentration at each integration time step is obtained and the average moisture content profile is compared with the experimental results. If the difference between the experimental and the predicted profile is beyond certain tolerance according to a predefined norm the diffusion coefficient is improved through an optimization algorithm until the desired tolerance is satisfied. The model is implemented in the software Berkeley Madonna discretizing the spatial variable of the distributed parameter model by finite differences and integrating the set of ordinary differential equation with one of the integration methods available in the software. The optimization step is carried on by means of the optimization algorithm with which Berkeley Madonna is provided with experimental radius-time data. The optimization procedure is carried on taking as objective function the minimization of the difference between the predicted moisture content and the experimental one at the time for which this difference is higher. After finding the optimal diffusion with experimental radius-time data, in the third step, by means of another optimization procedure, the model of the shrinking phenomena is improved taking as objective function the minimization of

the difference between the predicted radius and the experimental one at the time for which this difference is higher.

## 2.2. Model of the drying process considering shrinkage

Assuming that the drying process is described by the diffusion equation, considering that the concentration is a function of volume and time, that the volume is as well a function of time and, after transforming the moving boundary problem into a fixed boundary problem by means of a change of variable ( $z=r/R$ ) in order to have variations of the dimensionless spatial variable between 0 and 1 (Crank<sup>[10]</sup>), the following equation is obtained:

$$\frac{dc}{dt} = \frac{1}{(zR)^2} \frac{\partial}{\partial z} \left( z^2 \cdot D \frac{\partial c}{\partial z} \right) + \frac{1}{R} \frac{\partial c}{\partial z} z \frac{dR}{dt} \quad 0 \leq z < 1, t > 0 \quad (3a)$$

where  $r$  denotes the radial distance from the centre of the sphere (m). The consideration of a spherical particle leads to a symmetry condition at the centre of it:

$$\frac{\partial c}{\partial z} = 0 \quad z = 0, \forall t \quad (3b)$$

An equilibrium condition is assumed at the solid-gas interface:

$$c = c_{eq} \quad z = 1, \forall t \quad (3c)$$

A uniform moisture content profile inside the solid is assumed at the initial time:

$$c = c_0 \quad 0 \leq z < 1, t = 0 \quad (3d)$$

Assuming that the solid's volume reduction is proportional to the volume of water lost by it (Aguerre et al.<sup>[11]</sup>), the following equation gives the shrinking rate

$$\frac{dR}{dt} = - \frac{\beta D}{\rho_w R} \left[ \frac{\partial c}{\partial z} \right]_{z=1} \quad (3e)$$

Where  $\beta$  is a proportionality constant introduced in order to fit the model predictions with the experimental data to be found. The initial condition for this equation is:

$$R = R_0, \quad t = 0 \quad (3f)$$

The average volumetric moisture concentration  $\bar{c}(t)$  is given by

$$\bar{c}(t) = \frac{1}{V_p} \int_0^{V_p} c(r, t) dv \quad (4)$$

In order to solve the above equations when the diffusion coefficient is assumed to be known, the spatial variable is discretized by finite differences leading to a set of ordinary differential equations which are integrated with a proper method for stiff equations.

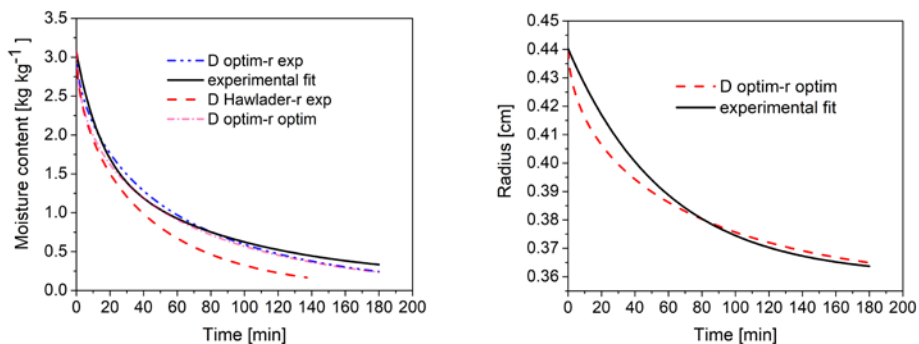

### 3. Results and discussion

This work departs from experimental data obtained in a small scale batch fluidized bed drier for drying of peas (Gómez et al.<sup>[12]</sup>). Peas were dried at three different temperature levels of the air fed to the drier: 50, 60 and 70 °C. The moisture content and the diameter of the peas were recorded along the drying time. These data were fitted by analytical expressions in order to have available the moisture content and the diameter at each time instant during the drying process.

**Table 1.** Diffusion coefficient and adjusted exponent in eq. (2) obtained with the Uddin method.

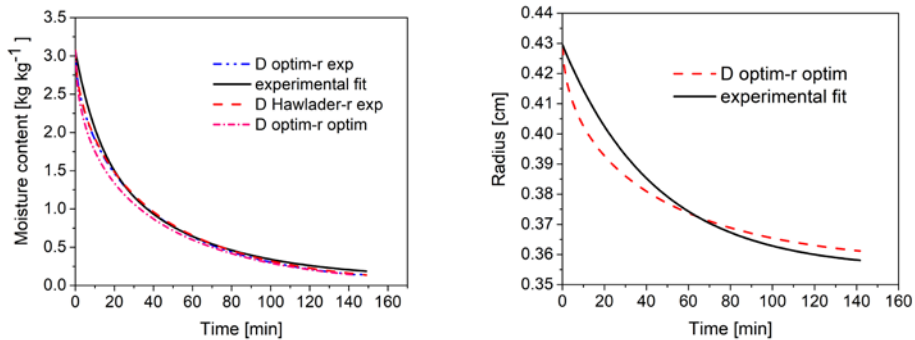

T [°C]	<i>n</i>	$D_{ef} \times 10^8$ [m <sup>2</sup> s <sup>-1</sup> ]
40	0.75	3.04
50	0.55	4.053
60	0.55	3.04
70	0.45	1.013

The effective moisture diffusion coefficients of peas dried at each one of the temperature levels at which the experiments were carried on were determined applying the methodology proposed by Uddin et al. described above. The values obtained are presented in Table 1 (Martínez et al.<sup>[8]</sup>). Posteriorly, the constant values obtained were tested in the more rigorous model of the drying process represented by equations (3a-3d and 4). These equations were solved discretizing the spatial variable (radius) by finite differences and the set of ordinary differential equations were integrated together with the boundary conditions by means of an integration method proper for stiff equations. In these simulations the experimental radius values corresponding to each integration time step were provided by the corresponding fitted expression to the radius-time experimental values. These values of the diffusion coefficients, as expected, led to poor predictions of the moisture evolution as shown by the dashed lines in Figs. 1, 2 and 3 which can be compared with the solid ones which represent the experimental values. The diffusion coefficients obtained are between  $1 \times 10^{-8}$  and  $4 \times 10^{-8}$  m<sup>2</sup>s<sup>-1</sup>.

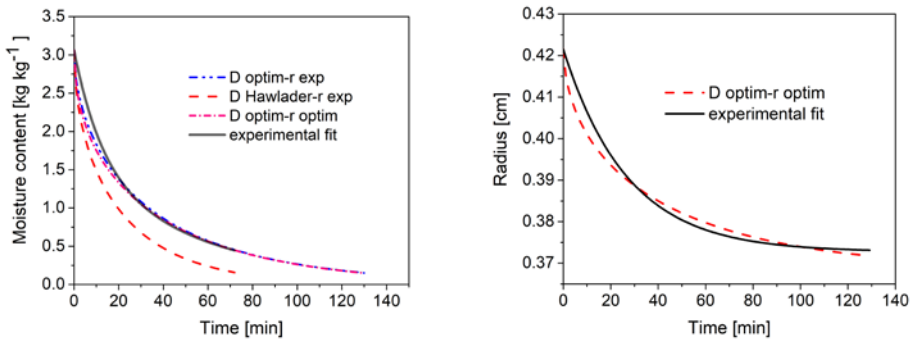

**Fig. 1.** Moisture content profiles and experimental and predicted radius profiles at inlet air temperature of 50° C.

In a second step the diffusion coefficients were improved in order to give a better agreement with the experimental moisture content profiles when the model given by equations (3a-3d and 4) was employed. This was done by an optimization procedure utilizing the optimization tool included in the software Berkeley Madonna. In this optimization step the experimental radius values given by the radius-time fitted expression were employed. The objective function to be minimized was the absolute value of the difference between the moisture content experimental value and the predicted one at each integration time step. The variable to be optimized was the effective diffusion coefficient. The profiles obtained with the optimized values in the rigorous model but still with the experimental radius values are shown in figures 1, 2 and 3 by the dash-dot-dot-dash lines. The improvement in the agreement between the experimental moisture content profile and the predicted by the simulations can easily be appreciated.

**Fig. 2** Moisture content profiles and experimental and predicted radius profiles at inlet air temperature of 60° C.

However, even though the moisture content predictions were quite acceptable, the radius evolution predictions given by equations (3e-3f) were quite poor. Therefore, a third step was carried on in order to improve the particle size predictions. This was done through a second optimization step with the optimization algorithm included in the software Berkeley Madonna in which the variable to be optimized was the parameter  $\beta$  introduced in equation (3e). The objective function to be minimized was the absolute value of the difference between the experimental radius and the predicted one at the time in which this difference was bigger before the optimization. The results in the moisture content are shown in figures 1, 3 and 5 by the short dash-dot-short dash lines. It can be appreciated that the predictions of the moisture content profiles employing the experimental radius values and those obtained with radius values given by the model does not differ appreciably. The radius profiles obtained with equations (3a-3f and 4) and the experimental ones are shown, for each temperature level considered in this work, in figures 1, 2 and 3. It can be seen that, even though, the particle size predictions are not as good as the moisture content predictions, they are acceptable.

*Fig. 5 Moisture content profiles and experimental and predicted radius profiles at inlet air temperature of 70° C.*

#### 4. Conclusions

A methodology proposed by Uddin and Hawlader for the determination of moisture diffusion coefficients taking into account the shrinkage of the stuff being dried that is easily applied provides diffusivity values that are taken as first guesses of an optimization procedure under a more rigorous model. Having obtained the optimal moisture diffusion coefficients employing the experimental radius evolution data a second optimization step is carried on in order to obtain an acceptable prediction of the radius evolution. The results obtained shows a very good agreement with the experimental moisture content evolution at the three temperature levels analysed and an acceptable agreement with the experimental radius evolution.

### **Abstract**

*A new model describing the variation in the rehydration ratio with rehydration time for yam slices is presented here. Also presented, is a new model for the rehydration kinetics of yam slices. Mass and moisture content rehydration data were collected while rehydrating 3.0 mm thick dehydrated yam slices. Regression analysis established that the mass rehydration data better fitted a two-term exponential equation rather than a second-order polynomial equation. Also, for the rehydration kinetics, the moisture content rehydration data was better fitted to a new empirical model rather than the Weibull, Peleg, and Exponential models.*

**Keywords:** *Rehydration Ratio Models; Rehydration kinetic models; Yam; Weibull, Peleg, and Exponential models.*

## 1. Introduction

White yams (*Dioscorea rotundata*) are very nutritious and are an excellent source of energy and dietary fiber [1,2,3,4,5,6]. Yams are eaten routinely and they constitute a dominant portion of the standard diet for many people. They are used, worldwide, in many different recipes. For this reason, there is a need for these commodities to be transported to the many locations where they are consumed. However, they are heavy, constituting of at least 70% water. Dehydrating yams like most foods and agricultural products are becoming an essential method of processing before being shipped to where they will be consumed. Dehydration is also performed for preservation purposes.

The dependence of many dehydrated food and agricultural commodities in the present marketplace is increasing as this is a means of extending the length of time that the products may be stored without becoming unfit for future use. Rehydration operations, therefore, are gaining importance as these dried products will need to be rehydrated before use. There is, therefore, need to understand the issues relating rehydration operations concerning the design and the operations of these processes.

Mathematical modeling has been useful in the study, design, optimization, and operations of these rehydration processes [7, 8]. This study involves investigating the rehydration kinetics and estimating other rehydration characteristics of the dehydrated products.

The models that have been used to study the rehydration characteristics of foods are the Peleg model [9], the Weibull distribution model [10, 11, 12] and the exponential model [9, 13]. However, for accurate use of these models, more knowledge, in addition to the rehydration data and knowledge of some physical parameter(s) of the product being studied, is required. For the Peleg, [14], Weibull distribution and Exponential models knowledge of the initial moisture content before rehydration is required. For the Exponential model, the equilibrium moisture content also, needs to be known; and for the Weibull model, knowledge of scale and shape parameters of the samples are required [15]. Presented in this study is a new rehydration model for yam that requires only the moisture content rehydration data, and a comparison of all the four (4) rehydration models are performed.

## 2. Materials and Methods

### 2.1 Sample Preparation

White yam tubers acquired from the local market were washed, peeled, cut into 3 mm thick slices. The slices were dried in a Refractance Window™ dryer until the moisture content was about 0.03g-water/g-solid. The dehydrated samples were kept in air-tight polyethylene bags and stored in a refrigerator until further use in the rehydration experiments.

### 2.2 Rehydration experiments

The dried samples were brought to room temperature before starting the rehydration experiments. Rehydration of the samples was done in 250-mL beakers filled with distilled water. The beakers were immersed in a thermostatically controlled water bath, and each set of experiments was performed at 27 °C, 40 °C, 60 °C and 80°C ( $\pm 0.5^\circ\text{C}$ ). Approximately  $3.75 \pm 0.25\text{g}$  was immersed in 100 ml of distilled water for periods of 10, 20, 30, 40, 50,

60, 80, 100, 120, 150, 180, 210 and 240 minutes. The temperature of the water inside the beakers was determined with a thermocouple. A perforated plexiglass cup was used to cover the samples to ensure they were entirely immersed in the water in the beakers during rehydration. After rehydration, the water was drained from the flask, and excess water on the samples was removed using tissue paper. The samples were then weighed. The moisture content of the samples was determined using an OHAUS moisture analyser <sup>[16]</sup>. Every experiment was done in triplicate.

### 2.3 Modelling The rehydration ratio

The rehydration ratio (RR) was calculated according to equation 1.

$$RR = W_t/W_o \quad 1$$

where  $W_t$  is the mass of rehydrated sample at time  $t$  and  $W_o$  is the initial mass of sample to be rehydrated.

The rehydration ratios and rehydration times were correlated first according to the two term exponential equation of the form given in equation 2 and then with the second order polynomial equation of the form given in equation 3 <sup>[17]</sup>.

$$RR = p_1 \exp(p_2 \cdot t) + p_3 \exp(p_4 \cdot t) \quad 2$$

where  $p_1, p_2, p_3,$  and  $p_4,$  are constants observed from regression analysis and  $t$  is the rehydration time in minutes.

$$RR = p_5 \cdot t^2 + p_6 \cdot t + p_7 \quad 3$$

where  $p_5, p_6,$  and  $p_7,$  are constants observed from regression analysis and  $t$  is the rehydration time in minutes.

### 2.4 Modelling The rehydration data

The experimental rehydration kinetics data were fitted to the equations 4, 5, 6 and 7 to determine the model that best describes the rehydration kinetics of the yam slices.

Peleg	$M_t = M_o + (t/(a+bt))$	4
-------	--------------------------	---

Weibull	$M_t = M_o [1 - \exp(-(t/\alpha)^\beta)]$	5
---------	---	---

Exponential	$M_t = (M_o - M_e) \exp(ct^d) + M_e$	6
-------------	--------------------------------------	---

New Model	$M_t = g \exp(ht) + j \exp(qt)$	7
-----------	---------------------------------	---

where  $M_t$  is the moisture contents at time  $t$ ,  $M_o$  is the initial moisture content,  $M_e$  is the equilibrium moisture content, and  $\alpha, \beta, a, b, c, d, g, h, j,$  and  $q$  are constants observed from regression analysis

For quality fit, the coefficient of determination ( $R^2$ ), should be closest to unity while the sum of square-error (SSE), and the root-mean-square-error (RMSE) should be closest to zero. The methods of estimating  $R^2$ , SSE and RMSE are discussed extensively in the literature <sup>[18, 19]</sup>. In this work, the software package from Matrix Laboratory (MATLAB) was used to perform the statistical analysis.

### 3. RESULTS AND DISCUSSIONS

#### 3.1 Evaluation of the Rehydration Ratio models

Four sets of rehydration experiments were performed at rehydration water temperatures of 27, 40, 60, and 80°C. The rehydration ratio at each rehydration time was calculated according to equation 1 using the weight data obtained during the rehydration experiments. Table 1 presents the statistical parameters when the rehydration ratios were correlated with rehydration time according to equations of the form given in equation 2 and 3. Table 1 clearly indicates that the two-term exponential model fits the rehydration ratio vs. time data better than the polynomial model. For the two-term exponential equation form, the R<sup>2</sup> values were closer to unity and the SSE and RMSE values were closer to zero than the polynomial equation form. Table 2 shows the constants obtained with a 95% confidence bound, by fitting the rehydration ratio data to the exponential equation form presented in equation 2.

*Table 1 Statistical Parameters for Yam when correlating Rehydration Ratios with Rehydration Time at different temperature*

S/N	Water Temp.	Exponential Equation Form			Polynomial Equation Form		
		R2	RMSE	SSE	R2	RMSE	SSE
1	27°C	0.9966	0.0180	0.0032	0.9245	0.0808	0.0719

		$p_2 = 0.0008455 \pm 0.00011835$	$p_6 = 0.003884 \pm 0.0016265$
		$p_3 = -0.4871 \pm 0.23$	$p_7 = 1.975 \pm 0.078$
		$p_4 = -0.0761 \pm 0.044295$	
4	80°C	$p_1 = 2.152 \pm 0.1395$	$p_5 = -7.178e-06 \pm 4.815E-06$
		$p_2 = 0.0009701 \pm 0.00033105$	$p_6 = 0.004868 \pm 0.0011835$
		$p_3 = -0.3082 \pm 0.1325$	$p_7 = 1.936 \pm 1.993$
		$p_4 = -0.0285 \pm 0.0284985$	

Fig. 1 shows a plot of the variation in the experimental and the predicted (Exponential) rehydration ratio with drying time at different temperatures for white yam. The plots of the experimental and predicted rehydration ratios vs. time are observed as expected to be a good fit as expected from the regression analysis shown in Table 1.

### 3.2 Evaluation of the Rehydration kinetics models

The moisture content data obtained from the rehydration experiments were fitted to the New Model, the Weibull model, the Peleg model, and the Exponential model presented in equations 4, 5, 6 and 7. Table 3 presents the statistical results of correlating the moisture content rehydration data using the Peleg, Weibull, and Exponential and New models. For quality fit, the model chosen to best fit the rehydration kinetics of the yam slices is the one that meets the following three criteria:  $R^2$  is closest to unity, and SSE and RMSE are closest to zero. While most of the models fitted the moisture content experimental data with a coefficient of variance values exceeding 0.9600, the  $R^2$  for the New model was the one closest to unity for all the temperatures. For the experiments performed at 27°C, 40°C, 60°C, and 80°C,  $R^2$  exceeded 0.995 for the New model.

Fig. 1 Variation in Rehydration Ratio with Drying Time at Different Temperatures for white yam

Table 3 Regression constants correlating the moisture content rehydration data using Different Models

S/N	Temp	Models	R <sup>2</sup>	RMSE	SSE	S/N	Temp	R <sup>2</sup>	RMSE	SSE
1	27°C	New	0.997	1.511	15.00	3	60°C	0.996	1.596	25.46
		Peleg	0.995	2.772	92.19			0.952	4.866	284.15
		Weibull	0.977	6.089	444.92			0.976	3.454	143.19
		Exponential	0.976	6.234	466.40			0.976	3.473	144.73
2	40°C	New	0.996	1.842	33.91	4	80°C	0.993	2.248	50.53
		Peleg	0.988	3.050	111.59			0.881	8.195	805.82
		Weibull	0.966	5.174	321.28			0.982	3.171	120.63
		Exponential	0.965	5.224	327.42			0.982	3.152	119.22

Also, for the temperatures considered, the SSE, and RMSE, values were the least for the New model. The implications are that the New model best fits the rehydration data among the models examined. However, the SSE, and RMSE values are large. This implies that the model should only be used in the range of process conditions studied and should not be used for predictions outside that range. The coefficients obtained by fitting rehydration moisture content data to the new model for the yam slices is presented in Table 4.

**Table 4 Coefficients Obtained By Fitting Rehydration Moisture content Data to the New Model For Yam Slices**

S/N	Temp	27°C	40°C	60°C	80°C
1	$\alpha$	99.76	46.11	24.63	17.3
2	$\beta$	0.5035	0.335	0.2729	0.3065
3	a	0.1588	0.06158	0.0321	0.03559
4	b	5.133e-3	5.282e-3	05.215e-3	4.904e-3
5	c	-0.0935	-0.2692	-0.408	-0.4084
6	d	0.5118	0.339	0.2757	0.3096
7	g	136.1	154.6	164.2	176.1
8	h	1.177e-3	8.899e-4	7.985e-4	8.05e-4
9	J	-128.4	-116.8	-85.58	-59.72
10	q	-0.03772	-0.06141	-0.06353	-0.03705

To further validate that the new rehydration model best fits the moisture content rehydration data, a simple linear regression analysis was performed between the experimental and predicted rehydration values. The relationship between the experimental and predicted rehydration moisture content values is also presented in Table 5.

**Table 5 Relationship Between the Experimental and Predicted Rehydration Moisture Content Values**

S/N	Temp.	Equation	R <sup>2</sup>
1	27	$PMC = 0.9991EMC$	0.9945
2	40	$PMC = 0.9997EMC$	0.9962
3	60	$PMC = 1.0018EMC$	0.9977
4	80	$PMC = 0.9998EMC$	0.9925

where *PMC* is the predicted moisture content and *EMC* is the experimental moisture content

Fig 2 shows the variation in moisture content of the yam samples with time rehydrated at different temperatures.

**Fig 2 Variation in Moisture contents of yam with rehydration time at 27,40, 60, and 80°C**

The plots show that for any given time, the moisture content of the yam sample is higher as temperature increases. The plots show that as the rehydration temperature increases the extent of rehydration increases. In the first ten minutes, the moisture content of the yam slices for rehydration temperatures of 27, 40, 60 and 80°C are 46.69, 91.53, 120.41, and 137.87 g-water/g-solid respectively. There is a 3-fold magnitude in the moisture content of the samples rehydrated with a water temperature of 80°C over the moisture content of sample rehydrated at 27°C. However, after about 240 minutes, the difference in the magnitude of the moisture contents decreases; the moisture content ranged from 179.02 - 212.60 g-water/g-solid for rehydration done in the temperature range of 27 -80 °C.

#### 4 Conclusions

White yam (*Dioscorea rotundata*) slices, 3.0 mm thick, were dehydrated in a Refractance Window™ dryer. The dehydrated yam slices were rehydrated at 27, 40, 60 and 80°C. Mass and moisture content variation data with time were collected. By fitting the mass

rehydration data to rehydration ratio models and the moisture content rehydration data to rehydration kinetics data, the following are the conclusions.

The two-term exponential equation fits the rehydration ratio variation data better than the second order polynomial equation proposed by Singh and Pandey<sup>[17]</sup>. For the rehydration temperatures considered, the  $R^2$  values for the two-term exponential equation were closest to unity in all cases. For the samples rehydrated at 27, 40, 60 and 80°C,  $R^2$ , for the two-term exponential equations was 0.9966, 0.9860, 0.9903, and 0.9864 respectively as opposed to 0.9245, 0.9447, 0.9420 and 0.9803 for the second-order polynomial equation. Also, for the samples rehydrated at 27, 40, 60 and 80°C, the root-mean-square-error (RMSE) were 0.0180, 0.0311, 0.0214 and 0.0317 respectively and the sum-of-squared-error (SSE) were 0.0032, 0.0097, 0.0046 and 0.0100 respectively. All the RMSE and SSE values are close to zero.

When rehydrating the slices, the mass (Fig. 1) and moisture content (Fig. 2) values reached higher values for the same rehydration time as the temperature increased. The rehydration ratio and moisture content for the slices rehydrated at 80°C were about 50% higher for samples rehydrated at 27°C after ten minutes.

For the moisture rehydration data, the new model better fits the rehydration kinetics than the Peleg, Weibull and Exponential rehydration models for the process temperatures studied. Among the models investigated, the  $R^2$  value for the new models was closest to unity for all the process temperatures studied.

### **Abstract**

*A discrete thermo-mechanical drying model is developed to investigate the interaction between the porous structure and the drying characteristics of dense particle aggregates. The solid phase consists of polydisperse spherical particles in the micrometer range and the void space is constructed by a complementary network of tetrahedral pores. A modified version of the classical invasion percolation algorithm is set up to describe the preferential evaporation of the confined liquid in the pores. Thus, the evolution of the liquid distribution throughout the complex disordered medium can be simulated. In a one-way coupling scheme, capillary forces caused by both fluid pressure and surface tension are computed over time from the filling state of pores and they are applied as loads on each primary particle in the discrete element method. Based on this robust approach the drying kinetics and the mechanical behavior of several different aggregates with various fractions of small and large particles are simulated and quantified.*

**Keywords:** Pore network model; discrete element method; Solid-fluid interaction; capillary force, Convective drying.

## 1. Introduction

Drying in porous media has been subjected to a wide range of scientific investigation, from soil layers [1] to a porous wick in loop heat pipe [2] or a membrane in a fuel cell [3]. This process consists of various complex events, such as two-phase flow together with phase change, or the interaction between fluid and solid phases, which may cause some undesired mechanical effects. These effects mainly depend upon moisture distribution, which is affected by drying conditions and the porous media skeleton. Substantial efforts have been made to numerically investigate the drying problem at the pore scale. After the pioneered work by Prat [4], many other studies have been conducted to take into account many physical effects, e.g. liquid viscosity [5], gravity [6] or liquid film [7].

In addition, the pore network modeling method has been combined with discrete element method (DEM) to account for the solid phase geometry explicitly [8]. Therefore, local effects on a solid phase (such as cracks or shrinkage) has been described for the case of *monosized* aggregates having regular [9] or irregular [10] pore structure. Such effects are caused by capillary forces, which depend on the evolution of the liquid-gas interface as well as surface tension during the drying process. The solid phase is defined as a particle aggregate and based on this a pore network is generated using the Voronoi tessellation that can approximate the void phase [11]. However, this Voronoi graph has a shortcoming when applied for a polydisperse aggregate, which is a packing composed of primary particles with different sizes. In this case, regular Delaunay triangulation generates the graph to weighted points, which are the radii of particles [12]. This regular Delaunay triangulation method has been used in a pore assembly approach developed by Bruno et al. [13] in order to study the fluid flow problems in granular porous media. The fluid flow model has been coupled with DEM to calculate the capillary force exerting on each particle of the aggregate. This approach has been further improved and applied for several applications. Based on this approach, Catalano et al. [14] investigated the fluid-solid interaction for the case of oedometer test; Chao Yuan et al. [15] studied the hydromechanical response (shrinkage and swelling) during drainage; Sweijen et al. [16] simulated swelling of super absorbent polymers.

The goal of this work is to develop a versatile discrete model that can simulate the mechanical behavior of particle aggregates during convective drying. In this meso-scale model, the solid phase is explicitly described as an assembly of spherical primary particles. The fluid flow within the void space structure is modeled using the pore assembly method while the geometrical representation and the mechanical behavior of the solid skeleton are simulated by DEM. The coupling between these two parts is achieved by handling the interfacial interaction between the fluid and the solids phase. Impact of the internal structure of the porous media on the drying kinetics, for the case of 3D particle aggregates with various fractions of coarse and fine primary particles, has been presented.

## 2. Materials and Methods

### 2.1. Aggregate generation - solid phase representation

The solid phase is represented by a packing of particles. This particle aggregate is generated by using YADE [17], which is an open-source software based on the discrete element method. A set of very loose particles with a uniform size distribution is enclosed in a parallelepiped. The resulting packing conforms in a gas-like state with no contacts between particles. Mechanical loading is subsequently applied to confer a solid-like nature to the packing.

*Fig. 1 Representation of monodisperse (left), bidisperse (middle), and polydisperse (right) particle aggregates.*

### 2.2. Pore network generation - void space representation

The void space between primary particles is represented by a network of pore bodies and pore throats (see Figs. 2 and 3). This pore network is defined by a weighted Delaunay tessellation of the granular assembly. The pore body is subtracted from the finite volumes of the corresponding tetrahedral cell, which has its vertices locating at centers of associated particles (Fig. 2a), by the part of the solid volume of these associated particles locating within the domain of the tetrahedral cell. Each pair of pore bodies is connected to each other through one common facet (pore throat) between them (Fig. 2b). This pore throat has no volume and serves as the capillary threshold between the two corresponding pore bodies. Therefore, at a given time, the geometry of the packing defines an open network of connected voids.

*Fig. 2 Representation of a pore body and associated neighboring particles (a) and of two neighboring pore bodies sharing one mutual pore throat (b).*

Fig. 3 Pore network triangulated based on the particle aggregate.

### 2.3. Drying algorithm

The isothermal discrete drying algorithm used in this work was based on the work of Metzger et al. [18]. The drying phenomenon is interpreted as an invasion percolation driven by evaporation of liquid into vapor. Vapor diffusion in gas-filled pore bodies is governed by diffusion with Stefan correction. The boundary conditions are applied here for the vapor pressure as saturation value at liquid-gas interface and value of bulk air at top of boundary layer. Besides, the pore size is big enough (more than 100  $\mu\text{m}$ ) so that the Kelvin effect, i.e. the reduction of equilibrium vapor pressure over a curved liquid-vapor interfaces may be neglected [18]. The movement of this menisci is not tracked continuously since the time is discretized based on each complete emptying of one single pore in each simulation step. This is due to the assumption that the movement of the liquid-vapor interface, which can be referred to as a Haines jump [19], is much faster than the duration of the evaporation occurring at that meniscus. During each calculation step, vapor flow rates are assumed as constant without accounting for local accumulation of vapor in the gas phase. Additionally, in the gas-filled section of the partially saturated pore bodies, it is assumed that the gas is saturated with vapor (local equilibrium), hence neglecting any vapor resistance in this section. Then, the following mass balances are applied for all gas-filled pore bodies of unknown vapor pressure  $p_v$ :

$$\sum_{j=1}^4 \dot{M}_{v,i} = \sum_{j=1}^4 A_{ij} \frac{\delta}{L_{ij}} \frac{p \tilde{M}_v}{\tilde{R}T} \ln \left( \frac{p - p_{v,i}}{p - p_{v,j}} \right) = 0 \quad (1)$$

Due to the random spatial distribution of the pore size, the liquid phase in the liquid-filled region of the network tends to be gradually separated into numerous isolated liquid clusters [6]. In the absence of viscous and gravity forces, liquid flow within these isolated clusters is totally controlled by capillary pressure, which is the pressure difference at the liquid-gas interface in each pore body locating at the boundary of each liquid cluster. If it is assumed that the gas pressure is the same everywhere within the gas-filled section of the void space,

then due to capillary pumping effect there is only one pore body in each liquid cluster, whose saturation changes in each calculation step. This pore body is the one having the highest liquid pressure, i.e. lowest capillary pressure, and it will hereafter be referred as entry pore. For every moment of the simulation, each liquid cluster has one entry pore and different entry pores can have different pore volume, pore saturation and evaporation rate. Consequently, the time required to totally invade these entry pores will be different. Therefore, the time step of the drying simulation is determined based on the liquid cluster which has its entry pore empty totally first.

### 2.4. Capillary force calculation

The capillary force exerting on each particle consists of two contributions. The first contribution is induced by the fluid pressure in pore bodies. It is calculated based on the gas and liquid pressure and the surface area of the solid particle being in contact with each corresponding fluids. The second capillary force contribution is the result of interfacial tension acting on the three phase (solid-liquid-gas) contact line. The method used for calculating this capillary force follows the work in [16].

### 3. Simulation results

We consider here a three-dimensional pore network initially saturated with single-component liquid (pure water). In this network the effects of gravity and liquid viscosity are neglected. The water vapor can only elude from the network through the boundary layer locating at the top surface of the sample while a zero-flux condition is applied at other surfaces. It is also assumed that the bulk air is totally dry, i.e. vapor pressure is equal to zero. The temperature of the entire network is uniform at 20 °C. We also neglect the liquid film effect – which can be significant for pores with square or polygonal cross section [21].

Fig. 4 Normalized drying curves of mono, poly and bidisperse particle aggregates.

The drying curves obtained for four different particle size distributions, i.e. mono, poly and two bidisperse aggregates with different volume fractions of coarse and fine particles, are presented in Figure 4. These curves show similar drying characteristics: a sharp drop at the beginning followed by a semi-constant evaporation rate period and ended with the falling rate period. These observation is in agreement with previous works [20]. Besides, the total time required to dry the aggregates are also presented. Although these four aggregates have approximately equal porosity and the same physical size of the whole domain, they still have differences in the spatial distribution of the fluid channel within the network. The liquid distribution obtained from the fluid flow calculation in each invasion step is the input for the calculation of capillary force in DEM module. Dynamic simulations are run to visualize the evolution of capillary forces during the drying process of the polydisperse aggregate (Fig. 5). Such capillary forces will subsequently be loaded to primary particles as external loads, and thus the particle motion shall be computed using DEM. We conjecture that different local distributions of fluid can lead to different mechanical responses. Detailed and systematical analysis will be addressed in the near future.

*Fig. 5 Evolution of capillary force field (shown by arrows) in a polydisperse particle aggregate during drying.*

#### 4. Conclusion

A new discrete pore network model has been developed to investigate the fluid flow problem in dense particle aggregates consisting of spherical particles. The proposed approach integrates the pore assembly method with DEM. The aggregate was first generated using DEM based on given micro-scale properties, i.e. porosity, geometrical dimension and particle size distribution. Then, a numerical algorithm is developed to solve the fluid flow problem for the case of convective drying. It was shown that the developed model is capable of capturing the typical characteristic of this classical drying problem, i.e. constant rate period, falling rate period. Moreover, the obtained liquid distribution is then used as an input for calculating the capillary force field exerting on each particle of the aggregate. This is the first

step to couple the fluid flow model with DEM in order to simulate the thermo-mechanical behavior of *polydisperse* particle aggregates during drying.

## 5. Nomenclature

$\dot{M}$	Mass flow rate	$\text{kg s}^{-1}$
A	Area of cross section	$\text{m}^2$
L	Distance between the center of two adjacent pore bodies	m
p	Atmospheric pressure	Pa
$\tilde{M}$	Molar mass	$\text{kg kmol}^{-1}$
$\tilde{R}$	Ideal gas constant	$\text{J kmol}^{-1} \text{K}^{-1}$
T	Temperature	K

Greek letters

$\delta$	Vapor diffusivity	$\text{m}^2 \text{s}^{-1}$
$\gamma$	Surface tension	$\text{Nm}^{-1}$

Subscripts

v	vapor

### **Abstract**

*To validate the particle motion in flighted rotating drum (FRD), a laboratory FRD was built and operated at 15% filling degree and 10 rpm rotation speed using plastic balls as bed material. The particle tracking velocimetry (PTV) and magnetic particle tracking (MPT) techniques were applied to investigate the particle flow behavior. The 3D particle flow was modeled by Discrete Element Method (DEM) with LIGGGHTS. The height of the barycenter for overall particles and particle instantaneous velocity were calculated from PTV and DEM data. The 3D time-averaged particle velocity distribution obtained from MPT experiment and DEM simulation was compared.*

**Keywords:** *flighted rotating drum; particle motion; particle tracking velocimetry; magnetic particle tracking; DEM simulation.*

## 1. Introduction

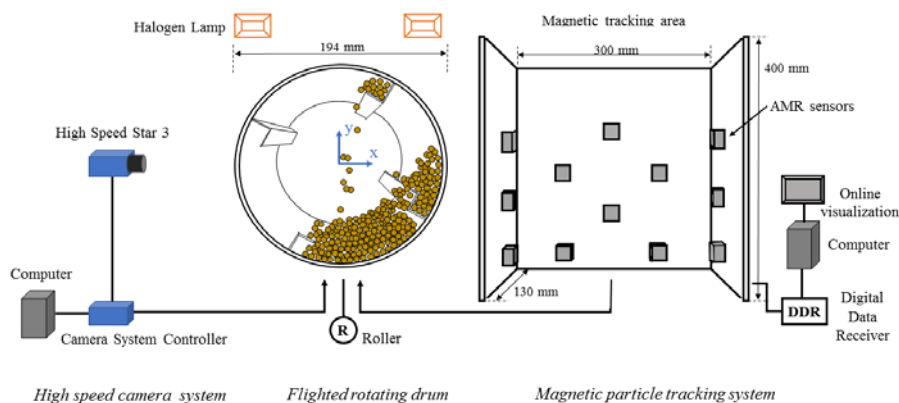

Flighted rotary drum (FRD) has been widely used in food and mineral industries for drying or cooling processes, as flights lift up particles and give them a higher chance to contact with gas. In last decades, much work has been carried out on FRD including particle mixing behavior, residence time distribution and discharge characteristics of flights [1]. However, few papers reported on particle movement, which is closely related to drying or cooling performance of drum. This is perhaps due to the limitation of experimental conditions and the complicated particle motion.

In order to investigate the characteristics of particle movement in FRD, particle tracking velocimetry (PTV) technique was utilized in current work to provide detail information of particle distribution and instantaneous velocities. Moreover, the magnetic tracking technique (MPT) was applied to evaluate particle velocity distribution in 3D. To simulate the particle motion, a 3D DEM model was developed, and the results obtained were compared with experimental data.

## 2. Materials and Methods

### 2.1. Experimental setup

The experimental setup consisted of a laboratory FRD, a high-speed camera system, and a magnetic tracking system as Fig. 1 schematically depicts.

*Fig. 1 Sketch of experimental setup, including a flighted rotating drum (middle), a high-speed camera system (left) and a magnetic particle tracking system (right).*

#### 2.1.1. Flighted rotating drum (FRD)

Figure 1 shows the horizontally placed drum with inner diameter of 194 mm and length of 150 mm. Four rectangular flights were installed with a flight-length-ratio of 1.0. Fine sand (0.1 - 0.3 mm) was glued on inner wall to prevent particle slippage; but end walls were kept

smooth and transparent. The drum was made of acrylic glass, flights were made of aluminum. Spherical plastic balls were used as bed material with a diameter of  $d_p=6$  mm and a bulk density of  $\rho_b = 596$  kg/m<sup>3</sup>. The experiments were conducted at 15% filling degree (volume based) and 10 rpm of drum rotating speed.

### 2.1.2. High-speed camera system

A high-speed camera system including a Photron high-speed camera (LaVision, CMOS chip) and a DaVis image acquisition software (LaVision) were used. Detailed parameters of the image system are listed in Table. 1. Two continuous illuminating 400 W halogen lamps

*Table 1. Parameters of the image system.*

Parameters	Value	Unit
Display resolution	1024 × 1024	pixel
Frame rate	500	fps
Exposure time	1/11,000	s
Dynamic range	10	bit
Local length	60	mm
<i>f</i> -number	2.8	-

were utilized to provide sufficient light, as shown in Fig. 1. The camera was positioned in front of the drum and adjusted to get a full view field of drum with  $200 \times 200$  mm<sup>2</sup>. With this setting, an approximate spatial resolution scale factor  $S_f$  of 5.17 pixel/mm was obtained from the standard geometry calibration process in the DaVis software. The experiment lasted 19.2 s with a number of 9600 images, which was sufficient to represent the periodicity of particle flow in the FRD. The experiments were repeated three times.

### 2.1.3. Magnetic tracking system

In the magnetic tracking system, 12 Anisotropic Magneto Resistive (AMR) sensors were installed on three acrylic glass plates, which provided a closed tracking volume of 300 mm × 400 mm × 130 mm as shown in Fig. 1. The sensors were arranged and calibrated to provide an optimal measurement of the magnetic field strength. All sensors were connected to a data acquisition device, which recorded data and sent them to a lab computer via USB interface. Online visualization and data evaluation were achieved by associated software ‘MagDat’ and ‘MagCal’, respectively.

## 2.2. Measurement techniques

### 2.2.1. Particle tracking velocimetry

The particle tracking velocimetry (PTV) is a non-intrusive, image-based measurement technique to acquire particle velocities. By combining particle segmentation and tracking algorithms, a large number of particles could be tracked simultaneously.

The particle-mask correlation method was applied to identify and determine the positions (coordinates  $x$  and  $y$ ) of individual particles [2, 3]. A template particle matrix ( $m \times m$  pixels), a key parameter in this process, was defined with the size of  $d_p \cdot S_f$  pixels (rounding down to the nearest even number). The value of template matrix was averaged from 20 template particles that were selected manually. Then, a tracking algorithm named probability relaxation method was utilized to establish particle trajectories by tracking particle positions in consecutive image frames [3, 4]. During this process, three radiuses - the maximum displacement radius, neighboring radius and the quasi-rigidity radius - were defined as  $1.2 \cdot U_{\max} \cdot S_f \cdot \Delta t$ ,  $1.0 \cdot U_{\max} \cdot S_f \cdot \Delta t$  and  $0.12 \cdot U_{\max} \cdot S_f \cdot \Delta t$  pixels, to search candidate particles and neighboring particles in the 1<sup>st</sup> or 2<sup>nd</sup> frame. The  $U_{\max}$  was calculated based on the particle velocity during free fall in gas.

### 2.2.2. Magnetic tracking technique

The magnetic monitoring is based on continuous tracking of the magnetic marker. The evaluation of the measured data provides accurate information about the movement of tracer and, thus, enables investigating particle motion in a dense granular bed [5]. In this work, a 5 mm long cylindrical neodymium-iron boron with diameter of 3 mm was used as the magnet. By embedding it into a plastic ball, the tracer kept the same shape and size with other particles. With a measuring frequency of 250 Hz, the MPT system could record the Cartesian coordinates  $x$ ,  $y$ ,  $z$  of tracer every 6 ms. One experiment lasted 6 minutes and was repeated three times.

### 2.3. Discrete element method (DEM) simulation

In the current work, the open source software LIGGGHTS was adopted for the DEM simulation. The motion of each particle in the Lagrangian framework was calculated by the Newton's second law with ignoring the particle-fluid interaction due to the big density difference between particle and gas phase. Based on a filling degree of 15% in the experiment, 3474 particles were inserted into the simulation chamber as shown in Fig. 2.

Fig. 2 Snapshot of particle distribution in the DEM simulation.

The particle interactions were calculated by the Hertzian contact model with tangential history tracking [6]. In this soft-sphere contact model, the effect of spring and dash-pot

appear through stiffness  $\kappa$  and damping coefficient  $\eta$ , which were determined by the physical material properties of Poisson ratio  $\sigma$ , Young's modulus  $E$  and the coefficient of restitution  $e$ . The detailed material properties of particles are listed in Table. 2. DEM simulation was run for 120 s in total, but only from the last 30 s data was extracted at 0.002 s intervals for further analysis.

**Table 2. Material properties and model parameters for DEM simulation.**

Parameters	Value	Unit
Young's modulus $E$ [7]	$10^7$	Pa
Poisson ratio $\sigma$	0.3	-
Rolling coefficient $\kappa_r$ [8]	0.01	-
Coefficient of restitution $e$ [9]	0.68	-
Friction coefficient $\mu_f$ [10]	0.2	-
Time step $\Delta t_{\text{DEM}}$	$5 \times 10^{-6}$	s
Simulation time $t_{\text{sim}}$	120	s

## 2.4. Post-processing of experimental and simulation data

### 2.4.1. Barycenter calculation

To describe the location of the overall particles in the FRD, the barycenter  $r_c$  was used as calculated from Equation (1a). The  $r$  represents the particle coordinates value  $x$ ,  $y$  or  $z$ . The  $m_i$  denotes the mass of particle  $i$  and  $n$  the particle number. Considering that the plastic balls are regular spheres with uniform density, the equation is simplified as Equation (1b).

$$r_c = \frac{\sum_{i=1}^n m_i \cdot r_i}{\sum_{i=1}^n m_i} \quad (\text{a}); \quad r_c = \frac{\sum_{i=1}^n r_i}{n} \quad (\text{b}); \quad (1)$$

### 2.4.2. Particles velocity calculation

The particle instantaneous velocity was calculated from the particle coordinates  $r(t_2)$  and  $r(t_1)$  for the case  $t_2 \rightarrow t_1$  by Equation (2). With the spatial velocity components  $v_x$ ,  $v_y$  and  $v_z$ , the total particle velocity can be determined by Equation (3) in 3D.

$$v(t_1) = \lim_{t_2 \rightarrow t_1} \frac{r(t_2) - r(t_1)}{t_2 - t_1} \quad (2)$$

$$v_{3D}(t) = \sqrt{v_x(t)^2 + v_y(t)^2 + v_z(t)^2} \quad (3)$$

## 3. Results and Discussion

### 3.1. Barycenter migration

Due to the pushing force of the flights, the position of the overall particles was raised increasing the particle-gas contact and, thus, heat transfer. Figure 3 represents the

normalized Y coordinate of the barycenter for overall particles over time for two drum rotations (12 s duration) as obtained from the PTV measurement and DEM simulation. As the figure illustrates, the barycenter rotated every 1.5 s corresponding to a quarter of one rotation of the flights. Furthermore, the DEM data agreed well with the PTV measurement.

**Fig. 3** Normalized Y coordinate value of particles barycenter in 12 s duration time (two rotating circles) by PTV method and DEM model.

### 3.2. Particle instantaneous velocity

Figure 4 shows the particle instantaneous velocity fields from PTV measurement and DEM simulation for the flight positions of  $0^\circ$ ,  $30^\circ$ ,  $60^\circ$  to the horizontal, respectively.

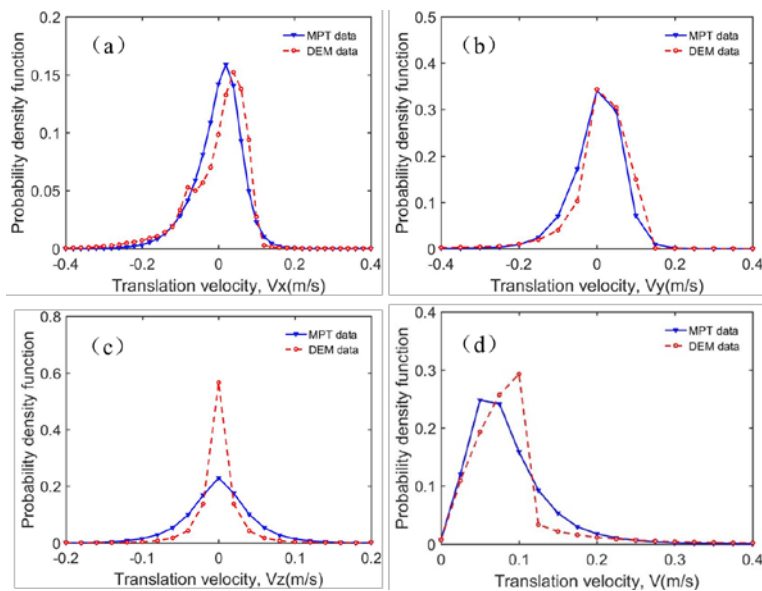

**Fig. 4** Instantaneous particle distribution (a1-a3) and velocity vectors from PTV measurement (b1-b3) and DEM model (c1-c3) at the time of 0 s (a1, b1, c1), 0.5 s (a2, b2, c2) and 1.0 s (a3, b3, c3).

Since the PTV is limited to 2D studies, the particles located in the first layer behind the front plate were chosen in DEM simulation to generate the particle velocity fields. The figures a1-a3 show the images of instantaneous particle distributions. The vortex in the dense phase at the bottom is clearly visible in Fig. 4 b1-b3 and c1-c3. The passive phase on flights presented a relatively homogeneous velocity distribution as they moved synchronous with the rotating wall. It is important to notice that, with different location of the flights, not only the position of vortex center dynamically changes but also the thicknesses of active and passive layers. This effect greatly accelerates the mixing of dense phase and, thereby, the heat transfer. The DEM data are in good agreement with PTV data.

### 3.3. Particle velocity distribution

Considering that PTV is limited to 2D, the 3D time-averaged and normalised velocity distributions were compared between MPT and DEM data in Fig. 5 to further validate particle motion in the FRD.

**Fig. 5** Probability density distribution of particle translational velocity components by MPT measurement and DEM simulation: (a)  $V_x$ ; (b)  $V_y$ ; (c)  $V_z$ ; (d) total velocity  $V$ .

It should be noted that the MPT data was obtained from 18 mins (three repeated experiments) to ensure a high accuracy of data distribution. While, due to computational limitations, the data from all particles (3,474 in total) were chosen from the last 30 s (5 rotating circles) of the DEM simulation for comparison. For radial velocity  $V_x$  and  $V_y$ , very similar distributions were obtained from MPT and DEM data, see Fig. 5a, b. The curves are asymmetric in shape which may be due to the influence of flights. Whereas, the axial velocity distribution  $V_z$  shows symmetry (Fig. 5c). Furthermore, the DEM data display a narrower distribution and a sharper peak. Potential reason for this difference could be attributed to the collision model selected in DEM. The total velocity distribution of the

MPT and DEM data show a comparable trend in lower velocity region, but apparent differences in higher velocity region, as shown in Fig. 5d. In general, there is reasonable agreement in the velocity distribution between MPT experiment and DEM model.

#### **4. Conclusion**

To investigate the particle motion in the FRD, two experiment techniques, PTV and MPT, were applied. The particle motion was modeled by using the DEM. A periodically upward movement of particles was confirmed. Moreover, the position of the vortex generated in dense phase varied over time, and the particle transient velocity distributions displayed asymmetric profiles. All these effects are caused by the flights. In addition, the DEM results agreed well with the PTV and MPT measurements.

### **Abstract**

*Lignite is a domestic strategic reserve of low rank coals in many countries for its abundant resource and competitive price. Combustion for power generation is still an important approach to its utilization. However, the high moisture content always results in low efficiencies of lignite-direct-fired power plants. Lignite pre-drying is thus proposed as an effective method to improve the energy efficiency. The present work focuses on the flue gas pre-dried lignite-fired power system (FPLPS), which is integrated with fan mill pulverizing system and waste heat recovery. The thermo-economic analysis model was developed to predict its energy saving potential at design conditions. The pre-drying upgrade factor was defined to express the coupling of pre-drying system with boiler system and the efficiency improvement effect. The energy saving potential of the FPLPS, when applied in a 600 MW supercritical power unit, was determined to be 1.48 %-pts. It was concluded that the improvement of boiler efficiency mainly resulted from the lowered boiler exhaust temperature after firing pre-dried low moisture content lignite and the lowered dryer exhaust gas temperature after pre-heating the boiler air supply.*

**Keywords:** lignite; pre-drying; thermodynamic analysis; thermo-economics.

## **1. Introduction**

Lignite is still considered as a domestic and abundant energy source for many countries. [1] Power generation is an important approach to utilization of lignite resources. However, the high moisture content always results in low efficiencies of lignite-direct-fired power plants. Pre-drying is an effective method to improve the energy efficiency because it removes the redundant moisture and increases the heating value of the lignite entering the furnace. [2,3]

Many works have been performed concerning the performance analysis of the pre-dried lignite-fired power systems (PLPSs) based on energy and exergy criteria and/or economic and environmental indicators. In China, Liu et al. [4] conducted process modeling of the steam pre-drying power system using Aspen Plus, and investigated the exergy destruction distributions of a 600 MW unit under nominal and partial loads. Moreover, biomass pre-drying [5] and solar pre-drying [6] were studied, respectively, to further demonstrate the energy saving potential of pre-drying. Zhu et al. [7] carried out an energy analysis of a lignite steam pre-drying power system with an efficient waste heat recovery system. Xu et al. [8] modeled a lignite power system integrated with boiler exhaust gas pre-drying, and analyzed the energy saving potentials with different lignite types and pre-drying degrees. Recently, different configurations of solar pre-drying were proposed by Xu et al. [9] The selection of drying heat source is gradually extended to renewable energy sources, which aims to further improve the energy efficiency of low rank coals. In Greece, Atsonios et al. [10] examined various scenarios of lignite drying and utilization depending on power load variation of the plant during certain periods of the day, in order to simultaneously increase the plant efficiency and reduce the electricity cost. Rakopoulos et al. [11] assessed different lignite-fired plant configurations for combined heat and power production for use in district heating networks, in terms of environmental, technical, and economic criteria. Avagianos et al. [12] presented a thermodynamic methodology for the prediction of lignite fired boilers at low power loads; even below the current technical minimum, when pre-dried lignite is employed. Drosatos et al. [13] conducted numerical simulation of a lignite-fired boiler using pre-dried lignite as supporting fuel for flexible operation. As summarized by Agraniotis et al. [14], state-of-the-art lignite pre-drying technologies can not only improve the energy efficiency but also operation flexibility. Energy saving of lignite pre-drying also attracts other researchers worldwide lately. For example, Fushimi et al. [15] developed drying process based on self-heat recuperation technology and evaluated the thermal efficiency penalty and costs. Kambara et al. [16] compared the thermal efficiencies for an existing 316 MWe power plant with and without steam tube dryers (STDs), and found that the improvement can be up to 4.2 %-pts. Giuffrida et al. [17] presented a detailed analyses based on mass and energy balances of lignite-fired air-blown gasification-based combined cycles with CO<sub>2</sub> pre-combustion capture. Akkoyunlu et al. [18] carried out an economic assessment of drying prior to grinding mill process in lignite-fired thermal power plants. It was indicated that the growth in the boiler efficiency ranged between 3.9-12.6% when there

was a 10% decrease in moisture content. Moon et al [19] developed a combination of low rank coal drying with power generation, and investigated the influences of steam extraction point and amount of drying coal on the thermal efficiency. In brief, an agreement has reached that pre-drying can improve the efficiency of lignite power generation, but system optimization still requires specifications and methodologies.

The authors have reported earlier predicted energetic performance of the FPLPS at off-design conditions [20] and suggested possible performance improvement through the energy matching in the drying process [21]. It is necessary to provide a comprehensive idea of technical and economic feasibility of lignite pre-drying. The major objective of this study is thereby to be a demonstration of a detailed thermo-economic analysis of flue gas mill pre-drying concept. It is continuation of works associated with lignite pre-drying power systems.

## 2. Materials and Methods

### 2.1. System Layouts

A conceptual schematic of the FPLPS system is depicted in Fig. 1. The common features of the FPLPS include the use of flue gas as drying agent in the drying tubes and fan mills, the integration of an open pulverizing system with the boiler, the concentration of water vapor in the dryer exhaust gas, and the air pre-heating by the dryer exhaust gas. More specifically, the flue gas dryer exhaust gas, containing a large amount of water vapor, is not recycled to the furnace but led to the heat recovery system, in which the waste heat is utilized to pre-heat the air supply of the boiler.

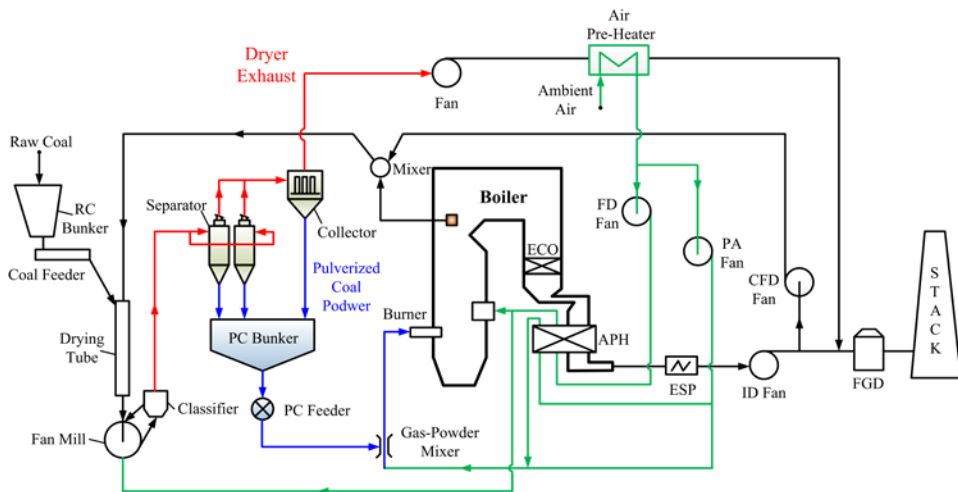

Fig. 1. System layout of the FPLPS.

### 2.2. Thermo-economic analysis model

Raw lignite is fed into the dryer, in which a part of the moisture content is removed and the heat supply is basically conserved with the latent heat of moisture evaporation  $\Delta M \cdot h_v$ . Accordingly, the LHV of the pre-dried lignite is derived as:

$$\text{LHV}_{\text{pc}} = (\text{LHV}_{\text{ar}} + \Delta M \cdot h_v) / (1 - \Delta M) \quad (1)$$

where  $\Delta M$  is the mass of evaporated moisture per kg raw lignite ( $\text{kg} \cdot \text{kg}^{-1}$ ), also defined as **pre-drying degree**, and  $h_v$  is the water latent heat of vaporization.

$$\Delta M = (M_{\text{ar}} - M_{\text{pc}}) / (100 - M_{\text{pc}}) \quad (2)$$

where  $M_{\text{ar}}$  and  $M_{\text{pc}}$  are the moisture contents in the raw and pre-dried lignite, respectively.

The moisture content of pre-dried lignite can be calculated as:

$$M_{\text{pc}} = 0.048 \cdot M_{\text{ar}} \cdot R_{90} \cdot t_{\text{de}}^{-0.46} \quad (3)$$

In the present work, a dimensionless **pre-drying upgrade factor** is defined as:

$$k_{\text{pd}} = 1 + \Delta M \cdot h_v / \text{LHV}_{\text{ar}} \quad (4)$$

In this way, boiler efficiencies on different basis can be derived as:

$$\eta_{\text{b},t_{\text{ref}}=t_0} = k_{\text{pd}} \cdot \eta_{\text{b},t_{\text{ref}}=t_{\text{sp}}} \quad (5)$$

The plant thermal efficiency,  $\eta_{\text{tot}}$ , can be calculated by the combined product of the efficiencies of the main components, and is expressed as follows:

$$\eta_{\text{tot}} = \eta_{\text{b}} \eta_{\text{p}} \eta_{\text{sc}} \eta_{\text{m}} \eta_{\text{g}} \quad (6)$$

where  $\eta_{\text{b}}$  is the boiler efficiency ( $t_0$  basis),  $\eta_{\text{p}}$  the heat supply pipe efficiency,  $\eta_{\text{sc}}$  the steam cycle efficiency,  $\eta_{\text{m}}$  the mechanical efficiency, and  $\eta_{\text{g}}$  the electric generator efficiency.

The plant thermal efficiency improvement,  $\Delta\eta_{\text{tot}}$ , is calculated as:

$$\Delta\eta_{\text{tot}} = \eta_{\text{tot},\text{FPLPS}} - \eta_{\text{tot},\text{CLPS}} \quad (7)$$

### 3. Results and Discussion

#### 3.1. Case Study

##### 3.1.1. Benchmark parameters

To evaluate the energy saving potential of the FPLPS comprehensively, simulation calculations on a 600 MW water-cooled supercritical unit were carried out based on the simulation algorithm introduced above. Detailed specifications in simulation and calculation, such as the thermal parameters of the heat regenerative system, can be found in Ref.[21]. The properties of the Chinese Yimin lignite, with 39.5% moisture content are given in Table 1.

Table 1. Properties of Chinese Yimin lignite

$M_{\text{ar}}$ , %	$A_{\text{ar}}$ , %	$C_{\text{ar}}$ , %	$H_{\text{ar}}$ , %	$O_{\text{ar}}$ , %	$N_{\text{ar}}$ , %	$S_{\text{ar}}$ , %	LHV, $\text{MJ} \cdot \text{kg}^{-1}$
39.50	12.09	34.59	2.03	11.30	0.35	0.14	11.79

To conduct thermodynamic analysis, it is firstly necessary to determine the moisture content of pre-dried lignite with given parameters. According to the empirical correlation (Eq.1), the moisture content after grinding and milling can be obtained, as a function of pre-drying degree and  $R_{90}$  (Fig. 2).  $M_{\text{pc}}$  is calculated as 9.82% when  $t_{\text{de}}$  equals 110 °C. The heating value can also be calculated, as shown in Fig. 3. The HHV and LHV are elevated by 49.1% and 59.5%, respectively. Obviously, with higher pre-drying degree, the rank of

the lignite is improved. The plant efficiency benefit is expected. As summarized in Table 2, compared with conventional lignite-fired power system (CLPS), the plant thermal efficiency can be improved by 1.48 %-pts.

Fig. 2.  $M_{pc}$  in terms of  $R_{90}$  and  $t_{de}$ .

Fig. 3. Heating value in terms of  $\Delta M$ .

Table 2. Comparison of the parameters and thermo-economics of the CLPS and FPLPS

Items	Unit	CLPS	FPLPS
Boiler exhaust temperature, $t_{be}$	°C	144	110
Air pre-heating temperature, $t_{ap}$	°C	-	55
Dryer exhaust temperature, $t_{de}$	°C	150	110
Boiler efficiency on $t_{ap}$ basis, $\eta_{b,t_{ref}=t_{ap}}$	%	-	89.49
Pre-drying upgrade factor, $k_{pd}$	-	-	1.07
Boiler efficiency on $t_0$ basis, $\eta_{b,t_{ref}=t_0}$	%	92.59	95.76
Steam cycle efficiency, $\eta_i$	%	47.67	47.67
Plant thermal efficiency, $\eta_{tot}$	%	43.26	44.74

### 3.1.2. Thermodynamic analysis

The joint influences of boiler exhaust temperature ( $t_{be}$ ), dryer exhaust temperature ( $t_{de}$ ), air pre-heating temperature ( $t_{ap}$ ) on the energy efficiency improvements are depicted in Fig. 4. It can be seen in Fig. 5 that the plant efficiency improvement varies with  $t_{be}$ ,  $t_{de}$ , and  $t_{ap}$  linearly. The  $\Delta\eta_{tot}$  increases by 0.09 %-pts when  $t_{de}$  decreases by 10 °C, 0.18 %-pts when  $t_{be}$  decreases by 10 °C, and 0.16 %-pts when  $t_{ap}$  increases by 10 °C. To sum up, the decrease of  $t_{de}$ ,  $t_{be}$  and increase in  $t_{ap}$  contribute to the total  $\Delta\eta_{tot}$  by 0.38 %-pts, 0.62 %-pts, and 0.48 %-pts, respectively.

The pre-drying upgrade factor ( $k_{pd}$ ) is defined in the present work to demonstrate the energy saving mechanism of pre-drying from energy analysis perspective. It is shown in Fig. 6 that the  $k_{pd}$  increases linearly with the pre-drying degree ( $\Delta M$ ) with given lignite properties. It is calculated as 1.07 for Yimin lignite, which means that the boiler efficiency is increased by 7%. The  $k_{pd}$  increases by 0.02 with 0.1 kg.kg<sup>-1</sup> increase in  $\Delta M$ . As a result, the boiler efficiency increases with the pre-drying degree (Fig. 7).

Fig. 4. Schematic of the key temperatures in FPLPS.

Fig. 5. Influence of  $t_{be}$ ,  $t_{de}$ , and  $t_{ap}$  on  $\Delta\eta_{tot}$

Fig. 6.  $k_{pd}$  as a function of  $\Delta M$ .

Fig. 7. Boiler efficiencies in terms of  $\Delta M$ .

### 3.2. Parametric analysis

Apart from the key temperatures above, the plant efficiency improvement also depends on drying process parameters. Pre-drying degree and dryer efficiency are the parameters, from the perspectives of moisture removal and thermal conversion, respectively. The uncertainty in the calculation of the moisture content should be taken into consideration, as well as the dryer efficiency. Therefore, it is necessary to investigate the variations of the improvement.

#### 3.2.1. Influence of pre-drying degrees

It is shown in Fig. 8 that the  $\Delta\eta_{tot}$  increases  $\Delta M$  linearly. Moreover, the slope increases with  $t_{be}$ . It means that for lignite-fired boilers with high exhaust temperature, the energy saving potential is remarkable. For example, when  $t_{be}$  is equal to 144 °C and 110 °C, respectively, the  $\Delta\eta_{tot}$  increases by 0.12 %-pts and 0.05 %-pts, with 0.1 kg·kg<sup>-1</sup> increase in  $\Delta M$ .

#### 3.2.2. Influence of dryer efficiency

The dryer efficiency influences the energy saving potential significantly, as shown in Fig. 9. When the dryer efficiency drops below the design value, the  $\Delta\eta_{tot}$  decreases sharply. Especially, there exist critical dryer efficiencies with given boiler exhaust temperature. For example, when  $t_{be}$  is equal to 144 °C, the  $\eta_{d,cri}$  is approximately 80%. When the dryer efficiency gets lower than that, the FPLPS does not save coal any more. It can be attributed to the fact that although  $k_{pd}$  does not change with dryer efficiency, the heat load of the dryer increases with decreasing dryer efficiency and the boiler efficiency drops.

Fig. 8.  $\Delta\eta_{tot}$  as a function of  $\Delta M$ .

Fig. 9.  $\Delta\eta_{tot}$  as a function of  $\eta_a$ .

#### 4. Conclusions

A theoretical framework of modeling and thermo-economics on lignite pre-drying is presented in the present work, which offers a comprehensive idea of economic feasibility of lignite utilization integrated with flue gas fan mill pre-drying. The main conclusions are:

- 1) A pre-drying upgrade factor was defined to decouple the drying and boiler systems. When the moisture content decreased from 39.5% to 9.82%, the pre-drying degree was 0.33 kg·kg<sup>-1</sup>, and pre-drying upgrade factor was calculated to be 1.07. As a result, the plant thermal efficiency improvement of the FPLPS compared with CLPS can be up to 1.48 %-pts, when the boiler exhaust gas temperature, the dryer exhaust gas temperature and the air pre-heating temperature were set as 110 °C, 110 °C, and 55 °C, respectively.
- 2) Through parametric analyses, the contributions of key design temperatures and pre-drying conditions to the energy saving potential of the FPLPS were analyzed. Results showed that the plant efficiency improvement resulted from pre-drying and air supply pre-heating increased by 0.09 %-pts, 0.16 %-pts, and 0.18 %-pts with 10 °C increase in the dryer exhaust temperature, 10 °C decrease in the air pre-heating temperature, and 10 °C decrease in the boiler exhaust temperature, respectively.

### **Abstract**

*In order to conserve *cuminum cyminum L.* during long storage periods, the drying kinetics of this seed undergoing microwave-assisted fluidized bed dryer at various microwave output power (300, 600 and 900w), air velocity (10, 15 and 20 m/s) and air temperatures (45, 55 and 65°C) were studied. The main aim of this research is developing a mathematical model of mass transfer to investigate the microwave-assisted fluidized bed drying of *cuminum cyminum L.* seed. In this paper, we tried to discover a good model to evaluate moisture effective diffusivity ( $D_{eff}$ ).*

**Keywords:** *cuminum cyminum L.*, microwave-assisted drying, mathematical modeling,

## 1. Introduction

Cumin (*cuminum cyminum*) is one of the functional and valuable spices in food preparations. It is popular for its strong, sweet aroma and slightly bitter taste. In addition to its seasoning application, its pharmaceutical properties are influential. Cumin name originally derived from the Greek word “kyminon”. Several functional benefits of cumin consumption are: hypolipidemic, digestion stimulating, antispasmodic, wound-healing, anti-microbial, anti-oxidant, carminative and anti-inflammatory agent. Ground cumin is commonly used in Iranian culinary and confectionary, meaty Moroccan foods and classic German foods [1-4]. Iran was among the countries that devote themselves to the large surface area of the land was cultivated cumin, and its production in this area was about 12,000 tons per year [5].

Drying is frequently used in agricultural and food processing. Essential oils are important part in herbs, due to their importance and thermal sensitivity they have to be dried at moderate thermal condition and short time [6]. Fluidized bed drier has high thermal efficiency in solid drying. Direct contact between samples and heating medium leads to simultaneous as well as rapid heat, and mass transfer. However conductive heat transfer from surface to the inside of materials is still slow. This may be solved by using microwave assisted fluidized bed drier. This article focuses on mathematical modeling of cumin as an assumed cylindrical shaped seed, dried undergoing various treatment in order to assess water loss procedure.

## 2. Materials and Methods

### 2.1. Drying procedure

Cumin seeds were purchased from local grocery in Karaj city (north of Iran) in October. At first they were cleaned manually then got uniformed by a sieve having 20 meshes. Predetermined amount of water added to a certain quantity of samples obtain determined moisture content. A pilot-scale microwave- assisted fluidized bed dryer was applied for dehydration experiments. For each test, 50 g cumin seeds slightly poured into drying dish to make them uniform. The drying tests were conducted at three levels of power (300, 600, 900w), air temperature (45, 55, 65°C) and air velocity (5, 7.5, 10 m/s) to reach a specific moisture content (5.66% d.b).  $V=4.5$  m/s is experimentally determined as the minimum fluidization velocity. Moisture ratio was calculated based on following equation [7]:

$$MR = \frac{M - M_e}{M_0 - M_e} \quad (1)$$

*Table.1 independent variables*

Factor	Name	Units	Minimum	Maximum	Mean
A=X <sub>1</sub>	temperature	°c	45	65	55
B=X <sub>2</sub>	Microwave power	w	300	900	600
C=X <sub>3</sub>	Air velocity	m/s	10	20	15

**2.2. Mathematical modelling and Moisture diffusivity determination**

In order to facilitate the calculation of the effective diffusion coefficient, a new method was designed and developed. In this case, the oval shaped cumin seed was considered as a cylinder with the surface are a similar to the elliptical cumin seed. So firstly, side surface area of elliptical cumin particles were calculated by circulating equation (2) around horizontal “a” axis (fig 1) [8].

*Figure 1. Cumin seed scheme for the model geometry*

$$s = 2\pi \int_0^a y\sqrt{1 + y'^2} dx \tag{2}$$

For an entire ellipsoid:

$$s = 4\pi \int_0^a y\sqrt{1 + y'^2} dx \tag{3}$$

Then via equating ellipsoid surface area with cylinder surface area, the radius (r<sub>c</sub>) was calculated from following equation:

$$2\pi r_c(2a) + 2\pi r_c^2 = 2\pi ab \left[ \frac{\text{Arcsin}\sqrt{a^2 - b^2}}{\sqrt{a^2 - b^2}} + \frac{b}{a} \right] \tag{4}$$

Large radius of 20 seeds were measured by digital caliper with an accuracy of 0.01 mm (Mitutoyo, Japan) and their average value was considered as ‘a’ factor in above equation.

Water loss process during solid dehydration consists of several complex mechanisms. With regard to this fact, Fick's second law effective diffusivity have been considered as a combination of mentioned mechanisms [6, 9].

$$\frac{\partial M}{\partial t} = \text{Div}[D_{\text{eff}}(\text{grad}M)] \quad (5)$$

Initial and boundary conditions of eq (9) with ignoring shrinkage are defined as follow:

$$t = 0, \quad M = M_0$$

$$t > 0, \quad r = 0, \quad \frac{\partial M}{\partial r} = 0$$

$$t > 0, \quad r = r_c \quad \text{and} \quad z = L, \quad M = M_e$$

Fickian equation solution could be simplified to infinite slab and cylinder and finite cylinder by assuming the first part in series expansion of their equation respectively [9, 10]:

$$MR_{is} = \frac{M - M_e}{M_0 - M_e} = \frac{8}{\pi^2} \exp(-B_{is}t) \quad (6)$$

$$MR_{ic} = \frac{M - M_e}{M_0 - M_e} = \frac{4}{\beta_1^2} \exp(-B_{ic}t) \quad (7)$$

$$MR_{fc} = \frac{M - M_e}{M_0 - M_e} = \frac{32}{\pi^2 \beta_1^2} \exp(-B_{fc}t) \quad (8)$$

Wherein:

$$B_{is} = \pi^2 D_{\text{slab}} / L^2 \quad (9)$$

$$B_{ic} = \beta_1^2 D_{\text{cyl}} / r_c^2 \quad (10)$$

$$B_{fc} = \frac{\pi^2 D_{\text{slab}}}{L^2} + \frac{\beta_1^2 D_{\text{cyl}}}{r_c^2} \quad (11)$$

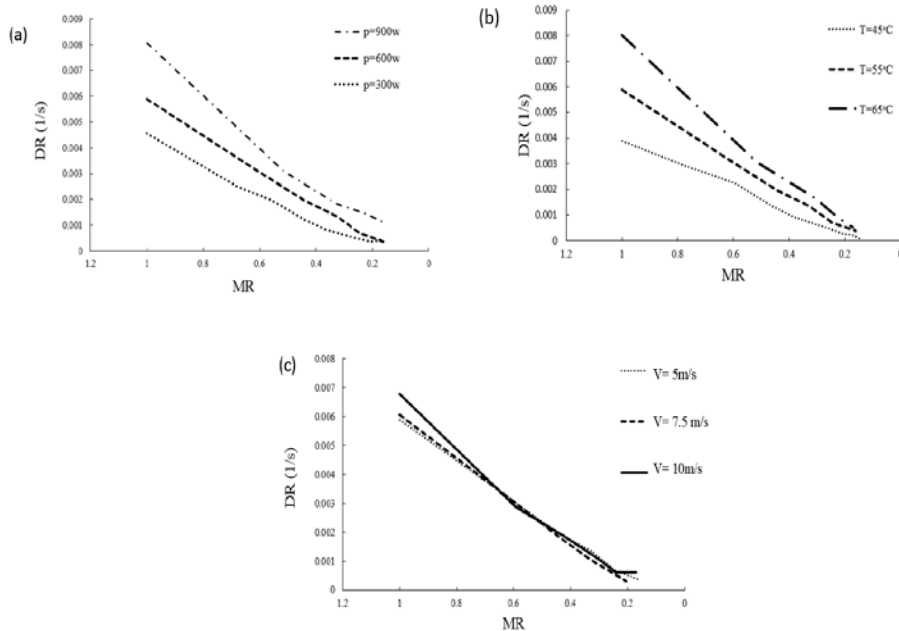

Where  $D_{\text{slab}}$  and  $D_{\text{cyl}}$  are the moisture diffusivities that were assumed equal.  $L$  and  $r_c$  are the real length of cumin seed and the computed radius of the cylinder in eq (4) in the order given and  $\beta_1=2.4048$  was obtained from the tables of the first kind of zero order Bessel function ( $J_0(\alpha_n)=0$ ) [10]. The constant  $B$  can be determined by plotting  $\ln(MR)$  against drying time (s) for any experiment.

### 3. Results and discussion

#### 3.1. Drying kinetic

The Cumin samples ( $M_0 = 35.44\%$  (d.b)) were dried to  $M = 5.66\%$  (d.b). Central composite design (CCRD) with three independent variables includes microwave output power, air temperature, air velocity, on three levels, at the central point plan was applied. As expected, moisture content kept decreasing by increasing drying time, temperature and microwave power, (fig.2 a and b). In table.2 drying rate values based on different test conditions, are provided. During microwave heating, water components due to their higher dielectric loss factor, absorb a greater amount of microwave energy and reach the boiling temperature, consequently the pressure in the interior of the material develops, this causes the moisture to move from the inside to the surface [11, 12]. At first, internal heating caused by microwave, moves liquid water towards surface of samples (Darcy's law). With the progress of the drying procedure, internal moisture supply is not able to provide the surface evaporation process. Thus, after this stage, dehydration is driven by vapor diffusion and Darcy's flow [13]. As can be seen in fig.2c, air flow rate increase to more than minimum fluidization velocity (15 m/s) has no effect on drying rate and drying time, because increasing air velocity, increases bed pressure drop.

**Fig.2 effect of microwave power (a:  $v=15\text{m/s}$ ,  $T=55^\circ\text{C}$ ) air temperature (b:  $p=600\text{w}$ ,  $v=15\text{m/s}$ ) and air velocity (c:  $p=600\text{w}$ ,  $T=55^\circ\text{C}$ ) on drying rate.**

From a certain speed onwards, the amount of pressure drop has been stabilized and there isn't much change in it. Constant pressure drop is due to change in the nature of the bed particles from fixed state to fluid state, so from this point on, pressure drop will be same as liquid static pressure drop and depend on height of bed [14].

### 3.2. Effective moisture diffusivity and activation energy

*Effective moisture diffusivity:* Radius value obtained from eq (8) is 0.373 mm. by using slope of fig.3 graphs and putting them in eq (15), effective moisture diffusivity under various test conditions was determined. The measured  $D_{eff}$  values for cumin seeds are presented in table.2.

As shown,  $D_{eff}$  values were ranged from  $3.820 \times 10^{-11}$  to  $2.746 \times 10^{-10}$  m<sup>2</sup>/s. This result is in accordance with results obtained from most food stuffs ( $10^{-12}$  - $10^{-8}$  m<sup>2</sup>/s) [15, 16]. It is observed that the highest amount of  $D_{eff}$  is related to P=900w and T=65°C and the lowest amount of  $D_{eff}$  is related to P=300w and T=45°C. It was observed that increasing the temperature of drying air and microwave power, increased the effective moisture diffusivity.

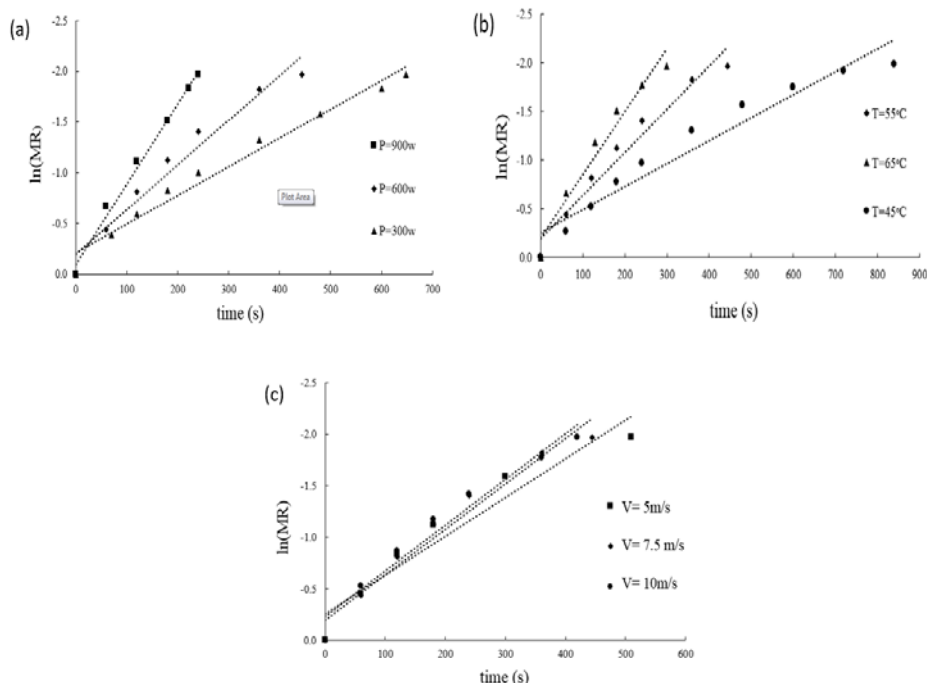

Fig.2 effect of microwave power (a: v=15m/s, T=55°C) air temperature (b: p=600w, v=15m/s) and air velocity (c: p=600w, T=55°C) on drying rate.

These results are in agreement with the results of microwave drying of pandanus leaves [17] and hot-air and microwave drying of pineapple [15] and fluidized bed drying of canola [16]. There is no significant effect of various velocity of drying air on slope of fig.3c and consequently on  $D_{eff}$  was observed. As mentioned earlier, this action is due to the mechanism of pressure drop during drying procedure.

**Table. 2 Amounts of DR, RMSE, SSE and  $D_{eff}$  of cumin seed undergoing different drying condition**

Microwave power (w)	Air temperature (°C)	Air velocity (m/s)	Drying rate (1/s)	$D_{eff}$ (m <sup>2</sup> /s) ×10 <sup>-10</sup>	R <sup>2</sup>

#### 4. Conclusion

Drying specifications of cumin seeds were assessed during microwave-assisted fluidized bed drying at various levels of air temperature, microwave power and air velocity. The entire dehydration process occurred in the falling rate period. Applying higher values of microwave output power, air temperature and air velocity enhanced drying rate and  $D_{eff}$ . Although increased to more than the minimum fluidization velocity of air flow rate, did not show a significant impact on drying rate. Simulation elliptical cumin seed to cylinder, to obtain  $D_{eff}$  and  $E_a$  offered good results with high amount of R<sup>2</sup>. Usage of RSM ensured that the selected factors had significant effect on responses and on each other as well. Increment in air temperature and air velocity used in this study, caused decrement in  $E_c$  value but microwave power affected on  $E_c$  in increasing manner. And finally optimum condition obtained by RSM offered that operating minimum fluidization velocity, maximum value of microwave power and air temperature, maximize drying rate value and minimize energy consumption value.

### **Abstract**

*Osmotic dehydration of apple was modeled considering the mechanisms involved in the solutes transfer within the plant matrix: impregnation and diffusion. The model mathematical writing includes the impregnation layer thickness, the diffusion thickness, a water bulk flow and the convective resistance. Apple cylinders were dehydrated at 30, 50 ° C and 30, 50 ° Brix and a motion of 0.15 m/s. The Reynolds number was of 250 for 30°C-30°Bx and 500 for 50°C-50°Bx. Schmidt numbers was of 4000 for 30 ° C-30 ° Bx and 4200 for 50 ° C-50 ° Bx.*

**Keywords:** *transfer; solute; impregnation; osmotic dehydration.*

---

## **1. Introduction**

The understanding of the mechanisms involved in the solutes transfer within the food is fundamental to develop a predictive model of the osmotic dehydration operation. The mechanisms present in the solute transport of the osmotic solution within the plant tissue have not been elucidated. The solute transfer models developed so far, describe the osmotic solution migration by calculating a global transfer coefficient that considers a gradient of solute concentration uniform inside the food, limiting the identification of the mechanisms involved: diffusion or impregnation (Muñiz and others, 2017).

These models apply Crank's solutions to Fick's law to determine the transfer coefficient and they suppose some simplifications that contradict experimental findings that show the presence of solutes concentrated layers on the material surface, particularly when saccharides and sweeteners are used as osmotic solutions, which are evidence of an unequal distribution of osmotic solution within the plant matrix (Assis and others, 2015; Seguí and others, 2012).

Unlike the models available in the literature that consider a global solute transfer coefficient, this work proposes a model that describes the mechanisms involved in the transfer of the solute within the plant matrix: impregnation and diffusion and assumes boundary conditions that they take in counts the effect of external and internal resistances in the fruit-osmotic solution interface.

## **2. Materials and Methods**

### **2.1. Boundary conditions for the modeling of solute transfer in osmotic dehydration.**

Apples samples were considered as slab and solute transported was assumed to occur in one direction. For boundary conditions the overall solute transfer process depend of the relationship of internal and external resistances in the osmotic solution-apple interface, determined by Reynolds and Schmidt numbers.

### **2.2. Movement velocity and dimensionless numbers.**

Apple samples were moved in a vertical in a vertical direction at frequency of 100 cycles/minutes about 0.15 m/s.

Solution movement was affected significantly by solute movement, therefore the interface resistance was not negligible. Thus at the solution-apple interface the boundary conditions is:

$$K(C_{\infty} - C_s) = -D_s \left( \frac{\partial C}{\partial x} \right)_s \quad (1)$$

K-mass transfer coefficient (m/s),  $C_{\infty}$ - solution concentration far from the interface ( $\text{kg/m}^3$ ) and  $C_s$ -solution concentration at the interface apple-osmotic solution ( $\text{kg/m}^3$ ).

The velocity was determined by the equation (2):

$$U = \frac{2\pi R\omega}{\cos(2\pi\omega t_m)} \quad (2)$$

U-vertical velocity (m/s),  $\omega$ -frequency (cycles/minutes), R- radius (0.015 m) and  $t_m$ -time of the movement (s).

The relative velocity of apple sample and solution was supposed to be the average velocity of apple. This velocity was used for calculation of Reynolds (Re) and Schmidt (Sc) numbers.

$$Re = \frac{LU\rho_s}{\mu} \quad (3)$$

$$Sc = \frac{\mu}{\rho_s D} \quad (4)$$

L-diameter of apple sample (m),  $\rho_s$ -solution density ( $\text{kg/m}^3$ ),  $\mu$ -viscosity of the sucrose solution ( $\text{kg/ms}$ ), D-binary diffusivity ( $\text{m}^2/\text{s}$ ). Sucrose solution viscosity and density were estimated from the literature.

### 2.3. Penetration depth of the solute or active zone.

The penetration depth of the solute ( $z_p$ ) was determined experimentally using the scanning electron microscopy (SEM) technique. The apple sample was analyzed in cross section from the surface to the center. The thickness of the area where structural changes are observed was determined and used to estimate the penetration depth of the solute or active zone. In addition, the tissue area beyond the zone of structural change was observed to check if it remained as at the beginning of the treatment.

Prior to SEM examination, the materials were osmotically dehydrated by applying a factorial experimental design at two levels for temperature (30, 50°C), a sucrose osmotic solution concentration (30, 50 °Bx) and a motion level of 0.15 m/s. Three replicates for each treatment were conducted. High-quality stereo images and surface parameters were recorded from samples osmotically dehydrated and cut in cross section. For the study by SEM, the cross section of the apple sample was analyzed dividing it into 5 areas from the

outermost layer to the center. Area 1 corresponds to the outermost surface of the sample and area 5 to the material center.

#### 2.4. Modelling of transport mechanisms during osmotic dehydration of fruit in sucrose solution.

Modifying the mathematical writing of the equations that describe the solutes transport in OD requires an analysis of the mechanisms involved: impregnation and diffusion. For this it is necessary to take into account the following considerations: water bulk flow acts as a resistance that opposes the transfer of the solute and limits it to migrate mostly in the superficial layers of the food; the water flow from food is greater than the flow of solutes entering the plant matrix; water flow is the sum of: water in the pores (free water) + water in the extracellular volume + water in the intracellular volume (bound water); water that leaves the plant matrix is transferred mainly by capillary diffusion; solute flow is the sum of: solute in the pores + solute in the extracellular volume concentration of the osmotic solution inside the food changes; the highest concentration of the solute is impregnated on the surface of the plant matrix when solutions of saccharides and natural sweeteners are used; hydrodynamic boundary layer influences the initial concentration of the impregnation layer  $C_i$ ; thickness of the impregnation layer  $\delta_{imp}$  changes with the time of the process. Based on the above assumptions, the following equations are proposed to determine the transfer of solutes in OD:

$$\frac{\partial c}{\partial t} = \text{solute flow potential} - \text{water flow potential} \quad (5)$$

$$\frac{\partial C}{\partial t} = \nabla^2 C_s - \nabla^2 C_w \quad (6)$$

$$\frac{\partial C}{\partial t} = \gamma(\text{Diffusion}) - \gamma(\text{Capillary diffusion}) \quad (7)$$

$\nabla^2 C_s$  -solute flow potential;  $\nabla^2 C_w$ -water flow potential; C-concentration (kmol/m<sup>3</sup>), t-time (s),  $\gamma$ -coefficient.

### 3. Results and discussions

Reynolds number (Table 1) for the experiment was found to be approximately 205 and 500 for 30°C-30°Bx and 50°C-50°Bx respectively with 0.15 m/s of motion level. The flow regime for both experience were thus laminar flow. The calculation of dimensionless

numbers showed the average Reynolds number of all the experiments was small (<600) and very high Schmidt numbers (4000 for 30 ° C-30 ° Bx and 4200 for 50 ° C-50 ° Bx).

**Table 1. Properties of the osmotic solution to determine the Reynolds number**

<i>Temperature</i> (°C)	<i>Concentration</i> (°Bx)	<i>Diameter</i> (m)	<i>Velocity</i> (m/s)	<i>Re</i>	<i>Sc</i>
30	30	0.015	0.10	250	4000
50	50	0.015	0.10	500	4200

During osmotic fruit dehydration, sucrose or synthetic osmotic solutions are generally used, in a mass fraction of 60% w / w or more. These solutions have high viscosity and have low diffusion. These operating conditions imply high Sc numbers and low Re numbers, generally in laminar flow regime (Bui and others, 2009).

From the thickness of the zone where the structural change was observed, the value of the penetration depth of the solute  $z_p$  was estimated. Scanning electron microscopy turned out to be an efficient technique (Figures 1 and 2) for the detection of structural changes areas in the osmotically dehydrated apple tissue.

**Fig. 1. Micrograph of dehydrated apple in sucrose 50 ° C-50 ° Bx. Increase 50x (S1-surface; S5-center).**

**Fig. 2. Micrograph of dehydrated apple in sucrose 30 ° C-30 ° Bx. Increase 50x (S1-surface; S5-center).**

In 1 and 2 areas the greatest structural changes are observed, these being the closest to the external surface of the material. In these areas, we observed certain zones where the structure of the tissue is collapsed with the presence of solids that clog the pores and the intercellular spaces disappear. In areas 3, 4 and 5 closest to the center of the sample, small and irregularly shaped intercellular spaces are observed, very similar to those presented in

the microscopy of the fresh apple. The values of the solute penetration depth estimated were 3.03 and 3.68 mm for the conditions of 30 °C-30 °Bx and 50 °C-50 °Bx.

#### **4. Conclusions**

This model can be useful for the design and optimization of the industrial osmotic dehydration process since it will be able to successfully predict the area where the superficial impregnation of the sucrose occurs and the area where the solute diffuses.

### **Abstract**

*The objective of this work was to establish a three-dimensional measuring method for the size, morphology and distribution of internal structure such as ice crystals, bubbles and solids content within an ice cream sample by using a cryogenic microtome spectral imaging system (CMtSIS). The 3-D images of ice crystals, bubbles and milk solids were recognized by reconstructing the circles in 2-D images into 3-D spheres; and the Overrun by Volume (ORV) was obtained by incorporating the area of bubbles on integrated image and the volume of bubbles in the 3-D image.*

**Keywords:** Ice crystal, Bubble, Internal structure, Spectral imaging, Micro- to macro-scale, Freeze-Drying

---

## **1. Introduction**

Most food materials are composed of limited structural elements such as a solid content, bubble and ice crystal. The internal structure in frozen food materials undergoes metamorphic changes due to recrystallization process which increases the size of ice crystals during frozen storage. The size and shape of internal structure formed in a frozen material strongly influence the final quality as well as the freezing rate or heat flux and the direction of heat flow within the material during freezing. For a proper understanding of the behavior of heat or mass transfer in frozen food materials and the behavior of freeze-drying, knowledge of the internal structure of frozen food materials is required. Ice cream is considered as a complex multiphase system consisting of bubbles, ice crystals and milk solids, and the final quality of which is influenced by the correlation between the size, morphology and distribution of the multiphase formed during the manufacturing process. Attempts have been made to observe bubbles and ice crystals on the cross sections of ice cream by using an optical microscope [1] or by indirect methods using SEM [2] or Cryo-SEM [3]. The SEM and Cryo-SEM allow the identification of morphological difference between bubbles and ice crystals by the micro asperity of a sublimated sample surface, but it is difficult to determine whether a sublimated seam is caused by an ice crystal or by a bubble. Furthermore, the measurement of bubble size by traditional methods would result in misleading numbers due to limitations in observing the entire volume of a bubble. Different cross sections would provide different diameters for the same bubble. And the values of the diameters reported by traditional methods might not correlate well with the final quality of ice cream since the measurements on bubbles, ice crystals and milk solids were taken from separate samples. X-ray micro-computed tomography (X-ray  $\mu$ CT) has been applied to three-dimensional (3-D) structural elements of frozen food materials [4, 5]. It is based on the contrast in X-ray images generated by differences in X-ray attenuation arising from differences in the density of material within a sample. Also, frozen food materials that contain water are freeze-dried to clarify density contrast. The objective of this work was to establish a 3-D measuring method for the size, morphology and distribution of internal structure such as ice crystals, bubbles and solids content within ice cream samples prepared at three different overrun levels.

## **2. Experimental Equipment and Materials**

### **2.1. Cryogenic microtome spectral imaging system**

The CMtSIS [6] consists of a microtome unit, an automatic high-precision XY stage, an image acquisition unit (visible, fluorescence and spectroscopic), and a 3-D image processor (Fig. 1). The CMtSIS allows consecutive image acquisition of the cross sections of a frozen sample exposed by multi-slicing with a minimum thickness of 0.25  $\mu$ m. The temperature of the heat exchanger is controlled from room temperature to  $-160^{\circ}\text{C}$  by regulating the flow

rate of liquid nitrogen and the power to an electric heater installed in the heat exchanger. Microscale and macroscale images can be obtained with a high-power objective lens of a microscope installed on the automatic high-precision XY stage (ALD-106-H1P, Chuo Precision Industrial Co., Ltd., Japan) that can be mechanically adjusted with a resolution of 6  $\mu\text{m}$  within a maximum area of  $60 \times 60 \text{ mm}^2$ . The image of each cross section is captured with a highly sensitive CCD and an NIR camera, and is recorded by the 3-D image processor. A 3D image is reconstructed from a series of consecutively acquired 2-D images.

*Fig. 1 Schematic diagram of cryogenic microtome spectral imaging system (CMtSIS).*

## 2.2 Materials and methods

A lump of vanilla ice cream mix (from ZAO, Yamada milk Co., Ltd. Miyagi, Japan) with a formulation of 8% milk fat, 10% milk solids-not-fat, sugar, honey, stabilizer and an emulsifier was taken from a commercially available soft ice cream. Ice cream samples at three different overrun levels (low, medium, and high) were produced by an automatic batch preezer (191 P/SP/N, Carpigiani group, bologna, Italy). Ice cream agglomerate shaped into a cylindrical sample with a diameter of 10 mm and a height of 10 mm was shock frozen in liquid nitrogen. The sample was embedded in an optimal cutting temperature (OCT) compound and a ring of dry ice. The sample, OCT compound, and the ring of dry ice fixed on the heat exchanger were sliced together, and cross-sectional images were then captured by the CCD camera through a microscope. Bubbles, ice crystals and milk solids in the ice cream sample were identified from the CMtSIS iamges by the microscale to macroscale measurement method previously reported by Do et al. [6].

## 3. Results and Disussion

### 3.1. Overrun by weight

Overrun is the industrial term for the amount of air added to frozen dessert products, and the percent overrun of ice cream by weight can be calculated by the following equation [7]:

$$\% \text{ Overrun by weight (OR)} = \frac{\text{Wt. of mix} - \text{Wt. of same vol. of ice cream}}{\text{Wt. of same vol. of ice cream}} \times 100 \quad (1)$$

The overrun of commercial ice cream can range from 24% (super-premium) to 94% (light and fluffy). Percent overrun by weight was measured for the ice cream samples prepared at three overrun levels and the mean values were 11.5%, 44.0% and 73.8% for low, medium, and high overrun levels, respectively (Table 1).

**Table 1. Precent overrun by weight**

Statistics	Overrun levels			
	Low	Medium	High	
OR	Maximun	12.7	46.7	75.7
	Minimun	10.3	40.9	72.0
	Mean	11.5	44.0	73.8
	SD	1.0	1.4	1.9

### 3.2. Measurement of bubble

A total of 36 image frames was obtained from a sliced surface by using the CCD camera, the  $\times 50$  magnification lens, and the automatic high-precision XY stage. Each frame covered an area of  $194 \times 154 \mu\text{m}^2$ . The 36 frames were integrated into a single image by a 3-D image processor. Fig. 2 shows an integrated raw image and a binary image representing the boundaries of identified bubbles covering a measurement area of  $1164 \times 924 \mu\text{m}^2$  with a total of  $7800 \times 6180$  pixels. Fig. 3 shows the distribution of equivalent circle diameters of the bubbles in the sample of 11.5% OR (low overrun). A total of 480 bubbles was recognized from the integrated image: the equivalent circle diameters ranged from 1.1 to  $101.9 \mu\text{m}$  with a mean of  $24.8 \mu\text{m}$ , and the measured areas ranged from 0.9 to  $8144.9 \mu\text{m}^2$  with a mean of  $637.8 \mu\text{m}^2$ . Fig. 4 shows the distribution of equivalent circle diameters of the bubbles found in the sample of 44.0% OR (medium overrun). A total of 1988 bubbles was recognized from

**Fig. 2 Binarization of an integrated image to identify the bubbles in an ice cream sample.**

**Fig. 3** Equivalent circle diameter of bubbles in the sample of 11.6% OR.

**Fig. 4** Equivalent circle diameter of bubbles in the sample of 44.0% OR.

the integrated image: the equivalent circle diameters ranged from 1.1 to 140.4  $\mu\text{m}$  with a mean of 25.8  $\mu\text{m}$ , and the areas ranged from 0.9 to 15479.8  $\mu\text{m}^2$  with a mean of 749.0  $\mu\text{m}^2$ . Fig. 5 shows the distribution of the equivalent circle diameters of the bubbles in the high overrun sample (73.8% OR). A total of 692 bubbles was recognized from the integrated image: the equivalent circle diameters ranged from 1.1 to 248.2  $\mu\text{m}$  with a mean of 40.3  $\mu\text{m}$ , and the areas ranged from 0.9 to 48362.0  $\mu\text{m}^2$  with a mean of 2035.9  $\mu\text{m}^2$ . The actual size of the integrated images was 1164×924  $\mu\text{m}^2$  and from these images the range of the areas of the recognized bubbles was determined to be from microscale of 0.9 to macroscale of 48362.0  $\mu\text{m}^2$ .

**Fig. 5** Equivalent circle diameter of bubbles in the sample of 73.8% OR.

### 3.3. Overrun by volume

The CMtSIS has functions to capture the cross-sections exposed by multi-slicing of a frozen sample with a minimum thickness of 1  $\mu\text{m}$  and to reconstruct a 3-D image utilizing a series of consecutively acquired 2-D images. The volume rendering method was employed as the optimum one for the system to measure internal structures. Using this method the volume can be determined from the surface areas of quantitative 2-D information. Overrun can be determined as the percentage increase in volume or area of the mix that occurs as a result of air addition, and can also be calculated by the following equation [7]:

$$\% \text{ Overrun by volume (ORV)} = \frac{\text{Vol. of ice cream} - \text{Vol. of mix used}}{\text{Vol. of mix used}} \times 100 \quad (2)$$

Fig. 6 compares the OR values calculated from the weight measurements and the ORV values obtained from the area of bubbles on integrated image analysis using the CMtSIS for the ice cream samples prepared at three overrun levels. The means of obtained ORV values were 10.5%, 42.8%, and 77.7% for low, medium, and high overrun levels, respectively; whereas the corresponding OR measurements were 11.5%, 44.0%, and 73.8%. Thus, the measurement accuracy of the CMtSIS was verified in estimating the percent overrun by volume for frozen ice cream samples.

Fig. 6 OR and ORV for different overrun levels.

### 3.4. Three-dimensional measurement of the internal structure of ice cream

An ice cream sample of 12.7% OR was prepared to measure the 3-D internal structure. Although the bubbles, ice crystals and milk solids could be recognized from an original 2-D image (Fig. 7) by visual evaluation, it was difficult to obtain a binary image of these only by applying automatic thresholding techniques. Therefore, the boundaries of individual bubbles, ice crystals and milk solid were traced manually on a digitizing board (Cintiq 21UXTZ-2100, WACOM Ltd, Japan) as shown in the upper row of Fig. 7. After extracting the pixels within the traced boundaries and obtaining binary images, the volumes of each bubble and ice crystal were calculated to represent the morphology. The 3-D images of bubbles, ice crystals and milk solids were reconstructed using 100 cross-sectional images (slicing thickness: 4  $\mu\text{m}$ ). The 3-D images of bubbles, ice crystals and milk solids (the lower row of Fig. 7) were reconstructed based on the binary images. The dimension of each 3-D image was 260  $\mu\text{m}$  in length, 206  $\mu\text{m}$  in width and 400  $\mu\text{m}$  in height. By using an image processing software (TRI/3D VOL, Ratoc Ltd, Japan), the volumes of each bubble and ice crystal were calculated from the 3-D images. A total of 1178 bubbles was recognized by reconstructing the circles in the 2-D images into 3-D spheres and their volumes ranged from 0.125  $\text{mm}^3$  to 490.421  $\text{mm}^3$  with a mean of 2.342  $\mu\text{m}^3$  as shown in Fig. 8. Furthermore, an ORV of 14.8% was obtained by incorporating the volume of bubbles in the 3-D image for the ice cream sample of 12.7% OR. A total of 186 ice crystals were recognized by reconstructing the circles in the 2-D images into 3-D spheres and their volumes ranged from 0.125  $\text{mm}^3$  to 5493.684  $\text{mm}^3$  with a mean of 34.483  $\text{mm}^3$  as shown in Fig. 9. By observing the 3-D images (Fig. 7-b, c), it is recognized that the bubbles are evenly distributed in the ice cream sample, but the ice crystals are less evenly distributed. Milk solids are observed in the form of a retinal structure circumscribing bubbles and ice crystals as shown in Fig. 7-a.d. The bubbles are observed within ice crystals and milk solids.

Measurement of bubbles is difficult when using SEM or Cryo-SEM because of sublimation at the sample surface. Ice crystals and bubbles within a sample can be resolved by the vacant spaces left after freeze-drying. Since all vacant spaces are treated as ice crystals and bubbles in the analysis of a freeze-drying process, some questions may be raised to the identification of ice crystals and bubbles. Therefore, a 3-D measuring method for the size, morphology and distribution of internal structure such as ice crystals, bubbles and solids content within an ice cream sample was established in this research by using the CMtSIS.

Fig. 7 Morphology and distribution of internal structure of ice cream.

Fig. 8 Distribution of volume of bubbles.

Fig. 9 Distribution of volume of ice crystals.

#### 4. Conclusions

A novel technique was developed for the detection of 3-D internal structure of ice cream samples produced at different overrun levels and its high accuracy was verified by using the CMtSIS. The following conclusions were reached:

1. The actual size of the integrated images was  $1164 \times 924 \mu\text{m}^2$  and from these images the range of the areas of the recognized bubbles was determined to be from microscale of 0.9 to macroscale of  $48362.0 \mu\text{m}^2$ .
2. The means of obtained ORVs were 10.5%, 42.8%, and 77.7%, whereas the means of the measured ORs were 11.5%, 44.0% and 73.8% for the ice cream samples produced at three overrun levels (low, medium, and high, respectively).
3. The estimated volumes of bubbles ranged from  $0.125 \text{ mm}^3$  to  $490.421 \text{ mm}^3$  with a mean of  $2.342 \mu\text{m}^3$ , and those for ice crystals ranged from  $0.125 \text{ mm}^3$  to  $5493.684 \text{ mm}^3$  with a mean of  $34.483 \text{ mm}^3$  in the 3-D image for the ice cream sample of 12.7% OR.
4. The ORV of 14.8% was obtained by incorporating the volume of bubbles in the 3-D image in the case of the ice cream sample of 12.7% OR.

---

## 1. Introduction

Microwaves (mw) allows a volumetric heating method used to dry moist goods. The volumetric heating is faster than conventional drying as soon as the surface of the good becomes dry and the core is still wet [1]. The most common method for an mw source in industrial applications today is the magnetron. It builds on proven technology, is cost-effective and can also produce power in the kW range. But it also has some disadvantages such as the need of a high tension power supply and an output signal at a fix frequency. For optimum power transfer, the source is impedance matched to the load. However, during the drying process, materials change their electrical properties. And this will change the wave distribution inside the microwave applicator too. As a result, the impedance at the feed port of the applicator will change and the source is not matched anymore. The amount of reflected power increases and the process efficiency reduces. Figure 1 shows the measured reflected power in percentage in relation to the moisture content in a drying process. Underneath a certain moisture content, the reflected power increases. This is led by means of a circulator to an artificial load and converted into heat.

*Fig. 1 increasing power reflection of a magnetron heating system due to load change*

Frequency synthesizers and semiconductor power amplifiers for the 2.45 GHz ISM band are becoming available for industrial applications. An mw source based on these components is able to change the frequency and phase of the created signal. This enables dynamic impedance matching, based on a search for the best frequency and phase condition.

Three dimensional finite element electromagnetic field simulations of several microwave chambers and drying goods have shown, that two feed ports are especially a benefit in a drying process [2]. This comes from the fact that a two port applicator allows a smoother electromagnetic field distribution, even if the volume of the good is shrinking over the drying process. In addition, during the drying process the impedance matching of two ports must be adapted continuously. Simulation results presented in previous papers showed that the optimum frequency and the optimal phase shift between two feeds can be estimated by means

of complex scattering parameters [3] [4]. The objectives of our work were to verify the various simulation results by means of a lab scaled functional model of a two port applicator. In addition, we show the feasibility of a tunable mw source based on semiconductor components. Such a source is a prerequisite for searching the optimum operating point in the drying process.

Chapter two lists the applied methods and materials we used in our work. Chapter three describes the measurement and optimization algorithm. In the following chapter four, the system architecture of the two port mw source is explained. In chapter five measurement results are explained and discussed. The final chapter six contains the conclusion and hints for further work.

## 2. Materials and Methods

For the functional model of a semiconductor based two port mw source with frequency synthesizer, phase adaptation and embedded vector network functionality for measuring the scattering parameters (s-parameter), a suitable printed circuit board based microwave circuit was designed and produced. Although the available microwave output power was limited to 250 mW the measurement principles and the verification of the optimization algorithm could be done.

The two port mw source was connected to the applicator by means of WR340 waveguides. The applicator is made of aluminum and has a box type shape with the size of 0.61\*0.69\*0.51 m. It works as a multimode oven [1]. The test good is placed on a weighing system in the center of the applicator, which allows to continuously weight the good during the drying process. In order to avoid the condensation of water vapor on the walls of the applicator, a ventilation system was installed.

In order to check the quality of the measured s-parameters with the built-in measuring device, all parameters were additionally measured with a Rhode & Schwarz commercial network analyzer.

The used test good was a mixture of flour and water.

## 3. Algorithm for efficiency calculation

The overall efficiency  $\eta_{tot}$  of a microwave heating system depends on various efficiency factors of the subsystems.

$$\eta_{tot} = \eta_{gen} \eta_{feed} \eta_{trans} \eta_{appl} \quad (1)$$

The efficiency of the microwave source  $\eta_{gen}$  is mainly determined by the efficiency of the solid state power amplifier. The factor of feeder network efficiency  $\eta_{feed}$  covers the losses of coupling elements, waveguides, power combiner and feeder antennas. The efficiency

factor of transmission  $\eta_{trans}$  is a figure of how good the impedance matching works. The efficiency factor  $\eta_{appl}$  from the applicator describes the losses due to heating up the metal walls by means of electrical induction.

The focus of our work is the optimization of  $\eta_{trans}$ . This factor strongly depends on the impedance matching between the feeder and the applicator with its drying good. For optimizing the transmission efficiency, we define two ways how to measure and calculate it. Both methods are applicable for a microwave applicator with two feeds.

The first method is suitable if both sources are simultaneously active and the electromagnetic fields are overlapped. The efficiency is calculated from the ratios between the reflected waves  $b_{1,2}$  and the input waves  $a_{1,2}$  at the individual feeder ports of the microwave applicator. The indices give the individual port number. Because these waves represent voltage waves, the square of them are proportional to the power which leads directly to the needed power efficiency figure. The wave  $b_1$  is a superposition of the reflected wave at port one and the through connection part from port two. In the same way the wave  $b_2$  consists of the reflected wave at port two and the part which is transferred from port one.  $\eta_{trans}$  will be maximized if the individual wave reflection at the ports can be minimized and the feed trough parts can be minimized. To find the optimal operation point the measurement and calculation for  $\eta_{trans}$  must be done separately for every frequency and phase difference between the two sources.

$$\eta_{trans} = 1 - \frac{1}{2} \left| \frac{b_1}{a_1} \right|^2 - \frac{1}{2} \left| \frac{b_2}{a_2} \right|^2 \quad (2)$$

The second method is based on the s-parameters and thus only one source must be active during the measurement process. This method is more complex but needs less measurements [4]. This is possible because the phase information for the superposition of the two sources is included in the s-parameter. The s-parameter is defined as a ratio between an input wave  $a$  and a reflected wave  $b$ . The index gives the individual port number. The first index of an s-parameter gives the number of the destination port and the second index the number of the source port. The s-parameters are complex numbers.

$$s_{11} = \frac{b_1}{a_1}, \text{ with } a_2 = 0 \quad (3)$$

$$s_{12} = \frac{b_1}{a_2}, \text{ with } a_1 = 0 \quad (4)$$

$$s_{21} = \frac{b_2}{a_1}, \text{ with } a_2 = 0 \quad (5)$$

$$s_{22} = \frac{b_2}{a_2}, \text{ with } a_1 = 0 \quad (6)$$

The transmission efficiency for a desired phase difference  $\Delta\varphi$  can now be calculated by

$$\eta_{trans} = 1 - \frac{1}{2} |s_{11} + s_{12}e^{j\Delta\varphi}|^2 - \frac{1}{2} |s_{22} + s_{21}e^{-j\Delta\varphi}|^2 \quad (7)$$

For finding the optimal operating point with the highest  $\eta_{trans}$ , measurements must be done over all frequencies and calculations over all phases and frequencies.

#### 4. Architecture of the system

To proof the concept that a microwave heating system based on semiconductor components allows a high transmission efficiency for several goods and moisture levels, a test hardware was built. The architecture of the system is shown in figure 2.

*Fig. 2 block diagram of the functional prototype*

The two sinewave signals are created with high performance, wideband rf synthesizers LMX2582 from Texas Instruments. This synthesizers are able to adjust both the output frequency and phase with a 32-bit resolution.

As for proofing the concept a high power is not needed, the two sinewave signals are only amplified with a driver amplifier MGA-30489 from Avago. The amplifier delivers 250 mW of microwave power.

For executing the s-parameter measurement the forward and the reflected signal wave must be separated first. A high power integrated directional coupler X3C26P1 from Xinger is used for this task. Only -30 dB of the individual signal waves are decoupled for the measurement.

The s-parameter measurement is done with an rf gain and phase detector AD8302 from Analog Devices. In the system control part a microcontroller is used for calculating the efficiency parameter. It also calibrates the measured values [5] and controls the other sub-systems such as sinewave generation, phase shifting and amplification.

### 5. Results and Discussion

To validate the concept and the prototype hardware several measurements with various material mixtures as indicated in table 1 have been done.

**Table 1. Material mixtures**

Moisture level:	Water:	Flour:
80% water	400 g	100 g
50% water	100 g	100 g
20% water	25 g	100 g

For the different measurement campaigns the frequency range from 2.4 GHz till 2.5 GHz with a step size of 1 MHz was swept through. For each frequency point the s-parameters where measured. With these set of s-parameters the efficiency for all frequencies and phase differences with a resolution of one degree where calculated with (7). Subsequently the highest efficiency  $\eta_{trans}$  over all phase differences is searched for each frequency. This maximum efficiency for all frequencies of the three moisture levels are depicted in figure 3.

**Fig. 3 calculated transmission efficiencies based on s-parameter measurements**

The optimal frequency and phase difference changes during the drying process. Table 2 shows the best values found for the three moisture levels. The efficiency value remains almost on the same high level over all three measurement series.

**Table 2. Ideal parameters**

moisture level:	best efficiency:	frequency:	phase difference:
80% water	0.984	2.452 GHz	190°
50% water	0.997	2.451 GHz	202°
20% water	0.993	2.450 GHz	201°

For validating the measurement accuracy of the prototype hardware, a comparison of the calculated efficiency values have been done. The results are illustrated in figure 4. The blue color curve shows the calculated values with (7) based on s-parameter measurements done with the vector network analyzer ZVL6 from Rhode&Schwarz. The yellow curve shows the results calculated with (7) based on s-parameter measurements of the prototype hardware. And the green curve are the results based on the calculation method of (2). All three methods are very close to each other if the reflected power is small. However, the calculated efficiency values differ with increasing reflections.

**Fig. 4 comparison of measurement methods (mixture with 50% moisture level)**

## **6. Conclusions**

A microwave heating system is a fast and efficient way to dry goods. The classical solution based on a magnetron as microwave source gets problems to put the energy into the dry good if electrical properties changes at low moisture levels. A heating system based on a semiconductor solution as microwave source shows promising results. Such a system allows the adaptation of operation frequency and phase and offers an impedance tuning function during the running process. With an s-parameter measurement the optimal frequency point and phase difference can be determined and allows a maximization of the transmission efficiency. For a proof of concept, a lab scaled functional model was developed. An embedded system with two frequency synthesizers generates the two feeder signals. The power, frequency and phase of the signals can be controlled by means of a microcontroller system. For measuring the s-parameters during the process, an embedded two-port vector network analyzer was added. The obtained measurement results fulfill the expectations.

### **Abstract**

*In this work, an isothermal pore network model has been utilized to investigate ion transport and crystallization in layered porous media during drying. Said network consists of two distinct layers each with a different pore size distribution. One-dimensional approximation at the throat level describes transport phenomena for liquid, vapor, and dissolved salt. An explicit time stepping scheme has been used to obtain fluid pressure fields and ion concentration. Various simulations are carried out which indicate the effect of mean pore size disparity in the top and bottom layer, as well as the effect of drying rate on final crystal distribution.*

## **1. Introduction**

Layered materials are among the most essential products influencing our lives ranging from everyday use to construction and industrial processes. Painted surfaces, interior wallpapers, composite materials, and fuel cell membrane-electrode combination are among many examples of layered materials. Depending on the application these layered materials may be exposed to a solution (or suspension) at one or several stages of their lifetime. Additionally in the majority of cases said exposure is accompanied by drying that has varying effects which also depends on production and applications of these materials. To this goal, it is paramount to study and identify factors affecting each scenario. In order to provide more context as to which parameters influence precipitation pattern several studies will be looked into in this section.

Preservation of masonry and cultural heritage is an important area where undesired crystallization within porous material is to be avoided. In this framework Pel et al.<sup>[1]</sup> studied one-sided drying of fire-clayed bricks contaminated by salt solution. In that work, nuclear magnetic resonance technique was used to measure moisture and NaCl content within the material. In the end it has been concluded that in historical objects generally the formation of efflorescence cannot be avoided. In a similar study the effect of crystallization inhibitors, whose function is to allow a higher degree of supersaturation before nucleation, on drying of fired-clay bricks and Granada limestone is studied by Gupta et al.<sup>[2]</sup>. Satisfactory results were achieved as the mass percentage of the nondestructive efflorescence has been dramatically elevated in the presence of inhibitors. Norouzi Rad et al.<sup>[3]</sup> studied the pattern of efflorescence formation depending on the spatial distribution pores sized at the surface of a packing of sand grains. Observations indicate that salt crystals are more inclined to form at the small pores as they stay wet for a longer time during drying as pores are sufficiently large to avoid blockage. That study points to the importance of porous media heterogeneity in crystal formation.

With sufficient context on drying induced crystallization in porous media, several studies on crystallization in layered porous structures will be reviewed here. One-sided drying of plaster/substrate systems, where evaporation happens always at the plaster surface, was studied through various experiments by Petković et al.<sup>[4]</sup>. Small pores are at the evaporating side when plaster is paired with Bentheimer sandstone. This leads to the majority of salt crystals to form at the surface or within the plaster layer. On the other hand, in a plaster/calcium-silicate brick system (smaller pores located in the substrate) although some salt crystallized in the plaster layer, a significant amount of crystals was found within the brick. The aforementioned nuclear magnetic resonance technique is used to study the effect of paints on drying behavior of plaster/substrate systems and stone specimens by Diaz Gonçalves et al.<sup>[5]</sup>. It is concluded that crystallization pattern varies depending on many variables such as the pore size of the interior region, hydrophobicity of the paint, and the

salt itself. This indicates that for such systems any kind of predictive statement should be limited to the specific framework and conclusions should be drawn very cautiously.

In this work, a 3D pore network represents the void space of the porous material. The bi-layered structure is modeled by two networks stacked on top of each other leading to a so-called “near surface” (top) and “interior” (bottom) region. Each region has its distinct pore size distribution which is sampled from a normal distribution. The entire network is initially filled with salt solution and evaporation takes place from the top. Simulations are carried out for various combinations of pore size distribution in the bottom and top layer as well as various drying rates. For the sake of comparison the top layer is kept identical among all simulations. Results are presented as solid deposit mass as well as saturation profiles.

## **2. Model description**

The selected pore network model consists of two different types of pore geometry. The volume of the liquid in the network is located in the cylindrical pore-throats which are positioned perpendicular to one another. The connection between the throats is established via pore-nodes with no volumes. The nodes provide the computational grid required for vapor and liquid pressure calculation.

### **2.1. Pore network drying model**

Drying is considered only from the top, therefore the vapor flow out of the network is modeled in a diffusive boundary layer above the network. The liquid and vapor flow in the entire network are considered quasi-stationary within the network time-steps. It is important to mention that all colligative properties of the salt solution is neglected or in other words the liquid is considered as pure water for liquid flow calculations. This leads to variation of several physical properties, in the course of drying, to be neglected. Said physical parameters include: liquid-gas surface tension, vapor pressure, liquid viscosity, etc.

Vapor diffusion within each throat in the gas-side network is calculated using Stefan correction coupled with the isothermal conditions. The equation can be written as follows:

$$\dot{M}_{v,ij} = A_{ij} \frac{\delta P \tilde{M}_v}{L \bar{R} T} \ln \left( \frac{P - p_{v,i}}{P - p_{v,j}} \right), \quad (1)$$

where  $\delta$  is the binary diffusion coefficient between water vapor and air ( $\text{m}^2/\text{s}$ ),  $A_{ij}$  and  $L_{ij}$  the throat cross-sectional area and length ( $\text{m}^2$  and  $\text{m}$ ) respectively,  $P$  the gas pressure (Pa),  $T$  the air temperature (K),  $\tilde{M}_v$  molar mass of water ( $\text{kg}/\text{kmol}$ ),  $\bar{R}$  universal gas constant ( $\text{J}/\text{kmolK}$ ), and  $p_v$  partial pressure of water in the gas phase.

The vapor pressure field is calculated by using Equation (1) in mass conservation law for every gas pore with unknown vapor pressure coupled with pores at  $P_v^*$  and  $P_{v,\infty}$  as boundary conditions, which leads to a system of algebraic equation.

Liquid flow rate in the network is governed by the Hagen-Poiseuille equation which is written for a throat as follows:

$$\dot{M}_{w,ij} = \frac{\pi r_{ij}^4}{8\mu_w L} (P_{w,i} - P_{w,j}), \quad (2)$$

where  $r_{ij}$  represents the throat radius (m),  $\mu_w$  the dynamic viscosity of water (Pa·s), and  $P_w$  the liquid pressure at the nodes. Similar calculation procedure as for the vapor pressure is considered here for liquid pressure field. The boundary conditions are defined as pressure level for moving menisci and liquid flow rate for stationary menisci. More detailed discussion on the basic drying model can be obtained in Metzger et al.<sup>[4]</sup>.

## 2.2. Ion migration model

Salt concentration in liquid throats in the network is modeled by a 1D advection-diffusion equation. Advection term is assumed to follow a plug flow and Fick's law governs diffusion in the throats. Discretizing said equation over the space in the throat-node geometry leads to the following:

$$\frac{dC_{ij}}{dt} = U \left( \frac{C_i - C_{ij}}{L_{ij}} \right) + 2D \frac{C_i - 2C_{ij} + C_j}{L_{ij}^2}, \quad (3)$$

where  $C$  is the concentration of salt in the solution ( $\text{kg/m}^3$ ),  $U$  the superficial velocity of liquid in the element (m/s), and  $D$  the binary diffusion coefficient between solute and solvent ( $\text{m}^2/\text{s}$ ). Indices  $i$  and  $j$  refer to nodes on either side of the throat  $ij$  with liquid flow from node  $i$  to node  $j$ .

## 2.3. Crystallization

During drying, enrichment of salt takes place due to evaporation of solvent. In this model, salt concentration is tracked over time steps and rises as time goes by. At the end of every time step all liquid throats in the network are scanned and throats that exceed a certain degree of supersaturation ( $C^{*+}$ ) are subject to crystallization. In that case the excess amount of salt is precipitated until salt concentration falls below the saturation concentration ( $C^{*-}$ ). Therefore, said amount of precipitated salt is calculated as follows:

$$M_{s,ij} = V_{ij} (C_i - C^{*+}). \quad (4)$$

It is assumed that the time scale for crystallization is significantly shorter than that of the ion migration which leads to an instant crystallization model in this case.

### 3. Simulation results

Pore network simulations are carried out with a 3D cubic pore network comprised of 15 (lateral)×15 (lateral)×19(vertical) nodes. This network is constructed as two distinct layers stacked on top of each other with each layer containing 9 counts of slices in the vertical direction. Throats throughout the network have a uniform length of 6 μm whereas their radii are sampled from a different normal distribution function for each layer. The top layer is kept identical across all simulations with a mean throat radius of 1000 nm whereas the bottom layer has 2 different variations presented in Table 1.

**Table 1. Throat radii distribution of the bottom layer**

network	1	2
mean radius (nm)	100	1500
standard deviation (nm)	20	150

The physical parameters used in the simulations are shown in Table 2.

**Table 2. Physical parameters.**

$\mu_w$ (Pa.s)	$\rho_l$ (kg/m <sup>3</sup> )	$\sigma$ (N/m)	$\delta$ (m <sup>2</sup> /s)	D (m <sup>2</sup> /s)	C* (kg/m <sup>3</sup> )
$1 \times 10^{-3}$	$1.27 \times 10^3$	$7.2 \times 10^{-2}$	$2.5 \times 10^{-5}$	$1 \times 10^{-9}$	$1 \times 10^2$

#### 3.1. Network 1

Network 1 is comprised of two layers with monomodal pore size distributions. In this case the bottom layer has smaller throats compared to the top layer. Final crystal mass profile obtained by slice averaging is presented in Fig. 1 for 3 different drying rates. These various drying rates are simulated by adjusting the value of saturation vapor pressure ( $P_v^*$ ) until the desired drying times, as shown in Table 3, are achieved.

**Table 3. Drying rate date**

drying rate	slow	moderate	fast
$P_v^*$ (Pa)	160	1600	7384
drying time (s)	1200	120	24

Low initial salt concentration of 10 kg/m<sup>3</sup> is considered for the first set of simulations which provides enough room for ion diffusion in the liquid before saturation concentration is reached. It is observed that the profile for the case of slow drying (Fig. 1 (a)) is far more homogeneous and the gradient increases as drying rate speeds up. Moreover, looking directly at the first slice (at the surface) it can be seen that almost double the amount of crystals are found at the surface for the case of fast drying (Fig. 1 (c)) compared to slow drying. Another important factor that can play an important role depending on the

application is the amount of solid deposit found at the interface between the two layers. This value seems to remain unchanged between these sets of simulation yet it is quantified as a moderately low amount.

**Fig. 1.** Final crystal mass profile of network 1 with initial salt concentration of  $10 \text{ kg/m}^3$  for (a)

*slow drying, (b) moderate drying, and (c) fast drying.*

Elevating the initial salt concentration to  $90 \text{ kg/m}^3$  (very close to saturation) drastically alters the final solid distribution in the system. It can be seen that such high initial concentration eliminates final gradient in crystal distribution except for the top and interfacial slices (Fig. 2).

**Fig. 2.** Final crystal mass profile of network 1 with initial salt concentration of  $90 \text{ kg/m}^3$  for (a) slow drying, (b) moderate drying, and (c) fast drying.

**Fig. 3.** Saturation profiles in the course of drying for network one obtained from simulations with (a) slow drying and (b) fast drying.

Additionally the profiles look much more alike for the three different drying rates. These effects are attributed to the lack of ion diffusion caused by high initial concentration. This significant similarity also hints at lack of change in the liquid transport regime between for the various drying rates. This has been confirmed by comparing saturation profiles for the cases of slow and fast drying which look close to identical (Fig. 3).

### 3.2. Network 2

The final set of simulations are carried out with network 2 where the bottom layer has considerable larger throats and the top layer. In this case the trend of crystal mass profile for varying drying rate is very similar to that of the network 1 as no viscous stabilization of the drying front is achieved. Therefore a comparison of network 1 and 2 is presented here which is more fruitful.

Fig. 4. Final crystal mass profile of network 2 with initial salt concentration of  $10 \text{ kg/m}^3$  for (a) slow drying, (b) moderate drying, and (c) fast drying.

The important characteristic of the network 2 is that once breakthrough to the bottom layer takes place in the absence of viscous stabilization the majority of the evaporated liquid is supplied by large throats in the bottom layer due to high capillary pressure. This continues until the connection between the liquid in the top and bottom layer is lost and capillary pumping is not possible. This behavior is completely opposite to that of the network 1 (Fig. 1) where almost no capillary pumping from the bottom layer to the top layer is possible. This explains the significantly lower amount of solid deposit in the bottom layer and the elevated amount in the top layer for network 2 (Fig. 4). The fact that liquid connection is almost entirely lost at the early stages of drying explains lack of crystal mass gradient in the bottom layer as ion back diffusion from evaporation site to this region is not possible.

The results for increased concentration demonstrate significant accumulation of crystals at the top slice (Fig. 5) which was also observed for network 1 (Fig. 2). However the clear difference between the two networks is observed at the interface of the two layers. Almost no accumulation of crystals at the interface is observed for network 2 (Fig. 5). The accumulation that is observed at the interface for network 1 is due to the fact that the bottom is almost fully saturated as the top layer dries out (a result of small pores with low capillary pressure). This means that as the drying front arrives at the interface, the bottom

layer starts to dry in a similar fashion as to the top layer. In case of network 2 at the moment that drying front reaches the interface the liquid connection in the bottom layer has already been lost (due to capillary pumping to the surface). Consequently recession of drying front continues without a halt to the end of drying.

Fig. 5. Final crystal mass profile of network 2 with initial salt concentration of  $90 \text{ kg/m}^3$  for (a) slow drying, (b) moderate drying, and (c) fast drying.

#### 4. Conclusions

In this work, a 3D pore network model has been utilized to run simulations for drying of layered porous materials in the presence of dissolved components. The majority of salt crystals are accumulated in the top layer for network with large pores in the bottom. For low concentration similar amount of crystals is obtained in both layers for network with smaller pores in the bottom. Moreover, enrichment at the interface between two layers is achieved only with high initial concentration and network with smaller pores in the bottom layer.

### Abstract

*Pore-network simulations are carried out for monomodal and bimodal pore structures with spatially correlated pore-size distributions. The internal and surface relationships between the partial vapor pressure and saturation as well as the moisture transport coefficient for these model porous structures are identified from the post-processing of the corresponding pore-network model solutions. The simulation results show that the deviation of the partial vapor pressure from the saturation vapor pressure in the presence of liquid – which is referred to as non-local equilibrium effect – in the bimodal pore structures is less pronounced than in the monomodal pore structures. For the monomodal pore structures the moisture transport coefficient profile is not unique over the entire drying process, whereas this profile depends marginally on the drying history of the bimodal pore structures. Finally the ability of the continuum model to predict the results of the pore-network simulations for multiple realizations of the pore space is assessed.*

## **1. Introduction**

The drying characteristics of porous media can essentially be described via modeling on two different length scales: at the effective-medium scale, continuum models (CM) based on volume averaging have been developed, in which the underlying transport phenomena are described by gradients in spatially averaged quantities and controlled by nonlinear effective parameters [1]. While the CMs are readily competent on the application side, they require macroscopic parameters and suffer from major shortcomings in theoretical aspects. The alternative approach operates at the pore scale and is referred to as discrete pore-network modeling. Discrete network models with different representations of the pore space have been developed, which can be divided into two categories: In the work of Yiotis et al. [2] the entire pore space is represented by pore bodies, leaving the throats as conductors and capillary barriers. This representation is suitable for the large pore volume. It may however fail to represent properly the structures with small pores. Prat et al. [3] and Metzger et al. [4] approximated the void space with hydraulic pore throats and numerical pore nodes. This model is referred to as throat-node-model (TNM) in this work.

Metzger et al. [4] investigated how important is the role of pore structure (with monomodal pore size distribution (PSD) and bimodal PSD) on the intraparticle heat and mass transfer and thus drying kinetics. Vey recently, Moghaddam et al. [5] assessed the classical continuum model by the help of pore network simulations. In these simulations pore networks were generated with a throat radius distribution of  $250 \pm 25 \mu\text{m}$ , resulting in a network porosity of 0.594. In these networks the pore space volume is overestimated due to the throat overlaps at nodes. This void space overestimation is avoided in throat-pore-model (TPM), which is developed in this work. Moghaddam et al. [5] calculated the continuum model parameters from TNM simulations. The results indicated that the moisture transport coefficient and the vapor pressure-saturation relationship are not unique over the entire drying process.

The relationships between the pore structure and the CM parameters are unknown. The aim of this work is to study the dependence of the parameter functions – the internal and surface relationships between the partial vapor pressure and saturation as well as the moisture transport coefficient – on the spatially correlated structures by means of the TPM. The ability of the continuum model to predict the results of the TPM simulations for multiple realizations of the pore space is also assessed.

## **2. Model descriptions**

### **2.1 The continuum model**

Assuming isothermal condition and constant gas pressure during the entire drying process, the mass transport is dominated in the direction perpendicular to the medium surface which

provides the evaporation demand. According to the total conservation of moisture (liquid and vapor phases), the continuum model is thus expressed by:

$$\varepsilon \frac{\partial S}{\partial t} = \frac{\partial}{\partial z} \left( D(S) \frac{\partial S}{\partial z} \right), \quad (1)$$

with the boundary condition of no accumulation at the interface:

$$\dot{m}_v = - \frac{D_{va} \tilde{M}_v}{\tilde{R} T \delta} \ln \left( \frac{P - P_{v\infty}}{P - \phi P_v^*} \right), \quad (2)$$

where  $\varepsilon$ ,  $S$ , and  $t$  (s) denote the porosity, the *local* saturation ( $0 < S \leq 1$ ) and the time, respectively;  $P_{v\infty}$  (Pa) the vapor pressure in the bulk air,  $P$  (Pa) the atmosphere pressure,  $\delta$  (m) the thickness of the diffusive mass boundary layer, which is located between the network open surface and the bulk air. The time-dependent moisture transport coefficient  $D$  ( $\text{m}^2/\text{s}$ ) as well as the boundary conditions need to be known in order to solve Eq. 1. Two parameters  $D$  and  $\phi$ , which is called the vapor pressure-saturation, are estimated from pore network simulations.

## 2.2 Pore network drying model

The pore network model is defined on a three-dimensional regular lattice of pores and throats. The pores are spherical space and throats are cylindrical tubes (Figure 1a). The throat and pore radii are randomly set from normal distributions with corresponding means and standard deviations. The pore radii are chosen such that the pore radius is larger or equal with the largest radius of neighboring throats. Initially all throats and pores are saturated with liquid existing as free water. Periodical boundary conditions are applied on the lateral faces of the network. The extended boundary layer is considered in this model, which is a playground for the external mass transfer of vapor.

Figure 1 Schematics of throat-pore-model (TPM) in 3D (a) and in 2D (b).

Three kinds of pores and three kinds of throats are classified in the algorithm: empty pores and throats; full pores and throats; and partially filled pores and throats. The pores contain variables of interests, namely the liquid pressure and the vapor partial pressure. Transport phenomena are described at the discrete level of pores and throats in one spatial dimension. In this model, the center distance between two pores ( $i$  and  $j$  in Figure 1b) are fixed ( $L=1000 \mu\text{m}$ ). The radii of pores ( $R_p$ ) and throats ( $R_t$ ) are drawn randomly from normal distributions. The throat length ( $L_t$ ) depends on the radii of two pores located at throat ends.

The Stefan law is used to describe the vapor transport in the gas-filled region of the network and the boundary layer. The quasi-steady vapor diffusion between two pores is described by:

$$\sum_j \dot{M}_{v,ij} = \sum_j g_{v,ij} P \ln\left(\frac{P - P_v^j}{P - P_v^i}\right), \quad g_{v,ij} = \frac{D_{va} \tilde{M}_v}{\tilde{R}T \left( \frac{R_{pi}}{A_{pi}} + \frac{L_t}{A_t} + \frac{R_{pj}}{A_{pj}} \right)}, \quad (3)$$

where  $A_p$  and  $A_t$  ( $\text{m}^2$ ) denote the cross section area of pore (i.e.  $\pi R_p^2$ ) and of throat (i.e.  $\pi R_t^2$ ),  $D_{va}$  ( $\text{m}^2/\text{s}$ ) the diffusion coefficient of vapor in air,  $\tilde{R}$  ( $\text{J}/\text{kmol K}$ ) the universal gas constant,  $\tilde{M}_v$  ( $\text{kg}/\text{kmol}$ ) the molar mass of vapor and  $T$  ( $\text{K}$ ) the temperature.  $P_v$  is the vapor pressure at pores.

The Poiseuille's law is used to describe the liquid viscous flow as:

$$\sum_j \dot{M}_{w,ij} = \sum_j g_{w,ij} (P_w^i - P_w^j), \quad g_{w,ij} = \frac{\pi \rho_l}{8\mu} \frac{1}{\left( \frac{R_{pi}}{R_{pi}^4} + \frac{L_t}{R_t^4} + \frac{R_{pj}}{R_{pj}^4} \right)}, \quad (4)$$

where  $\rho_l$  ( $\text{kg}/\text{m}^3$ ) denotes the liquid mass density, and  $\mu$  ( $\text{m}^2/\text{s}$ ) the liquid viscosity. Considering the viscous and capillary forces at the same time, stationary and moving menisci are determined in an iterative manner. The evaporation drives the drying process leading to drainage of moving menisci. The reimbibition can locally occur depending on the local liquid pressure. The time steps forward when one meniscus empties or (re)fills at every moment during drying. In the next steps the mass balance for vapor and liquid phases are solved again. Details on the algorithm can be found in Metzger et al. [4].

In this paper, we generated two pore network structures with monomodal PSD and bimodal PSD. The TPM was applied to generate these two structures. In the network with monomodal PSD, throat and pore radii are drawn randomly from a normal distribution with the given values of standard deviation and mean radius. The network with bimodal PSD is constructed with micro- and macro-channels. The macro-channels are placed vertically in the network.

### 2.3 Parameter functions

The PN simulations yield the vapor and liquid pressure fields as well as the liquid distribution over time. This information is used to determine both the internal and surface relationships between vapor pressure and saturation  $\phi$  as well as the moisture transport coefficient  $D$ . The finite volume method is applied to determine these parameter functions. A three-dimensional network is virtually divided into horizontal slices with constant thickness  $\Delta z$  at distinct times during the drying process. Details of this method is explained in Moghaddam et al. [5].

### 3. Simulation results

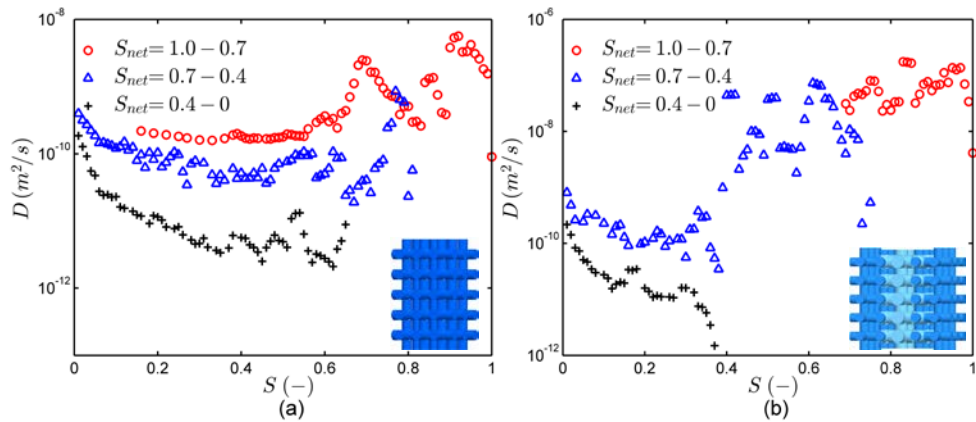

The continuum model parameters are determined from the simulations conducted for monomodal and bimodal pore structures with spatially correlated pore-size distributions. In order to reduce the level of uncertainty on parameter estimates, 10 realizations of pore network were considered. The structural characteristics of PN are given in Table 1.

*Table 1 Structural characteristics of pore networks.*

Structural property	Monomodal PSD	Bimodal PSD
Network size (pore)	$25 \times 25 \times 51$	$25 \times 25 \times 51$
Boundary layer size (node)	$25 \times 25 \times 10$	$25 \times 25 \times 10$
Mean radius ( $\mu\text{m}$ )	250	micro-channel: 200 macro-channel: 350
Standard deviation ( $\mu\text{m}$ )	25	25
Center distance between two pores (mm)	1	1
Network porosity	0.35	0.337

Figure 2 shows the calculated moisture transport coefficient for the two pore structures. As can be seen, the D-S curves depend strongly on the drying history in the networks with monomodal PSD. This dependency is however less pronounced in the networks with bimodal PSD. Similar moisture transport coefficient profiles are identified by Moghaddam et al. [5], but only for the pore structures with monomodal PSD. As can also be seen, the value of moisture transport coefficient increases when altering the pore structure from monomodal PSD to bimodal PSD, especially in the period during which moisture transport occurs mainly through the liquid phase ( $S_{net} = 1.0-0.7$ ). In the network with bimodal PSD the local saturation varies rather uniformly and confines within a small range of  $S = 1.0-0.65$  due to the presence of macro-channels. However, in the network with monomodal PSD the dry region develops rather early due to the presence of strong viscous effect.

Hence the saturation profiles vary with a broad range of  $S = 1.0-0.2$  during the first drying period ( $S_{net} = 1.0-0.7$ ). In the work of Moghaddam et al. [5], conducted with the pore structures of monosized PSD, the range of local saturation variation is wider  $S = 1.0-0$  during the first drying period. One reason for this wide variation could be due to the overestimation of the throat volume in the TNM.

**Figure 2** Simulated moisture transport coefficients  $D$  for the pore structures with (a) monomodal PSD and (b) bimodal PSD. The values are averaged over 10 realizations for local saturation  $S$  intervals.

The coefficient profiles are similar for the both pore structures when moisture transport occurs mainly through the vapor phase. This is so because the moisture transport in the vapor phase is driven by the vapor pressure difference, which is related to the liquid structure (or interfacial area).

The behavior of moisture transport coefficient in the vapor phase can be better understood from the vapor pressure-saturation relationship ( $\varphi$ ). Moghaddam et al. [5] observed a non-local equilibrium (NLE) effect, i.e. the deviation of the vapor pressure from the saturation vapor pressure in two-phase zone, in the pore network simulations. This effect is also observed in the both pore structures (Figure 5). The NLE is strong in the network with monomodal PSD. The liquid controlled range is enlarged in the networks with bimodal PSD due to an efficient capillary pumping. Figure 5 indicates that the vapor pressure deviates significantly from the saturation pressure at low saturation in the both pore structures. The NLE effect appears at early time of the drying process ( $S_{net} = 1.0-0.65$ ) in the networks with monomodal PSD. This is so because of the drying front stabilization by viscous force. However, this effect appears later ( $S_{net} = 0.55-0.45$ ) in the networks with bimodal PSD.

The two parameter functions calculated from the PN simulations are plugged into the continuum model (Eq. 1). The results obtained from the solution of the CM and from the

PN simulations are shown together in Figure 6. For the network with monomodal PSD, the CM predicts fairly the saturation profiles, except those profiles at high network saturation where the moisture transport coefficient values are scattered. This discrepancy may nonetheless be reduced when the parameters are determined for more realizations of larger pore networks.

A fairly good agreement between the CM predictions and the discrete simulations of the pore structures with bimodal PSD is observed (see Fig. 6b). The fact that at high saturation the variation of the moisture transport coefficient value is limited to a small range has led to this good match.

Figure 5 The vapor pressure-saturation relationships for the pore structures with (a) monomodal PSD and (b) bimodal PSD. The values are averaged over 10 realizations.

Figure 6 The continuum model predictions and the pore network simulations: (a) monomodal PSD and (b) bimodal PSD. The saturation profiles of PN are averaged over 10 realizations. From top the profiles belong to network saturation of 0.99, 0.9, 0.8, 0.7, 0.6, 0.5, 0.4, 0.3, 0.2, and 0.1, respectively.

## 4. Conclusions

In this paper, two different pore network structures (with monomodal and bimodal PSDs) are constructed. The values of moisture transport coefficient in the networks with bimodal PSD are large and confined into a narrow range of saturation in the first drying period. During the receding period of drying, the viscous drag forces dominate the capillary forces in both models. In this period, moisture transport mainly occurs in the vapor phase. Therefore, the moisture transport coefficient profiles are similar in the both pore structures during this drying period. The internal resistance for moisture transport is induced by the formation of liquid clusters and single menisci. The non-local equilibrium effect is observed for the both pore structures and it is more pronounced in the networks with monomodal PSD.

The continuum model is solved and assessed for the both pore structures. It has been seen that the one-equation CM is able to predict the saturation profiles obtained from the pore networks with monomodal PSD, except those profiles at high local saturation. This is because a small scatter of the moisture transport coefficient value can significantly impact the solution of the CM. The possible reasons for the scattered values could be due to both small network size and averaging method. Nevertheless, the agreement between the CM solutions and the PN simulations is improved when the networks with bimodal PSD are used.

### **Abstract**

*Freeze-drying is a dehydration method suitable for the stabilization of heat-labile pharmaceutical products, such as vaccines. Due to the vial-to-vial variability of heat and mass transfer during the process, the value of the critical process parameters (e.g., product temperature, sublimation rate) may be different between vials and batches often present significant product quality heterogeneity. The aim of this work was the development of a dynamic, multi-vial mathematical model making it possible to predict risk of failure of the process, defined as the percentage of vials potentially rejected by quality inspection. This tool could assist the design of freeze-drying cycle.*

**Keywords:** lyophilization; vaccines; heat and mass transfer; mathematical modeling; design space

---

## 1. Introduction

Freeze-drying is a discontinuous process used to dry heat sensitive products by means of sublimation of the previously frozen product (primary drying), followed by desorption of the unfrozen water (secondary drying). Due to the use of low temperature, freeze-drying process is often the only solution to produce pharmaceutical and biological products (e.g., vaccines) with acceptable characteristics of stability, shelf-life, and potency. During the process design, two main constraints need to be taken into account in order to guarantee acceptable quality attributes of the final product, such as the visual aspect of the freeze-dried cake and the moisture content. Firstly, the product temperature has to be maintained below a critical value (namely collapse temperature) during the sublimation and desorption steps, to avoid the loss of the porous product structure. Furthermore, the desorption step should be carried out long enough to reach the target value of residual moisture content in the final product. However, due to the vial-to-vial variability of heat and mass transfer, the value of the critical process parameters (e.g., product temperature, sublimation rate and desorption rate) may be different between vials and the process can often result in vial batches presenting a significant heterogeneity in the product quality. Several mathematical models [1-5] were developed for the design of the primary drying and secondary drying steps. Most of these models were based on average values of the model parameters (e.g., product resistance, vial heat transfer coefficient, characteristic desorption time) over the vial batch and only few of them took into account the variability of the model parameters [2, 3] due to differences in heat and mass mechanisms between vials processed in the same or different batches. The understanding and quantification of the mechanisms responsible for product quality variability can lead to a better prediction of the process parameters distribution and consequently of the risk of failure associated to the process.

Our goal in the present study was to develop a multi-vial dynamic mathematical model for freeze-drying for the process design, taking into account sources responsible for heat and mass transfer variability among vials. The developed model was then used to propose a new quality risk-based approach for the design of the primary and secondary drying steps of the freeze-drying process, which includes the evaluation of the percentage of vials potentially rejected for specific combinations of operating variables.

## 2. Theory

### 2.1. Mathematical model

The heat flux received during the process by the vial is assumed to mainly serve for the ice sublimation during primary drying and for the water desorption in secondary drying, the difference being responsible for temperature variation of product and vial in transient regimes. The evolution of product temperature  $T_p$  (assumed to be the same as the vial) during primary and secondary drying can be determined as:

$$C_p \frac{dT_p}{dt} = \dot{Q}_{SV} - \Delta H_{sub} \dot{m}_{sub} - \Delta H_{des} \dot{m}_{des} \quad (1)$$

*Heat transfer during primary drying*

The heat transfer between the shelf and the vial  $\dot{Q}_{SV}$  depends on the temperature difference between the shelf ( $T_S$ ) and the product ( $T_p$ ), and can be expressed in term of vial heat transfer coefficient  $K_V$ :

$$\dot{Q}_{SV} = \left( \frac{1}{K_V} + \frac{l_f(t)}{\lambda_{ice}} \right)^{-1} A_{BV} (T_S - T_p) \quad (2)$$

The term  $K_V$  depends on the vial bottom dimensions (vial–shelf contact area  $A_C$  and depth of bottom curvature  $l_{BV}$ ) and the chamber pressure  $P_C$  and can be defined as:[6]

$$K_V = C_1 A_C + K_r + \frac{C_2 P_C}{1 + C_2 \frac{l_{BV} P_C}{\lambda_v}} \quad (3)$$

$K_r$  being the radiation contribution of the top and bottom shelf.[6]

*Mass transfer during primary drying*

During primary drying the sublimation flux can be defined by the difference between the equilibrium pressure at the ice-vapour interface  $P_{vi}$  and the partial vapour pressure in the chamber  $P_{vC}$ :

$$\dot{m}_{sub} = \frac{A_i}{R_p} (P_{vi} - P_{vC}) \quad (4)$$

where  $R_p$  is the the mass transfer resistance of the dried layer, which depends linearly on the dried layer thickness for the considered product:[7]

$$R_p = R_{p_0} + l_d R_{p_1} \quad (5)$$

$P_{vi}$  can be calculated from the Clausius Clapeyron equation from the sublimation interface temperature,[6] and  $P_{vC}$  is defined as in Trelea et al.[8] assuming ideal gas law for water vapour in the drying chamber:

$$\frac{dP_{vC}}{dt} = \frac{R_g T_C}{V_C M_W} (\sum_1^{N_V} (\dot{m}_{sub} + \dot{m}_{des}) - \dot{m}_{CN}) \quad (6)$$

Finally, the fraction of ice  $f$  contained in the product evolves with time as a function of the sublimation rate  $\dot{m}_{sub}$  as:

$$m_0 \frac{df}{dt} = -\dot{m}_{sub} \quad (7)$$

### Mass transfer during secondary drying

The multilayer model developed by Trelea et al.[9] was used to describe the desorption kinetics in secondary drying.

## 2.2. Heat and mass transfer variability in freeze-drying

Four sources of inter-vial product quality variability were considered in this study:

➤ *Vial geometry*:  $K_V$  is influenced by the shelf-vial contact area  $A_c$  and the depth of bottom curvature  $l_{BV}$  (Equation 3). Thus, differences in these dimensions among the vials can result in variability of the heat transfer among the vials on the shelf. In the present study, the distributions of  $K_V$  at different chamber pressures over the vial batch were calculated based on the normal distributions of  $A_c$  and  $l_{BV}$ , as previously proposed by Scutellà et al.[6]

➤ *Edge vial effect*: It is well known that vials located at the periphery of the shelf receive an additional heat transfer by radiation from the wall and the rail and conduction through the gas between the chamber wall, the rail and the side wall of the vials. This phenomenon is known as edge vial effect. In the present study, the additional radiation heat flow rates from the wall and rail to the edge vials were calculated for edge vials using the Stefan-Boltzmann equation, as proposed in the 3D simplified radiation model developed by Scutellà et al. [10]

➤ *Mass transfer resistance*: The product resistance variability in a large batch of vials was previously quantified as normal distributions of  $R_{p_0}$  and  $R_{p_1}$  in Scutellà et al.[7]

➤ *Desorption kinetics*: The variability of the desorption kinetics was previously quantified as normal distributions of characteristic desorption times in Scutellà et al. [11]

## 2.3. Prediction of the risk of vial rejection

The developed mathematical model was used to propose a quality risk-based approach for the design of the primary and secondary drying steps of the freeze-drying process. The risk of failure of the primary drying step was calculated in terms of vials potentially rejected by considering two main constraints: (i) the product temperature had to be maintained at any time below a critical value (i.e., the glass transition temperature for amorphous products); (ii) the sublimation had to be completed at the end of primary drying (i.e.,  $f = 0$ ). For the design of the secondary drying step, the constraints were: (i) the final moisture content had to be equal or lower than the target moisture content (1.5 %) and (ii) the temperature at any moment had to be lower than the glass transition temperature of the dry product. The range of acceptable combinations of operating variables (i.e.,  $T_s$ ,  $P_C$ , operating time) was then identified based on the target level of risk. The capability of the pilot freeze-dryer was considered to be not limiting regardless of the operating conditions.

## 2.4. Numerical solution

The developed model was solved using Matlab R2014b software provided of the Statistics Toolbox (The MathWorks, Inc., Natick, MA). The analysis of the effect of the heat and mass

transfer variability on the critical process parameters during freeze-drying was performed using the Monte Carlo method. This method consisted in simulation of batches of 100 representative vials with random normal distributions of the considered model parameters ( $A_C$ ,  $I_{BV}$ ,  $R_{p0}$ ,  $R_{p1}$ ,  $\tau_{ref1}$  and  $\tau_{ref2}$ ). Due to computer limitations, the number of simulated vials (100) was significantly smaller than the actual number of vials in the freeze-dryer (2310).

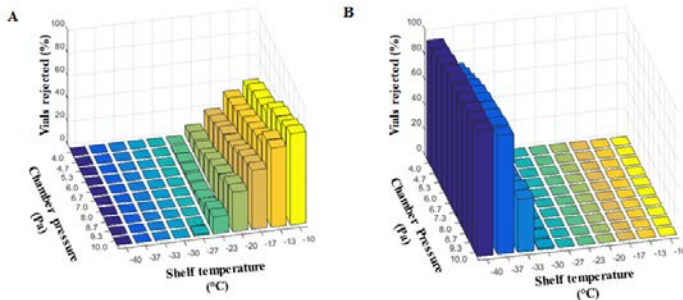

### 3. Simulated system

In the present work, the model was used to simulate freeze-drying process performed in the pilot freeze-dryer REVO (Millrock Technology, Kingston, United States). The equipment was composed of a drying chamber equipped with three shelves and a condenser running at temperature of  $-75\text{ }^\circ\text{C}$ . A total of 770 glass tubing vials (Müller + Müller, Holzminden, Germany) were supposed to be loaded on each shelf. The vials had a total volume of 3 mL and were all filled with 1.8 mL of 5 % aqueous sucrose solution. Furthermore, the vial array was surrounded by a metallic rail (shielding 70 % of the lateral wall of the vials). The shelf was considered to be at a temperature of  $-50\text{ }^\circ\text{C}$  at the beginning of primary drying.

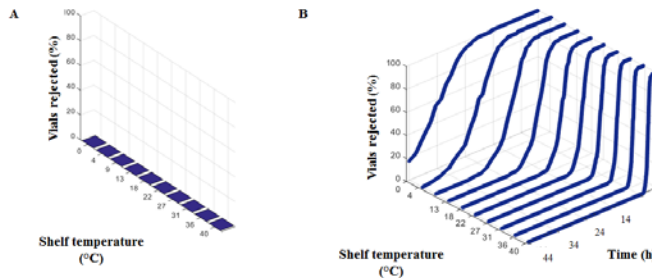

### 4. Results

The developed model was used to predict the risk of failure of the process in terms of percentage of vials potentially rejected. Potential vial rejection of the primary and secondary drying steps were predicted for different combinations of operating variables (shelf temperature, chamber pressure, operating time) to select the best cycle at the maximum allowed risk (1 %). Figure 1A presents the percentage of vial rejection due to a product temperature higher than  $T'_g$  observed performing a primary drying of 84 hours in function of the chamber pressure and shelf temperature. Typical ranges of chamber pressure and shelf temperature used in the pharmaceutical industry were explored, respectively between 4 and 10 Pa, and  $-40\text{ }^\circ\text{C}$  and  $-10\text{ }^\circ\text{C}$ . The results shows that, if a value of shelf temperature higher than  $-27\text{ }^\circ\text{C}$  is applied during primary drying, the percentage of vial rejection become higher than 1 % for most of the pressures tested. Furthermore, Figure 1B presents the percentage of vial rejection due to the sublimation not completed at the end of primary drying observed performing a primary drying step of 84 hours in function of the shelf temperature and chamber pressure. A shelf temperature higher than  $-30\text{ }^\circ\text{C}$  has to be considered to avoid the presence of ice at the end of the primary drying time. Thus, the use of a shelf temperature of  $-27\text{ }^\circ\text{C}$  and a chamber pressure between 4 and 9.3 Pa during primary drying step of 84 h results in a percentage of vial rejection lower than the maximum allowed one (1 %). Figure 2A presents the risk of vial rejection associated to the secondary drying step due to a product temperature higher than  $T_g$ . A range of shelf temperatures between  $0\text{ }^\circ\text{C}$  and  $40\text{ }^\circ\text{C}$  was explored, and the pressure was maintained constant at 6 Pa. The product temperature remains below the critical value regardless of the shelf temperature applied during the secondary

drying step, because the product dries enough during the shelf temperature ramp ( $1^{\circ}\text{C min}^{-1}$ ). Figure 2B presents the risk of vial rejection of associated to the secondary drying step due to a final moisture content in the product higher than the target value of 1.5 %. A shelf temperature higher than  $4^{\circ}\text{C}$  will lead to no vial rejection if secondary drying is carried for at least 45 h. As product temperature remains below the critical value regardless the shelf temperature value used, the optimal operating conditions for secondary drying will be a shelf temperature of  $40^{\circ}\text{C}$  and an operating time of 4 h, which leads to a vials rejection lower than 1 %.

**Fig. 1** Potential vial rejection (%) in primary drying performed at different chamber pressures and shelf temperatures due to (A) a product temperature higher than the critical value ( $T'_g$ ) and (B) sublimation not completed after 84 h of primary drying.

**Fig. 2** Potential vial rejection (%) in secondary drying due to (A) a product temperature higher than the critical value ( $T_g$ ) during the whole duration of the secondary drying step and (B) product moisture content higher than the target value (1.5 %) for different shelf temperatures and operating times.

## 5. Conclusions and perspectives

In this work, a multi-vial, dynamic mathematical model of the primary and secondary drying steps of the freeze-drying process was developed, including the heterogeneity of parameters such as the vial dimensions, the vial position on the shelf and the random nucleation process. The model was used to calculate the risk of failure of the primary and secondary drying steps for a 5 % sucrose solution processed in a pilot freeze-dryer, expressed in terms of percentage of vials potentially rejected. In the future, the proposed model will be experimentally

validated and used to calculate the design spaces of primary and secondary drying for the cycle transfer and scale-up of the process.

### Nomenclature

$A$	Cross sectional area ( $m^2$ )
$C_1, C_2$	Parameters of Equation 3 ( $W m^{-4} K^{-1}$ ), ( $W m^{-2} K^{-1} Pa^{-1}$ )

### **Abstract**

*Three numerical methods, finite differences, finite volume and finite element, were compared to know their convenience in the simulation of convective drying of fruit slices. The mathematical treatment, the stability, the convergence and the sensibility were analysed for each method. The data of the simulations were compared with the data of feijoa dried at 60°C, 5 mm of thickness and air velocity of 0.5ms<sup>-1</sup>. The error was 7%, 13% and 17% for finite element, finite volume and finite differences respectively. The method selection depends on the software, the required data precision and the use of the model.*

**Keywords:** *mathematical model; convective drying; numerical methods*

## 1. Introduction

Feijoa fruit (*Acca Sellowiana* Berg) is a crop adapted from Brazil and North Uruguay to the Colombian Andes [1] [2]. In Colombia, there are 1000 ha planted. Drying is an alternative to extend the shelf life of the fruit and to preserve the functional characteristics of the fruit. The convective drying of fruits is the most used drying technique to remove the moisture of the fruits because of its simplicity and low cost [3, 4]. The mathematical modelling is a useful tool to predict and understand the mass, heat and momentum transfer during drying. The theoretical models are based on the fundamental physics of drying. The use of the theoretical models is increasing thanks to the availability of the advanced numerical computation and to its relevance for the fruit drying understanding.

Choosing the numerical method to solve the PDEs system is a key step in the modelling of convective drying. Three common numerical methods applied are finite differences, finite volume and finite elements, also known as gridbased methods [5]. The finite differences method use the decomposition of the differential terms of PDE in discrete representations through the domain discretization in a rectangular grid. This method generates time evolution chains linked to initial conditions. The finite volume method also discretizes the domain generating several polyhedral volumes. Those volumes are controlled by numerical methods related to differential and integral approximations [6]. The finite elements method uses the same type of domain decomposition as finite volume, but the approximation is different. The weak formulation of the model is necessary for the generation of the algorithm. The aim of the present study is the comparison between the finite differences, finite volume and finite element methods for the modelling of convective drying of feijoa slices.

## 2. Materials and Methods

### 2.1 Mathematical modelling

Three numerical methods to simulate the convective drying of fruit slices were compared. The model was formulated with the following assumptions:(i) the geometry is a slab ; (ii) the model is in 2D; (iii) mass transfer inside the fruit is performed by diffusion and the heat transfer by conduction; (iv) the evaporation occurs only at the surface; (iv) thermophysical properties of fruit dependent of composition and temperature; (v) effective diffusion is constant and (v) shrinkage is accounted. Eqs (1) and (2) represent the heat and mass transfer equations [7, 8].

$$\frac{\partial T}{\partial t} = \alpha \left( \frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} \right) \quad (1) \quad \frac{\partial X}{\partial t} = D_{\text{eff}} \left( \frac{\partial^2 X}{\partial x^2} + \frac{\partial^2 X}{\partial y^2} \right) \quad (2)$$

At initial time ( $t=0$ ), the moisture content and the temperature of the slice correspond to its initial values.  $X_0 = 5.53$  Kg water/Kg dry solids.  $T_0 = 305\text{K}$ . The boundary conditions for moisture transport are represented by Eqs 3 and 4.

$$\left. \frac{\partial X}{\partial z} \right|_{z=0} = -\frac{h_m}{\rho_s D_{eff}} (C_0 - C_{air}) \quad (3)$$

$$\left. \frac{\partial X}{\partial z} \right|_{z=L} = \frac{h_m}{\rho_s D_{eff}} (C_0 - C_{air}) \quad (4)$$

The signs depend on the position of the boundary. In an analogous way, boundary conditions for heat transfer were considered. The concentration of water vapor in the air and in the fruit surface ( $C_{air}, C_0$ ) were determined with the equations reported for the ASHRAE. [9]. The shrinkage was included with the approximations used by [8,10,11].

## 2.2 Numerical methods

The finite difference method was applied with two approaches, the explicit, where the derivative of the temperature and moisture with respect to the position was based on the information of the previous time. Through central finite differences an equation with an only unknown variable was obtained, which is easy to solve. The second approach was the implicit method where the Crank- Nicholson method was applied to the second term of Eqs. 1 and 2. Here, the derivative was performed in the next level of time. Algebraic equations expressed through tridiagonal matrices were obtained and thus solving the system. This is repeated until complete the time of simulation. This method was implemented through an in house code programmed in Matlab 8.3.

The volume finite method started with the prediction of the moisture and temperature at the boundaries. For this purpose, a triangular and regular mesh through the domain was established. Then, a recursion algorithm that uses the information of the previous time was employed. Then the moisture and temperature distribution inside the domain was calculated by the Green theorem application. This theorem solves the right side of Eqs 1 and 2. With this approach a volume integral is converted in a line integral. The PDEs system in 2D passes to 1D facilitating the implementation of the numerical method. The moisture content and temperature at the center of each triangle of the mesh was determined. Then, the moisture and temperature values were determined at the vertices and so on until complete all the triangles of the mesh. This process was repeated for each time step during the simulation time. This approach uses linear equations system that lead to the creation of tridiagonal matrices. This method was implemented through an in house code programmed in Matlab 8.3.

The finite element method was implemented in the software FreeFem++ 3.46. For the implementation the weak formulation of the mass and heat transfer problem was required. The software uses an algorithm based on the Gauss theorem which is applied to the right side of Eqs. 1 and 2. This theorem is a generalization of integration by parts. It allows to

rewrite a line integral which is related with the boundary conditions of the PDE. This approach allowed the equations solution with algebraic methods.

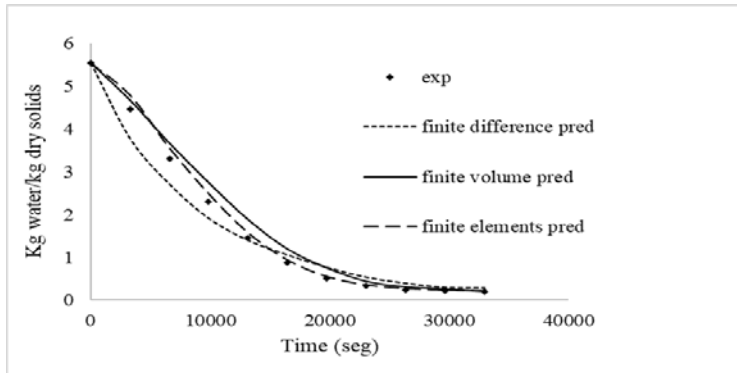

The simulation data was compared with moisture content curves of feijoa slices of 5mm, dried at 60°C, air velocity of 0.5ms<sup>-1</sup> and parallel to the samples. The convective dryer (EDIBON) was used. The goodness of fit was evaluated through the mean relative deviation modulus.

### **3. Results and discussion**

The averaged experimental and predicted moisture content by the three numerical methods are presented in Fig.1. The relevance of the numerical solution method for accurate simulations was observed. First, the moisture content curve obtained by the finite difference method was lower than the experimental values at the beginning of the process. Then, in the middle of the drying, the predicted data were higher than the experimental data. The error for the finite difference method was 17%. Second, the volume finite method showed a curve over the experimental data, but closer than the finite differences. The error of finite volume method was 13%. Finally, the simulated curve by the finite elements method was slightly over the experimental values. Then, as the drying time progresses, the simulated and experimental values are closer. The error was of 7%. The simulations behavior can be explained through the numerical approximation employed by each solution method. Also, by the assumptions and parameters of the mathematical model.

The explicit finite difference method is easy to apply. However, this method was unstable in time intervals partitions of space because the derivative is based on the information of the previous time. On the other hand, the implicit method establishes that the derivative of the temperature or moisture with respect to the position is not performed in the previous time [13]. The derivative is performed in the next level of time. This numerical approximation is more stable against time jumps, partitions of space and variable parameters of the model such as physicochemical and transport properties. Also this method allows to couple the mass and heat transfer with acceptable accuracy. A disadvantage is the rectangular grid structure. This does not allow better data accuracy. Also it is not suggested for irregular geometries. This is important because the knowledge of the simulation conditions are related with the existence of a solution to the PDEs system and good convergence of the model[14].

The application of the volume finite method allowed a better simulated data than finite differences. This indicates that the numerical approaches used by this method and the model parameters allowed good data accuracy. With the use of an in house code and accessible software an initial moisture transfer analysis can be done. However, the coupling between mass and heat transfer was more difficult with the use of an in house code. To overcome this problem the finite elements method is suggested.

**Fig 1. Averaged moisture content predicted by the three numerical methods compared to the experimental data.**

The simulated curve obtained by the finite element method had a good agreement with the experimental data. Also, the use of the method and the software allowed the consideration of more real drying parameters for the model such as variable physicochemical, transport properties and shrinkage. Also, it was possible to optimize the convective transfer coefficients obtaining better results than the programming of the finite volume which constant transport properties were considered.

The Fig. 2 represents the evolution of moisture content in function of the slice thickness during drying time. This figure was determined through the finite differences method. As expected, the boundaries are first dried and finally the center of the product.

**Fig 2. Moisture content evolution in fruit slice during drying by finite difference method**

The Fig. 3 also shows evolution of moisture content in function of the slice thickness during drying time. This figure was obtained with the volume finite method in 2D. It is

observed a representative drying behavior which corresponds to the initial loss of moisture in the boundaries followed by the inner of the product.

**Fig 3. Moisture content evolution in fruit slice during drying by volume finite method**

Simultaneous heat and mass transfer was predicted by the finite elements method. The Fig. 4 shows the temperature distribution inside the slice during drying by the finite elements method. The heat transfer from the surface of the product to its interior was observed. This corresponds to the sensible heat transferred by convection from the air to the product and its transport inside the product by conduction. Then, the temperature increases close to the air temperature.

**Fig 4. Temperature distribution inside the slice during drying simulation by the finite elements method. (a) 3000 s. (b) 6000 s. (c) 12000 s. (d) 15000 s.**

#### 4. Conclusions

The method of finite differences allowed to coupled the heat and mass transfer but with stability and convergence problems. However it is recomendable for apply the approaches of the numerical solutions at initial stages of drying studies.

The coupling of the system with an in-house code was more difficult for the finite volume method. The finite volume method was suitable to predict moisture diffusion as a first step in drying modelling.

The finite element method was the most suitable method. The model can be improved and the parameters of the model can be optimized with this method.

The finite volume and finite elements methods require strong mathematical treatment which increases the computational costs. However, these methods present less convergence and stability problems than finite differences. Also, they are recommended for multi-scale studies.

The three methods have disadvantages for modelling irregular geometries, deformable boundaries and large deformations due to the 'grid' nature of those methods.

The understanding of the numerical method allowed to know the numerical approximations to solve the PDEs and therefore to know the benefits and challenges of the method.

### **Abstract**

*Coffee drying and roasting are usually performed in rotated dryers; therefore, the study of particle dynamics in this equipment is of great relevance to improve their efficiency and hence the quality of the final product. Thus, this work aimed to investigate experimentally and numerically the dynamics of coffee beans in a rotary dryer. The Euler-Euler model was employed to reproduce the particle velocity profile in the rolling regime under different boundary conditions. The results shown that the lower specularity coefficient (0.01), which characterizes the smooth wall and free slip condition, reproduced the bed behavior that most resembled the experimental one. On the other hand, the other coefficients (0.1 and 1.0) showed an increasing deformation in the bed surface, different from the observed experimental behavior. It was also verified that, as the filling degree increases, the bed surface deformation becomes more pronounced.*

**Keywords:** coffee; rotated dryer; simulation; specularity coefficient.

---

## 1. Introduction

During the processing of coffee beans, roasting and drying can be performed in rotary drums. These equipment also have a wide range of applications in the industry, such as mixing, drying, granulation, milling and coating. Rotary drums can process many types of raw materials, with large size distributions and different physical properties.

The efficiency of rotatory drums, depending on the process in question, is highly dependent on the granular movement in the interior, which in turn is related to the energy, mass and momentum transfer rates <sup>[1]</sup>. Therefore, to improve the efficiency of these equipment requires detailed information about the movement of the particles inside.

Rotating drums can show seven different flow regimes (sliding, surging, slumping, rolling, cascading, cataracting and centrifuging), which depend on the rotational speed, filling degree, physical properties of granular materials and drum geometry<sup>[2]</sup>. Each one with its own specific flow behavior, which increase the complexity in its study.

Cristo *et al.* <sup>[3]</sup> recommend the rolling regime for coffee roasting, in order to ensure a uniform heat transfer within the equipment. This regime, which is studied in the present work, is characterized by two different regions: a passive region, found near the drum wall, where particles move as a solid body, and an active region, found near the bed material surface, where the particles avalanche and cascade downward. The physical mechanisms such as, mixing and segregation, heat and mass transfer, and so on, mainly occur in the active region.

Parallel to experimental studies, the numerical simulations arise as a complementary tool in the granular flows investigation. In the present paper, the granular flow was simulated using the Euler-Euler approach along with the kinetic theory of granular flow. In this kind of simulation both phases are treated as interpenetrating continua and the Eulerian approach solves a set of moment and continuity equations for each phase. However, the simulated results are very sensitive to the selected boundary conditions. So, the proper choice of these boundary condition on the wall is of crucial importance to represent the experimental behavior.

In the context of the multiphase granular model, the specularity coefficient appears as one of the boundary conditions to be used. The specularity coefficient is a representation of the fraction of collisions between the particle and wall (contour), which transfer lateral momentum to the wall <sup>[4]</sup>. This coefficient is closely related to the flow conditions and the properties of the wall and there are no experimental determination about it reported in the literature. The value of the specularity coefficient ( $\phi$ ) depends on the sliding condition of the wall and its roughness. Thus, it can range from 0, for perfectly specular collisions, with a smooth wall condition and free slip, and 1, for perfectly diffuse collisions with rough wall and zero slip <sup>[5]</sup>.

Despite the relevance of the boundary conditions for Eulerian simulations, there are few studies about the influence of interactions between particles and the wall on the behavior of the solid phase in rotary dryers. Therefore, the present paper aims to investigate the effect of the boundary conditions on the simulation results of the movement of coffee particles during the rolling regime in a rotating dryer, comparing the simulation with the experimental behavior.

## 2. Materials and Methods

### 2.1. Experimental Setup

Green coffee beans were the particulate material used in this study, with the following specifications: average diameter 5.24 mm, density 1368.3 kg/m<sup>3</sup>, sphericity 0.88, moisture (dry base) equal to 12.15 and angle of repose of 38.4°. The experimental tests were conducted in a stainless steel rotating dryer, with the following dimensions: diameter 21.5 cm and length 50 cm. The front and back walls of the cylinder are made of transparent glass that allows the visualization of the coffee beans movement inside the drum. The inner wall of the dryer was coated with a P80 sandpaper.

The particle velocity profiles were obtained by the image analysis technique using a high speed camera (up to 2000 frames/s). The videos were recorded for the following filling degrees: 10, 20, 30, 40 and 50% and at a rotational speed of 12.5 rpm, which characterizes the rolling regime. Using ImageJ® and Measure™ softwares, it was possible to trace the particles individually in different picture frames. Thus, the velocity of each particle was determined by subtracting the positions of the same particle in two distinct frames. That is, immediately after  $x_2$  and  $y_2$  (see Figure 1); and before  $x_1$  and  $y_1$  of the reference line, and then dividing this result by the time interval between the respective frames ( $t_2-t_1$ ). Figure 1 shows the positioning of the reference line over the bed radius ( $r$ ), along which the velocity were measured. From these profiles, it is possible to find the location of the interface between the active and passive layers along the reference line, determined by the point of inversion of the direction of displacement of the particles. In other words, the point where the particles velocity is nearly zero and delimits the transition between the two regions of rolling regime (active and passive) [8].

Fig. 1: Methodology for particle velocity measurement during the rolling regime.

## 2.2. Numerical Methodology

All simulations were performed in Fluent® 14.0 software, using the Eulerian methodology and the Eulerian Granular Multiphase Model to characterize the fluid and the granular phase behavior inside the rotating dryer. To describe the interactions between the solid phases (particle-particle and particle-wall), it was used the Granular Kinetic Theory. For the granular viscosity, the model of Syamlal *et al.* [6] was used. For the bulk granular viscosity, the solids pressure and the radial distribution function, the models of Lun *et al.* [7] were used.

The no-slip condition was used to describe the boundary conditions in the wall relative to the fluid phase. Meanwhile, for the solid phase, it was used the boundary conditions given by the specular coefficient [5]. Equation 1 expresses the tangential velocity of the solid phase at the wall ( $u_{sw}$ ) in terms of specular coefficient ( $\varphi$ ).

$$u_{sw} = \frac{-6\alpha_{S,max}\mu_S}{\sqrt{3}\sqrt{\theta_S}\pi\varphi\rho_S\alpha_S g_{0,ss}} \frac{\partial u_{sw}}{\partial n} \quad (1)$$

Where  $\alpha_s$  and  $\rho_s$  are the volume fraction and the solid phase density, respectively.  $\theta_s$  and  $\mu_s$  are the granular temperature and solid viscosity,  $g_{0,ss}$  is the radial distribution function.

## 3. Results and Discussion

### 3.1. Analysis of the wall boundary conditions: specular coefficient

For the purpose to verify the effect of the wall boundary conditions, different values of specular coefficient ( $\varphi$ ) were analyzed in the Eulerian simulation of the coffee beans in a rotary dryer. Hereafter, it is presented a qualitative analysis of the experimental and numerical results, the latter being obtained for the specular coefficients equal to 1.0; 0.1 and 0.01. Figures 3, 4, 5, 6 and 7 show the distribution of the solid phase in the front wall of the dryer and also in the transverse plane located in half the length, for filling degrees of 10, 20, 30, 40 and 50 %, respectively.

From the Figures 2, 3, 4, 5 and 6, it is possible to note that the simulations with the lowest specular coefficient value, which characterizes the smooth wall and free-slip condition, better reproduced the experimental behavior, for all filling degrees values evaluated. Concerning to the other specular coefficients values (0.1 and 1.0), it also can be observe an increasing in bed surface deformation, presenting a divergence from the observed experimental behavior. This is due to the fact that the highest specular coefficient (1.0) characterizes the rough wall condition, resulting in a high friction between the wall and the particles, and carrying the particles at higher heights. Also, it can be verified that as the filling degree increases, this bed surface deformation becomes more pronounced.

Comparing the solid fraction distributions in the front wall and in the plane at the half length of the dryer, it can be observed a difference in the bed behavior only for the specular coefficient equal to 1.0. For low values of this parameter, this wall effect is not perceived, since the solid distribution in the wall and in the plane in the middle are practically coincident.

Fig. 2: Solids volume fraction for different values of specularity coefficient at  $f = 10\%$

Fig. 3: Solids volume fraction for different values of specularity coefficient at  $f = 20\%$

Fig. 4: Solids volume fraction for different values of specularity coefficient at  $f = 30\%$

Fig. 5: Solids volume fraction for different values of specularity coefficient at  $f = 40\%$

Fig. 6: Solids volume fraction for different values of specularity coefficient at  $f = 50\%$

### 3.2. Particle velocity profiles

In addition to the qualitative analysis, it was also present a quantitative analysis of the particle velocity obtained by the simulation using different values of specularity coefficients. Figure 7 (a), (b), (c), (d) and (e) show the experimental and simulated results of the velocity profile of coffee beans, for filling degrees of 10, 20, 30, 40 and 50%, respectively.

Figure 7 results show that, for all filling degrees, the transition from the passive to the active layer obtained by simulation occurs at radial positions smaller than those obtained experimentally. Thus, the point of inversion of the direction of displacement of the particles is underestimated by the numerical model. This evidence is more pronounced for the lower specularity coefficient (0.01), which is justified by the greater slippage in the wall, characterized by this condition.

Moreover, it is noted that for the greater filling degrees, the behavior of the simulations performed with the higher specularity coefficients values (0.1 and 1.0), becomes more similar in the passive region. Such similarity is also observed for the active region in all evaluated filling degree values. Although there is a large difference between these two specularity coefficients values, the results presented by them are quite similar, suggesting that simulations performed within this range of values (0.1 - 1.0) would not result in different information.

Fig. 7: Experimental and numerical particle velocity profiles for different filling degrees.

## 4. Conclusions

This work assessed the boundary conditions effects on the coffee beans dynamics inside a rotating dryer by comparing numerical results with experimental data. It was observed that the lower specular coefficient (0.01), which characterizes the smooth wall and free slip condition, reproduced the qualitative bed behavior that most resembled the experimental one. On the other hand, the other coefficients (0.1 and 1.0) showed an increasing deformation in the bed surface, different from the observed experimental behavior. It was also verified that, as the filling degree increases, the bed surface deformation becomes more pronounced. However, the particle velocities profiles obtained by simulation with this lower specular coefficient lead to a transition from the passive to the active layer at radial positions smaller than those obtained experimentally.

### *Abstract*

Modeling of dring of capillary porous media is difficult due to the complex and coupled heat and mass transfer that occur at dynamic liquid-gas-solid interface. Thus far, drying was simulated using either continuum models or pore-network models, both of which have limitations. In this work, the Lattice Boltzmann Method (LBM) is used to simulate the drying in porous media. The LBM is ideal for such simulations as it can incorporate complex effects in a simple way to exhibit realistic fluid-gas interface during drying of capillary porous media.

**Keywords:** *Lattice Boltzmann Method; Capillary Porous media; Drying, Pore Network.*

---

## **1. Introduction**

Drying of porous media is one of the most energy intensive operations in numerous industries such as textile, food, agriculture and etc. Experimental methods have been established to understand the macroscopic drying kinetics, whereas experimentation for the detailed micro scale transport behavior such as phase and temperature distributions and the corresponding micro-macro interactions still need significant scientific development. Modeling and simulation provides an efficient method for investigating such microscopic behavior. Simulation of the drying of porous media is a challenging task as it involves mass, momentum and heat transfer in a three-phase system (solid, liquid and gas) [1]. Various modeling techniques have been used in the past to simulate such complex processes including classical continuum methods [2], discrete Pore Network Models (PNM) [1] and more recently, the Lattice Boltzmann Method (LBM) [3]. Classical continuum models simulate the complex behavior of the fluid in the porous media macroscopically. These models are derived from either homogenization [2] or volume averaging techniques [4]. The continuum assumption in these models imposes an additional length scale constraint on its application. Moreover, models based on Darcy's law ignore non-equilibrium and inertial effects as the flow is at low Reynolds numbers.

A more promising alternative is the discrete pore network model, which is derived from statistical physics concepts like percolation theory, fractal concepts and scaling theory[1]. These involve representing the void space in a porous medium as a pore network and solving the governing equations on this network. Discrete pore network models are especially useful when the effects of pore space or long-range correlations are strong. Despite its various advantages, the pore network models have numerous shortcomings that need to be addressed. For one, the actual porous media has to be converted into a pore network before simulating which is a complex and time-consuming process, especially for more complicated and broad pore size distribution. Further, such models have always assumed either the pore or the throats to be of zero volume which is unrealistic [1]. The fluid-air interface develops dynamically with time and depends on the capillary pressures and the pore and throat geometry. The inclusion of these effects is necessary to improve the accuracy of the pore network model. The Lattice Boltzmann Method provides an alternative by accommodating the actual geometry of porous media.

The LBM is a relatively new mesoscopic method [3] which has repeatedly proven its ability to simulate transport in porous media. It involves solving the discrete Boltzmann equation to reproduce the Navier-Stokes equation in the continuum limit. This can be shown by conducting a Chapman Enskog expansion of the Boltzmann equation [5]. It is simple and accurate to incorporation of complex geometries. And LBM is efficient with parallelization capabilities which make it ideal for simulations in porous media. Further, due to its roots in

statistical physics, it can easily simulate multi-physics processes including multiphase and multi-component flow, cavitation etc. without explicitly tracking the interface as is done in continuum and pore-network models. H. El. Abrach, et. al. [6] investigated the drying of deformable porous media using LBM, macroscopically. Sukop et.al. [7] demonstrated the applicability of the Lattice Boltzmann method in simulating several micro-scale porous phenomenon such as adsorption, wetting, liquid retention and capillary condensation. The present work explains on how LBM can simulate the intricate microscopic interactions between such phenomenon, leading to complex fluid behaviour, such as capillary pumping and haines jumps [8], in non-deformable porous media.

## 2. Lattice Boltzmann Method (LBM)

In LBM, the motion of fluid is described by a set of particle distribution functions (PDF), which helps quantify the number of particles with a particular velocity at a certain location in space. The evolution of this PDF with time is described by the lattice Boltzmann equation (LBE) with, in this case, the Bhatnagar-Gross-Krook (BGK) collision operator [9]. The LBE is written as

$$\frac{\partial f_k}{\partial t} + c_k \frac{\partial f_k}{\partial x_i} = \Omega_k(f) + F_k \quad (1)$$

Where,  $f_k$  is the particle distribution function in the  $k$ th direction,  $c_k$  is the velocity in the  $k$ th direction,  $F_k$  is the forcing term and  $\Omega_k$  is the collision operator given by

$$\Omega_k(f) = -\frac{1}{\tau}(f_k - f_k^{eq}) \quad (2)$$

Where,  $\tau$  is the relaxation time and  $f_k^{eq}$  is the equilibrium distribution function given by the Maxwell Boltzmann Distribution, which can be approximated into the following simple form:

$$f_k^{eq}(r, t) = \rho w_k \left( 1 + 3e_k u + \frac{9}{2}(e_k u)^2 - \frac{3}{2}u^2 \right) \quad (3)$$

The LBE is solved by discretizing the space, time and the velocity. Various different velocity discretization schemes have been developed. In this study, we use the two-dimensional nine velocity model (D2Q9).

For this scheme, the discrete velocities, and are given by:

$$e_k = \begin{cases} (0,0) & k=0 \\ (\pm 1,0)c, (0, \pm 1)c, & k=1,2,3,4 \\ (\pm 1, \pm 1)c, & k=1,2,3,4 \end{cases} \quad w_k = \begin{cases} 4/9 & k=0 \\ 1/9, & k=1,2,3,4 \\ 1/36, & k=1,2,3,4 \end{cases} \quad (4)$$

The macroscopic properties we require, such as the density and velocity are derived from the PDF as

$$\rho = \sum_{n=1}^n f_k \quad \rho u = \sum_{n=1}^n e_k f_k \quad (5)$$

### 2.1. Incorporating Phase Change Models

In LBM, phase separation is achieved by incorporating a force on the particles at a node based on the particle density in the adjacent nodes, i.e., fluid in one node will experience a force in the direction with the higher neighboring density. In this study, the interaction force is incorporated into the model by shifting the velocity in the equilibrium distribution as given below:

$$u^{eq} = u + \frac{\tau F_{int}}{\rho(x)} \quad (6)$$

It is also possible to incorporate the interaction force via direct body forcing, where an additional term is added after the collision process [10]. The most commonly used method is the one proposed by Shan and Chen for Multiphase simulation[11]The inter-particle force is then taken as:

$$F_{int}(x) = -G\psi(x) \sum_{k=1} w_k \psi_k(x+e_k) e_k \quad (7)$$

Where, G is an interaction strength constant and is either negative or positive for attraction and repulsion respectively,  $w_k$  is the weight function given in equation 4 and  $\psi$  is the effective mass, a function of density. This formulation results in an equation of state given by:

$$P = c_s^2 \rho + \frac{c_0}{2} g[\psi(\rho)]^2 \quad (8)$$

Where,  $c_s$  is the velocity of sound,  $c_0$  is a parameter determined by the chosen lattice structure and  $g$  is a parameter that controls the magnitude of the inter-particle forces.

The formulation of  $\psi$  can be designed to incorporate a more accurate Equation of State if required[12]. Equation 8 can be rearranged to give:

$$\psi(\rho) = \sqrt{\frac{2(p_{EOS} - c_s^2 \rho)}{c_0 g}} \quad (9)$$

Here,  $P_{EOS}$  is the equation of state used, which, in this case, is the Carnahan Starling equation of state, given by:

$$p_{EOS} = \rho RT \frac{1 + b\rho/2 + (b\rho/4)^2 - (b\rho/4)^3}{(1 - b\rho/4)^3} - a\rho^2 \quad (10)$$

Applying to equation 7 and combining the numerical approximations of the gradient [13], we get:

$$F_{int}(x) = c_0 \beta G \nabla \psi(x) - (1 - \beta) c_0 G \Delta \nabla \psi^2(x) / 2 \quad (11)$$

Where  $G$  is taken as  $-1$  to ensure a positive value under the root and  $\beta$  is a weighting factor that can be tuned for each equation of state. For the CS equation of state  $\beta$  is taken as  $1.16$ .

Here, wall interaction is incorporated in a similar way, by assuming the walls to have density equal to the liquid density. Therefore,  $\rho_{wall} = \rho_{liquid}$ . This gives the formulation:

$$F_{ads}(x) = -G_{ads} \psi(x) \sum_{k=1}^n w_k \psi_{wall}(x + e_k) e_k \quad (12)$$

### 3. Simulation Results and Discussion

In this study, we simulated the drying of two types of porous media: structured and irregular. The structured porous medium consisted of equally spaced horizontal and vertical throats intersecting in circular pores, while the irregular porous media did not exhibit any observable pattern. Figure 1 shows the simulated results obtained using Lattice Boltzmann method. In the porous medium as shown in Figure 1A, the radius of the pores are much higher than that of the throats. This implies that there is a sudden and large increase in radius of the meniscus, thereby making it unstable/instabilities during drying. Therefore, the interface moves rapidly to the next stable orientation. This causes the surrounding liquid to be pumped outward and thus causing smaller pores and throats to be filled. This phenomenon can be observed in Figure 1A. The emptying of the pore circled in red leads to the refilling of the vertical throat circled in blue. Such effects are more prominent and discernable near the edges of the porous media where the pumping is only possible in limited directions. This phenomena of Haines jump events can significantly change the liquid orientation in the porous media as well as cause fluctuations in drying rate. Predicting such phenomenon is therefore essential to creating accurate models of drying.

**Figure 1:** A) Occurance of Haines jump (red) leads to refilling of vertical throat (blue). B) Effect of surface tension impedes the emptying of pore (blue). C) Large extend of sluster formation.

Apart from the geometry of the porous media, the properties of the wetting fluid also plays a crucial part in the drying. One such property, the surface tension, can prevent the invasion of a pore even though its adjoining throats are empty, as shown in Figure 1B. It can be seen that the pore (circled in blue) does not invade for a considerable amount of time even though two of its adjacent throats are empty. As explained, emptying of pores creates unstable intermediate interfaces. This instability is due to the high surface energy present at the interface. Therefore, to invade a pore, the surface energy of the interface has to become equal to or larger than the intermediate interfacial energy. This is usually achieved due to reduction in pressure above the interface, and so, increase in surface tension and energy. Hence, pores are not invaded until the surface energy of the pore reaches a threshold value.

The structured porous media shown above is merely an approximation of the actual porous media, which vary widely in shape and size of both pores and throats. Figure 1C shows a more random type of porous media where the drying phenomena is simulated. Here, the wide range of sizes and shapes lead to clusters formation (red). These clusters may be very small and local to single throats, or large and spanning several pores. These clusters of liquid are bounded by interfaces of high capillarity. This implies that such clusters remain idle until and unless the surrounding pressure reduces sufficiently. It is therefore possible for clusters to exist even after the drying completes. Such bounded liquid can lead to significant problems in drying efficiency and quality of products and so, have to be accounted for.

## 4. Conclusions

Modelling of drying of porous media has been done in the past using various techniques such as Pore Network Models and Continuum models and have met with some success. Here, we used a Carnahan Starling equation of state based high density ration Lattice Boltzmann Method to model the same under realistic operating conditions. The following key observations were made from this study:

1. Haines jumps cause significant changes in liquid orientation and can lead to unexpected variations in drying rate.
2. Surface energy of the interface plays an important role in deciding which pore to invade and when.
3. Highly randomized and realistic porous media exhibit high levels of liquid entrapment and cluster formation

It can be concluded that the Lattice Boltzmann Method provides an accurate and plausible alternative to continuum and pore network models when it comes to modeling in porous media.

### **Abstract**

*Cellulose nanofibers (CNF) is used in various pharmaceutical applications due to its unique characteristics i.e., biodegradability, mechanical and biological properties. CNF is often produced by spray drying process, knowledge of the drying kinetics in terms of mass and heat transfer on the scale of single droplet is important for process development and model validation.*

*Acoustic levitator was used to study drying process of CNF suspension at different air temperatures and initial CNF concentrations. The unique property of acoustic levitation to hold single droplet contactless in the air, enables to study particle morphology during drying process, calculate evaporation rate and estimate particle porosity. Results show that packed particles result at lower initial concentration and temperature has a moderate influence on mean porosity of CNF dried particles.*

**Keywords:** *acoustic levitation; droplet; drying kinetics; Cellulose Nanofibers.*

## **1. Introduction**

Cellulose nanofibers (CNF), is a promising biopolymer. The high surface area of CNF makes it suitable as a nanofiller to enhance the mechanical properties of composite materials [1]. The rheological and physio-chemical properties, allow CNFs to stabilize emulsions of different types and improve the drug delivery of active materials in poor soluble aqueous solutions [2]. The strength with low weight and high surface area make CNF a good candidate for capsule reinforcement [3], on the other hand CNF can play a significant role in producing sustained drug release formulation, the CNFs form a fiber network that hinder the diffusion of drug [3].

Cellulose nanofibers are mainly produced from cellulosic botanical sources such as wood, cotton, hemp or flax. The isolation of Cellulose nanofiber is achieved via mechanical or chemical processes, which result in gel-like liquid suspension that held cellulose nanostructures. CNFs are extracted from the aqueous medium via evaporation of the solution through lyophilization [4], supercritical drying and spray drying [5].

Spray drying is widely used in many industries, e.g. chemical, food and pharmaceutical processing. In spray drying, droplets generation is followed by solvent/liquid evaporation leading to a final powder product. The short retention time in spray drying, makes it ideal for heat sensitive materials. Controlling the drying kinetics is decisive to minimize the liquid amount in the particles and enhance good mechanical properties. Physico-chemical properties of the solution together with operating parameters, greatly influence drying kinetics.

Since experiments on real sprays are difficult to interpret and only integral information about an ensemble of droplets can be obtained, simple and idealized configurations considering single droplets are often preferred for investigation of such spray drying situations.

The experimental work presented in this paper deals with the drying process of individual CNF suspension droplets. The focus of drying experiment was to determine the drying kinetics at various process parameters i.e., gas drying temperature, CNF loading. The acoustic levitation has been used, exhibiting an almost steady positioning of the sample; hence providing a unique opportunity to observe a droplet throughout the entire drying period. The imaging technique allows for accurate measurement of temporal change of droplet diameter and vertical size, that were used to calculate drying rate and mass of the droplet during the drying process and estimation of dried particle porosity.

The paper is organized as follows: in the next section, materials and methods i.e. acoustic levitation are described and the influence of the acoustic streaming on liquid evaporation is discussed, thereafter, the experimental and theoretical results are presented. The paper ends with the conclusions.

## 2. Materials and Methods

### 2.1. Materials

The CNF used for the microparticles production was obtained from Process Development Center University of Maine (Orono, USA) in form of 3.0% aqueous gel. The nominal fiber diameter is 50 nm and fiber length up to few hundred micrometers. Deionized distilled water was used to prepare CNF suspension.

### 2.2. Methods

#### 2.2.1. Preparation of CNF suspension for single droplet drying

The CNF aqueous gel solid content was proofed by drying 10 different samples of CNF aqueous gel in an oven at 60 °C for 10 hours, the mass fraction of dry fibers was estimated to be  $3.5\% \pm 0.13$ . The desired suspensions were prepared by diluting CNF aqueous gel using deionized distilled water. CNF suspension was homogenized using magnetic stirrer for 30 mins to assure homogeneity of the cellulose fibers suspensions. The desired concentrations of CNF suspension were 2,4 and 6 mg(CNF)/ml (water).

#### 2.2.2. Single droplet drying apparatus

The ultrasonic levitator was used for the drying experiments; the main setup is sketched in *Fig. 1*, it consists of an acoustic levitator which operates at 58 kHz sound frequency. The emitted ultrasonic waves leave the transducer and propagate through the gas medium to hit the concave reflector and then bounce to the transducer forming the so-called standing wave. The acoustic force generated by this standing wave is capable of stable positioning of the liquid or solid samples. The levitator is equipped with heating chamber, and drying temperature up to 120 °C of the gas can be achieved. The imaging system consists of a CMOS camera connected to a macro lens, it allows for monitoring the droplets. The droplet is illuminated via LED back light, the shadow image captured by the camera is analyzed online to calculate droplet equivalent diameter, vertical position and aspect ratio. A microliter syringe with long needle is used to insert axially the droplet into the acoustic field.

#### *Influence of the acoustic field*

The interaction between the acoustic field and CNF droplets suspended by the acoustic force generates streaming flow around the droplet. Several authors [6, 7] studied the induced flow and quantify its effect on the evaporation of the liquid. The acoustic streaming were first defined Schlichting [8], these streaming are divided into two categories; the inner acoustic streaming which drives the mass and heat transfer between the droplet surface and the surrounding gas medium [6, 9].

**Fig. 1** Schematic picture of the acoustic levitator.

The second streaming flow is called outer acoustic streaming which represent toroidal vortices, these vortices trap the evaporated liquid from the droplet. Therefore, the vapor is accumulated around the droplet and alter the far-field vapor concentration. As more vapor is trapped by the outer acoustic streaming, the evaporation rate is reduced and comparison with model become rather difficult. A depletion of the accumulated vapor from such vortices becomes mandatory to have reproducible results and enable model validation. An air flow of 0.85 l/min is inserted surrounding the droplet to destroy the outer acoustic streaming and remove the vapor accumulated around the droplet [10].

### 3. Results and Discussion

#### 3.1. NFC Microparticle production

CNF has strong affinity to water, at very small CNF concentration ca. 3.5% wt., a slurry is formed, in order to generate small droplets using the microliter syringe, suspension at very low CNF loading were prepared, namely 2,4, and 6 mg CNF per ml of water.

The drying temperature was varied in the range (20-80 °C), droplets of 1.0-2.0  $\mu\text{l}$  of the suspension was introduced into the acoustic field, once the drying experiment finished the particle was collected to study its morphology and surface structure under scanning electron microscopy. As shown in **Fig. 2**, the drying of CNF suspensions droplet results in water evaporation and an agglomerate of fibrous structure is formed. The initial droplet size was 1.5 mm. at the end of drying course in the acoustic levitator, the dried particle size is reduced to ca.~200-300  $\mu\text{m}$  diameter and an agglomerate of the nanofibers was obtained. It can be seen that particles are not spherical, **Fig. 2a** shows the surface morphology of the particle where the nanofiber consolidated together, **Fig. 2c** depicts the internal structure of the particle after it has been broken, the porous structure and the random alignment of the fibers can be

easily noticed, despite the length of the cellulose nanofibers, they have been folded inside the droplet due to high surface tension of the water comparing to the soft cellulose nanofibers structure.

**Fig. 2** Scanning Electron Microscopy images of dried cellulose nanofibers suspensions a) 6mg/ml at 80°C b) 6mg/ml at 60 °C and c) internal structure of broken particle.

### 3.2. Evaporation rate and porosity estimation

The drying rate and the mean porosity of dried particle is discussed in this section. Four different temperatures were investigated, the surface decay of the droplets is shown in **Fig. 3**, the higher the temperature is, the droplet drying rate becomes faster. The experiments in **Fig. 3** were conducted with the same initial volume namely 2μl and different loading of CNF was used. The drying curves in terms of normalized surface area decay can be divided into two stages, the first one, where the loading of CNF is very low, mass fraction of CNF is less than 0.05% wt., the evaporation rate here follows the well-known  $d^2$ -law. Actually, for small CNF loading, the drying curve is similar to the evaporation of pure water, once the loading of CNF increases, it starts competing with the available sites for water evaporation, as more of the solids accumulated on the surface, the evaporation of the liquid becomes slower i.e., second stage begins. Finally, the droplet forms an agglomerate of cellulose nanofibers, the size of the particle remains constant.

The evaporation rate was calculated from the slope of the temporal evolution of the surface decay curves and represented by a solid line in **Fig. 3**.

The porosity of the dried particle is an important parameter for modelling drying kinetics, the water passes through particle voids to reach the surface. On the other hand CNF can play a significant role in producing sustained drug release formulation, the CNFs form a fiber network that hinders the diffusion of drug [3]. At lower particle porosity, the drug diffusion becomes slower, porosity is calculated using the equation:

$$\varepsilon = 1 - \frac{m_s}{\rho_s V_p} \quad (1)$$

Where,  $\varepsilon$  is the porosity,  $m_s$ ,  $\rho_s$  is the mass and density of solids respectively,  $V_p$  is the volume of the particle in  $m^3$ . As depicted in **Fig. 3**, higher porosity is obtained for lower initial CNF concentration, while temperature has a moderate influence on mean particle porosity.

**Fig. 3** Temporal evolution of surface area decay of CNF suspension droplet for a) 4mg CNF/ml, b) 6mg CNF/ml at 20,40,60 and 80 °C, the initial droplet volume is 2.0  $\mu$ l. c) & d) calculated mean porosity of dried CNF particle as a function of CNF loading and drying temperature, respectively.

### 3.3. Constant and falling rate periods

Suspension of CNF droplet exhibit upon course of drying changes in physical properties, i.e., density of the droplet increases as more liquid is evaporated, the shape of the droplet changes until the final morphology evolves at the end of the drying. In case of mass transfer rate, droplet drying shows in general two regimes, the first one is called constant rate period and the second one is falling rate period [11, 12].

In constant rate period the evaporation of the liquid occurs from a wet particle surface. As depicted in **Fig. 4**, evaporation of the liquid is accompanied by size reduction i.e., droplet normalized surface area decreases with time. The shrinkage of droplet continues, and the concentration of CNF increases until a small particle or grain of CNF is formed. During the constant rate period the evaporation rate occurred occurs at constant wet bulb temperature, the evaporation rate is calculated form the volume change of the droplet of the liquid:

$$\left. \frac{dm_{a,c}}{dt} \right|_{const} = -\rho_d \frac{\Delta V}{\Delta t} \quad (2)$$

Where V is the volume of the droplet in  $m^3$  and  $\rho_d$  is droplet density in  $kg/m^3$ .

As the liquid evaporates, the droplet alters its vertical position in the acoustic field. The vertical position is function of droplet's volume and weight [6], it rises in the acoustic field towards pressure node as shown in *Fig. 4*.

Once the volume and aspect ratio of the droplet/particle seized, the *constant rate period* comes to its end and the *falling rate period* starts, this is marked by constant surface area in *Fig. 4*, here, the shadow image technique is not able any more to deliver information about the mass transfer rate because the particle/grain has now a constant volume that is calculated from its meridional section.

The evaporation of the liquid continues and by monitoring the vertical position of the grain in the acoustic field, further information about the mass transfer can be found. The acoustic force acts against gravity force and once the droplet volume is constant, any decrease in particle weight due to liquid evaporation force the droplet to move upwards to the adjacent pressure node.

The mass of the particle can be easily found by interpolation of the vertical position in the falling rate period, knowing that the rise of the particle in the acoustic field is now only function of the density.

$$m_{d,f}(t) = \frac{\Delta m_{f,max}}{\Delta y_{f,max}} \cdot (\text{vert. pos}(t) - \text{vert. pos}(t_{f0})) + m_{d,c} \quad (3)$$

Where,  $m_{d,f}$  is the mass of droplet in the falling in kg,  $\Delta m_{f,max}$  and  $\Delta y_{f,max}$  are maximum difference of particle mass and particle vertical distance respectively and calculated between the beginning and the end of the falling rate period.  $m_{d,c}$  is the mass of droplet at the end of constant rate period. The mass of the liquid at the end of falling rate period is approximately zero,  $t_{f0}$  is the time in seconds when falling rate period begins.

**Fig. 4** Vertical position of the droplet (CNF 6 mg/ml TE 40 °C) during the course of drying, the first stage of drying is designated by volume reduction of the droplet and the second stage of drying is designated by rise in the acoustic field at constant volume.

The above results show the importance of the acoustic levitator to measure the drying kinetics of CNF suspension droplets, and its ability to measure particle's drying rate in both constant and falling rate periods. The estimated porosity of dried particle which is an important product property and was obtained for different drying temperatures and CNF loadings.

#### 4. Conclusions

The drying kinetics and porosity of CNF dried particle has been investigated, a series of experiments were conducted in the acoustic levitator to mimic the spray drying process occurred in spray dryer. Drying rates and the evolution of particle morphology were monitored using the shadow imaging technique. Particle shape and inner structure of cellulose nanofibers were analysed by SEM technique. The drying rate of droplet increases at high temperatures. The porosity of the dried particles shows an increase for higher CNF initial concentrations and drying temperature has a moderate influence on particle porosity.

### **Abstract**

*Air drying kinetics of Bifurcaria bifurcata brown seaweed at 35, 50, 60 and 75°C were determined. Experimental drying data were modelled using two-parameter Page model (n, k). Page parameter n was constant (1.28) at tested temperatures, but k increased significantly with drying temperature from 35 to 60°C and was invariant at higher temperatures (up to 75°C). Drying experiments allowed the determination of the critical moisture content of seaweed ( $1.6 \pm 0.2$  kg water (kg d.b.)<sup>-1</sup>). Mass transfer coefficients during constant drying rate period and effective coefficients of water diffusion during falling drying rate period were evaluated, assuming cylindrical geometry and considering volumetric shrinkage.*

**Keywords:** *algae, diffusivity, drying kinetics, modelling, shrinkage*

---

## 1. Introduction

*Bifurcaria bifurcata* is a brown seaweed geographically distributed in the Western Europe and Sahara coasts. The main use is the extraction of compounds (alginates and other products) used by pharmaceutical, cosmetics and food industries [1]. Although the human consumption of this seaweed is not as extended as other seaweeds such as *Laminaria spp.*, *Undaria pinnatifida*, its high content of polysaccharides, proteins and minerals [2] and antioxidants [3] makes attractive the use of this seaweed as food product. In fact, the direct human consumption worldwide in recent years is increasing.

Drying is a very employed operation in order to obtain stable food products whose storage as fresh product can be difficult. In the case of seaweeds, traditionally the water removal is carried out by solar drying, but the increasing demand of more homogenous and better quality dried products must be satisfied by means of the use of other industrial methods like convective hot air drying. In this sense, the experimental determination of the more adequate drying conditions is necessary to obtain a final dried product with acceptable characteristics. A scarce number of studies on mathematical modelling of drying kinetics of seaweeds can be found in literature. In example, Lemus et al. [4] studied the drying kinetics of the red seaweed *Gracilaria chilensis* and Vega-Gálvez et al., [5] the drying of brown seaweed *Macrocystis pyrifera*. However, no studies on drying kinetics of fresh *Bifurcaria bifurcata* were found. The aim of this work was to determine the drying kinetics of *Bifurcaria bifurcata* at different temperatures and the corresponding modelling of the drying periods.

## 2. Materials and Methods

Fresh brown *Bifurcaria bifurcata* seaweeds ( $4.59 \pm 0.28$  kg water·(kg dry solid)<sup>-1</sup>, d.b.) selected with similar sizes (100-150 mm length and 1.5-2.0 mm diameter) were dried in a hot air convective dryer (Angelantoni, Challenge 250, Italy), at four air temperatures (35, 50, 60 and 75°C). Relative humidity (30%) and air velocity (2 m·s<sup>-1</sup>) remained constant. Seaweeds were placed on a metallic mesh (45x45 cm<sup>2</sup>) allowing the transversal air flow during drying. A thin layer configuration involving the use minimum amount of seaweeds to cover initially the drier tray (load density of  $2.04 \pm 0.02$  kg·m<sup>-2</sup>) was employed.

Samples were weighed using a balance (Cobos D-6000-CS,  $\pm 0.1$  g, Spain), during drying until achieve a constant weight. All experiments were performed, at least, in triplicate.

Drying kinetics were modelled by Page model [6], Eq. (1):

$$MR = e^{-kt^n} \quad (1)$$

where  $k$  (min<sup>-n</sup>) and  $n$  (-) are the model parameters. The dimensionless moisture content or moisture ratio,  $MR$  (-), was calculated by Eq. (2):

$$MR = \frac{X_t - X_{eq}}{X_0 - X_{eq}} \quad (2)$$

where  $X_t$  is the moisture content (d.b.) at any drying time,  $X_0$  is the initial moisture content (d.b.) and  $X_{eq}$  is the equilibrium moisture content of the sample (d.b.).

### 2.1. Sample surface area and shrinkage determination

Sample surface area and shrinkage of seaweeds were estimated following the same procedure. Samples (0.5-1.5 g) dried at several times were immersed into n-heptane at 21°C. The initial volume ( $V_0$ , m<sup>3</sup>) of the samples and the volume at different drying times ( $V$ ), were measured applying Archimedes' principle. A volume shrinkage with moisture content ( $V/V_0$  vs  $X$ ) relationship was obtained. External surface area of the monolayer was estimated assuming cylindrical geometry of the seaweed and the tray surface is fully covered initially. The initial radius of seaweed branches was determined ( $2.3 \pm 0.3 \cdot 10^{-3}$  m). Volume shrinkage was mainly governed by radius decrease ( $L/r_0 > 100$ ) and Eq. (3) was obtained:

$$\frac{V}{V_0} = \frac{\pi r_x^2 L}{\pi r_0^2 L} \rightarrow r_x = \sqrt{\frac{V r_0^2}{V_0}} \quad (3)$$

where  $L$  (m) is the length,  $r_0$  and  $r_x$  (m) the initial and the radius of sample at different moisture content. The surface area ratio of monolayer can be calculated by Eq. (4):

$$\frac{S_X}{S_0} = \frac{2\pi r_x L N_s}{2\pi r_0 L N_s} = \frac{r_x}{r_0} \quad (4)$$

where  $S_X$  (m<sup>2</sup>) is the surface area of seaweed monolayer at each moisture content,  $S_0$  the initial surface area of the monolayer and  $N_s$  is the number of seaweed samples that can be placed in the monolayer ( $L/(2 r_0)$ ). Employing the Eq. (3), the relationship between surface area of seaweed monolayer and volumetric seaweed shrinkage resulted on Eq. (5):

$$\frac{S_X}{S_0} = \sqrt{\frac{V}{V_0}} \quad (5)$$

The determination of surface area of seaweeds monolayers allowed the specific drying rate,  $w_s$  (kg water kg dry solid<sup>-1</sup> m<sup>2</sup> min<sup>-1</sup>), evaluation by means of Eq. (6):

$$w_s = \frac{1}{S_X} \frac{X_{t_{n-1}} - X_{t_n}}{t_n - t_{n-1}} \quad (6)$$

The  $w_s$  vs  $X$  curve was used for the critical moisture content ( $X_c$ , d.b.) evaluation at tested temperatures and the end of the constant drying rate period.

#### 2.1.1. Constant drying rate period modelling

During the constant drying rate period the coefficients of mass transfer ( $K_t$ , m s<sup>-1</sup>) and the convective heat transfer ( $h_t$ , W·m<sup>-2</sup>·K<sup>-1</sup>), were determined by Eqs. (7) and (8):

$$w = \frac{X_{t_{n-1}} - X_{t_n}}{t_n - t_{n-1}} = \frac{K_t \rho_{air} a}{\rho_s} (Y_i - Y_{air}) \quad (8)$$

$$w = \frac{h_t a}{\Delta H_v \rho_s} (T_i - T) \quad (9)$$

where  $w$  (kg water·kg dry solid<sup>-1</sup>·s<sup>-1</sup>) is the mass flow of evaporated water,  $Y_i$  and  $Y_{air}$  (kg water (kg dry air<sup>-1</sup>)) are the interphase and bulk absolute moisture content of air, respectively,  $\rho_{air}$  (kg·m<sup>-3</sup>) is the air density at drying temperature,  $\rho_s$  (kg dry solid·m<sup>-3</sup>) is the apparent density of seaweed layer,  $a$  (m<sup>2</sup>·m<sup>-3</sup>) is the total interfacial surface (assuming water transfer by both sides of the layer) per unit of layer volume,  $T_i$  and  $T$  (°C) are the interphase and dry temperature of air, respectively and  $\Delta H_v$  (J·kg<sup>-1</sup>) is the latent heat of vaporization of water at the interphase temperature. The interphase properties ( $Y_i$  and  $T_i$ ), during pre-critical drying period, were considered as the wet-bulb properties of the air employed for drying.

### 2.1.2. Falling drying rate period modelling

The falling drying rate period of drying was modelled employing the analytical solutions to Fick's diffusion equation to determine the effective coefficients of water diffusion through the sample under some assumptions [6]. Briefly, the distribution of the moisture within the product is uniform; at  $t > 0$  surface reaches equilibrium moisture and all resistances to water removal are inside the material (the external resistances are negligible). Moreover, the shrinking effect on the characteristic dimension ( $r_x$ ) of seaweeds was taken into account. The fitting of the experimental data of the falling drying rate period was carried out employing the following ratio, Eq. (10):

$$\frac{M_t}{M_\infty} = \frac{X - X_e}{X_c - X_e} \quad (10)$$

where  $M_t$  (g) is the amount of water removed at time  $t$  (min),  $M_\infty$  (g) is the total amount of water removed until the equilibrium is reached. The analytical solutions associated to the cylindrical geometry for short Eq. (11) and long Eq. (12) times are:

$$\frac{M_t}{M_\infty} = \frac{4}{\pi^{1/2}} \left( \frac{D_{eff} \cdot t}{r_x^2} \right)^{1/2} - \frac{D_{eff} \cdot t}{r_x^2} - \frac{1}{3 \cdot \pi^{1/2}} \left( \frac{D_{eff} \cdot t}{r_x^2} \right)^{3/2} \quad \text{when } 0 < M_t/M_\infty < 0.6 \quad (11)$$

$$\frac{M_t}{M_\infty} = 1 - \sum_{n=1}^{\infty} \frac{4}{\alpha_n^2} e^{-D_{eff} \cdot \alpha_n^2 \cdot t / r_x^2} \quad \text{when } 0.4 < M_t/M_\infty < 1 \quad (12)$$

where  $\alpha_n$  (-) are the roots of the first order Bessel function for each term  $n$ . In this case, three terms ( $\alpha_1$ ,  $\alpha_2$  and  $\alpha_3$  are 2.405, 5.520 and 8.654) of the Eq. (12) were considered enough to fit the experimental data. Water diffusivity values for short and long times were obtained using Microsoft Excel (Solver add-on) by means of nonlinear programming in which the root mean square error,  $E_{RMS}$ , between experimental and calculated data is minimized. The final values of water diffusivity for the whole falling rate period were calculated by the weighted

arithmetic mean (as function of the number of data for each time) of the water diffusivity obtained with the corresponding models for short and long times.

### 3. Results and Discussion

Figure 1 (left) shows the drying kinetics of *Bifurcaria bifurcata* at different temperatures. As it can be seen, a temperature increase from 35°C to 60°C decreased the drying time. The necessary drying time to achieve a MR of 0.03 was shortened from 100 to 60 min with no differences between drying at 60°C or 75°C.

Fig. 1 Experimental drying (left) and specific drying rate curves (right) for *Bifurcaria bifurcata* at 35°C (♦), 50°C (■), 60°C(▲) and 75°C (●). Lines correspond to Eq. (13) (right) and to diffusional model (postcritical period) and Eq.(8) (precritical period) for cylindrical geometry (right).

Drying kinetics experimental data were satisfactorily ( $R^2 \geq 0.999$ ) fitted employing Page model, Table 1. No significant differences existed between drying at 60°C and 75°C which means that regarding drying time, the drying at 60°C is more adequate. Moreover,  $n$  parameter of Page model was constant for all drying temperatures. This fact, allowed the establishment of a unified model able to fit drying kinetics throughout the range of temperatures tested (35-60°C):

$$MR = e^{-(-1.36 \cdot 10^{-3} - 2.90 \cdot 10^{-4} T)t^{1.28}} \tag{13}$$

Table 1. Values of the Page model parameters ( $k$ ,  $n$ ), Eq. (2) and statistical coefficients ( $R^2$ ,  $E_{RMS}$ ) for drying curves of *Bifurcaria bifurcata*.\*

T (°C)	$k \cdot 10^3$ (min <sup>-n</sup> )	n (-)	$E_{RMS}$ (-)	$R^2$
35	8.7±0.08 <sup>c</sup>	1.28	0.01	0.999
50	12.8±1.15 <sup>b</sup>		0.01	0.999
60	17.8±0.65 <sup>a</sup>		0.01	0.999
75	18.6±0.77 <sup>a</sup>		0.01	0.999

\*. Data value of each parameter with different superscript letters in columns are significantly different ( $P \leq 0.05$ ).

Comparing with other brown seaweeds dried in similar conditions it can be said that *Bifurcaria bifurcata* has a similar behavior with drying temperature of the one observed for *Fucus vesiculosus* (FV) [7]. However, this behaviour was different of the one observed for other brown seaweed such as *Ascophyllum nodosum* and *Undaria pinnatifida* where temperatures higher than 60°C significantly decreased drying time [8].

### 3.1. Sample surface area and shrinkage during drying determination

The specific drying rate in thin layer configuration was evaluated using Eq. (6) considering that  $S_x$  varied with seaweed moisture content according to a empirical non-linear relationship:

$$\frac{S_x}{S_0} = \sqrt{-1.0 + 1.06e^{-0.11X}} \quad (14)$$

The shrinkage of samples during drying significantly reduced the characteristic dimension ( $r$ ) of seaweeds.  $r$  from  $1.2 \pm 0.1 \cdot 10^{-3}$  to  $5.8 \pm 0.3 \cdot 10^{-4}$  m at  $X_c$ . No significant differences on shrinkage behavior of seaweeds with temperature were observed indicating that these properties are more related to moisture content than to air drying rate. Experimental shrinkage data in terms of variation of characteristic dimension with time were correlated with moisture content as follows:

$$r_x = \sqrt{-1.0 + 1.06e^{-0.11MR} \cdot (1.2 \cdot 10^{-3})^2} \quad (15)$$

where MR is evaluated by Page model, Eq. (1).

The specific drying rate vs moisture content for all tested temperatures is shown in Figure 1 (right). It can be clearly observed the common drying periods. Namely, at high moisture content the constant drying rate period and below  $X_c$  begins the falling rate period. No noticeable variations were observed on  $X_c$  with temperature ( $1.6 \pm 0.2$  d.b.).

### 3.2. Constant drying rate period: mass and heat transfer coefficients

The modelling of constant drying rate period employing Eqs. (8) and (9) showed that no significant differences were found in the convective mass ( $K_t$ ) and heat ( $h_t$ ) transfer coefficients with temperature.

In the case of  $K_t$  ( $(21.8 \pm 2.0) \cdot 10^{-3} \text{ m} \cdot \text{s}^{-1}$ ) the values are higher than those observed by da Silva et al. [9] who reported values of  $K_t$  from  $0.8 \pm 10^{-3}$  to  $1.9 \pm 10^{-3} \text{ m} \cdot \text{s}^{-1}$  for pear drying in a forced air oven at higher temperatures (between 68 and 92°C).

The corresponding values of  $h_t$  ( $19.9 \pm 0.9 \text{ W} \cdot \text{m}^{-2} \cdot \text{K}^{-1}$ ) are in the range reported by Bird et al. [10] who indicated that a typical magnitude of convective heat transfer coefficient varies from 3 to  $20 \text{ W} \cdot \text{m}^{-2} \cdot \text{K}^{-1}$ .

### 3.3. Falling drying rate period: effective coefficient of water diffusion through the seaweed

During the falling-rate period the shrinking effect on the characteristic dimension was taken into account in order to obtain the water diffusion coefficient through the seaweed. Diffusional modelling of drying during post-critical period was satisfactorily performed ( $R^2 > 0.986$  and  $E_{RMS} < 0.03$ ) by diffusional model for cylindrical geometry (Eqs. (11) and (12)), Table 2.

**Table 2. Effective coefficients of diffusion of water ( $D_{eff}$ ) and statistical coefficients ( $R^2$ ,  $E_{RMS}$ ) for *Bifurcaria bifurcata* seaweed drying at different temperatures.\***

T (°C)	$D_{eff} \cdot 10^{12}$ (m <sup>2</sup> ·s <sup>-1</sup> )	$E_{RMS}$ (-)	$R^2$
35	12.43±0.64 <sup>c</sup>	0.02	0.988
50	18.14±0.92 <sup>b</sup>	0.03	0.998
60	21.97±0.27 <sup>a</sup>	0.03	0.986
75	20.35±1.31 <sup>a</sup>	0.03	0.989

\*Data value of each parameter with different superscript letters in columns are significantly different ( $P \leq 0.05$ ).

Water diffusion coefficient ( $D_{eff}$ ) significantly increased with drying temperature below 60°C, but no differences were observed between drying at 60°C and 75°C. This trend of  $D_{eff}$  with temperature could be related to seaweed biopolymers could be washed away by the water flow and placed in the cell walls. This fact could make diffusion of water more difficult when drying above > 60°C takes place and consequently the typical increase of water diffusion with drying temperature is lost.

Compared with other works employing the same geometry, the obtained values were lower than those reported by Vega-Gálvez et al. [5] ( $2.8$  to  $22.4 \cdot 10^{-9}$  m<sup>2</sup>·s<sup>-1</sup>) for drying temperatures from 30 to 70°C for *Gracilaria chilensis* seaweed. Despite of this difference, it can be said that the values are in the range of the typical values for food stuff ( $10^{-9}$  to  $10^{-11}$  m<sup>2</sup>·s<sup>-1</sup> [11]).

## 4. Conclusions

*Bifurcaria bifurcata* drying experiments in thin layer configuration (from 35°C up 75°C) indicate that drying temperature increase up to 60°C significantly decrease drying time in order to achieve the same moisture content, but no differences exist between drying at 60°C 75°C. There are no significant differences on mass transfer coefficient with drying temperature increase during the constant drying rate period. However, the water diffusion coefficient during falling drying rate period shows a significant increase from 35 to 60°C, with no differences between drying at 60°C and 75°C which may be related to seaweed biopolymers washed away by the water flow and placed in the cell walls when drying above > 60°C takes place.

### Abstract

*To promote the hybrid solar dryers for use even under unfavorable weather and to overcome the intermittance state issue, the energy consumption should be optimized and the response time should be reduced. This work concerns a drying chamber connected to a solar absorber where the air can be heated also by combustion of gas and by electric resistance. To optimize the control parameters, an evolutionary optimization algorithm simulating natural selection was used. It was combined with a predictive model based on the artificial neural networks (ANN) technique and used as a fitness function for the genetic algorithm (GA). The ANN is a learning algorithm that needs training through a large dataset, which was collected using CFD simulation and experimental data. Then a GA was executed in order to optimize two objectives: The energy consumption and the t95% response time in which the drying chamber temperature reaches its set point (60°C). After optimization, a 30% decrease of the t95% response time, and 20% decrease of the energy consumption were obtained.*

**Keywords:** hybrid solar dryer; artificial neural network; temperature regulation; energy consumption; genetic algorithm.

---

## 1. Introduction

The solar drying process offers a promising alternative way of preservation foods and crops at a favorable energy cost unlike conventional energy sources. However, at night and in the cloudy time, the dehydration process slows extending the drying time. Even more, multiple rehydration of products harms their quality. Hybrid version of solar dryers can offer a wide respond to a wider demand. It reduces energy costs and the drying process is ensured in spite of the alternation of the climatic conditions. The hybrid dryer can ensure a continuous and controlled drying process by using a secondary energy sources [2].

The electric heating resistance was combined to solar air heater in previous works where a prototype was designed in a favorable conditions for optimized power consumption [3]. Unfortunately, this dryer is efficient just for the low air flow rates. In fact, the energy contribution by using the auxiliary heater increased from 74.92% to 86.78% by increasing the air flow rate from 1m/s to 2m/s.

The auxiliary heating system based on gas combustion has been studied in many cases. It was employed in a tunnel dryer by using a heat exchanger connected the gas burners and placed inside the drying chamber [4]. In addition, López-Vidaña et al. [5] suggested putting the burner inside the drying chamber. However, in most cases, the flue gases released by combustion affect the dried products.

In this work, a heat exchanger placed inside the solar collector with a separated exhaust of flue gases was considered. This new configuration seems to be practical, safe and easy to handle.

Modeling of the dryer is one of the most important aspects of drying technology. Most of these models were established by using several techniques such as: computational fluid dynamics (CFD), artificial neural network, Fuzzy, thermal modeling and energy balance mathematical modeling [6]. Computational Fluid Dynamics CFD is usually used to model and predict the temperature and velocity fields in the studied area.

The aim of this work is to optimize the control parameters in order to reduce the cost and the response time of drying. This case requires multi-objective optimization of a relatively complex system. Genetic algorithms are best suited for such application, since they allow the approximation of global optimums while avoiding local ones[7]. The flip side of a genetic algorithm is that it need a large number of design points for an accurate estimate output parameters. The design points were noted by using CFD tools as a predictive method of the dryer [8].

## 2. Materials and Methods

### 2.1. The hybrid solar-gas-electric dryer

The hybrid solar-gas dryer consists of a solar-gas collector where the air is heated by solar radiation and by 9 gas burners fitted in the collector (Fig.1). Geometric and thermophysical specifications of the solar-gas collector are given in [9]. The electric heating consists of two electric resistances of 2000W each one, positioned inside the drying chamber (Fig. 2). The drying chamber's volume is  $1\text{m}^3$ , and its walls are insulated by 5cm of mineral fiber.

Fig. 1 Solar-gas collector.

Fig. 2 Design and simulation of the hybrid solar-gas-electric dryer.

### 2.2. CFD modeling

3D simulations were done on SolidWorks Flow Simulation. The software solves Navier-Stokes equations with the Finite Volume Method (FVM). The  $\kappa$ - $\epsilon$  model was used in this calculation. Solar radiation is modeled to be perpendicular to the glass of the solar-gas collector. Whereas, the flames of the burners are modeled as volume heat sources located under a metallic sheet (exchanger). The electric auxiliary heater is modeled by two volume

heat sources of 2KW each as maximum value. Simulations were performed in forced convection at an air flow rate of 0.025kg/s in transient state for 90 min. The input parameters are solar radiation [0-900W/m<sup>2</sup>], gas power [0-5000W], and electric power [0-4000W]. The mean drying chamber temperature was controlled at 60°C. Hence, the electric and gas heaters are not always activated during the time dependent simulation. Their activation is dependent on the mean drying chamber air temperature that represents the goal value. They were turned on until the goal value is bit greater than the specified control value (60°C). The value of the dead band is considered as equal to 3°C, Thus, the volume heat sources is turned off until the control value became lower than 57°C.

The following specifications were used in the CFD modeling:

The solar-gas collector is oriented southward under an angle of 30° versus the horizontal.

- The model uses the discrete ordinates (DO) radiation model.
- The wind velocity is equal to 5m/s and its direction is 40°. Ambient temperature is equal to 25°C.
- Local refinement of the mesh is used in this model in order to take into account the peculiarities of the model’s geometry; the mesh is composed from 304179 cells.

### 2.3. Predictive modeling and optimization

A genetic algorithm (GA) was used to optimize the control parameters. This method starts by creating a population of random members of the same species as the optimized object. Then, the performance of each member of the population was evaluated according to fitness function. Upon the evaluation phase members with higher scores proceed to the crossover operation, where their control parameters can be transferred to next generation. To monitor the (GA) optimization process, the overall score of the population were tracked, and its distribution along with the best fit score. This case corresponds to a multiobjective optimization: quality (*q*), response time (*t*) and the cost (*c*). Many variants of the (GA) were used in order to get the best results, the Table 1 shows the used options in each variant:

*Table 1. Genetic algorithms configurations.*

(GA) ID	Fitness function	Population size	Mutation rate	Best fit criterion
1	Min( <i>q</i> , <i>t</i> , <i>c</i> )*	2000	0.3	Lowest score
2	RMS( <i>Q</i> , <i>T</i> , <i>C</i> )*	2000	0.4	Lowest score
3	Centroid of 3 objectives*	500	0.2	Lowest score
4	Sum of the objectives scores	500	0.2	Lowest score

\**q*, *t*, *c*: output of the dryer’s performance, the normalized to the worst possible output.

\**Q*, *T*, *C*: the raw output of the dryer’s performance.

\*The centroid method is based on a geometric tool which is the CENTROID of equilateral triangle, where its summits are the objectives. Each summit is weighted by the performance of the dryer in the objective. The fitness function is evaluated by calculating the distance of

a performance output centroid and the geometrical center. Lower the distance is, better the members fits the solution. The fit is evaluated as follows:

Let  $q$ ,  $t$  and  $c$  be the quality ratio, the time response ratio and the cost ratio respectively:

$$q = 1 - \frac{\text{Absolute error}}{\text{Maximum Absolute error}} \quad (1)$$

$$t = 1 - \frac{\text{Response time}}{\text{Drying time}} \quad (2)$$

$$c = 1 - \frac{\text{Energy invested}}{\text{Energy of full power functioning}} \quad (3)$$

The Euclidian distance of the generated point to the geometrical center of the triangle can be written as:

$$d = \frac{1}{q+t+c} \sqrt{\frac{1}{4}(c-t)^2 + 3\left(\frac{q}{3} - \frac{t+c}{6}\right)^2} \quad (4)$$

The implementation of the genetic algorithm was done on MatLab, using the “GA” built in function. However, this method requires the evaluation of the output of a large number of control points. Since a CFD simulation response time is inadmissible big, the Artificial Neural Networks (ANN) method developed here is more suitable to predict the solar dryer response for each input parameters. A neuron is fundamentally a node that accepts weights inputs and fires an output from 0 to 1 depending on whether the weighted sum of the inputs exceeds a threshold or not. The threshold is called the bias of the neuron. The neural networks method is a learning algorithm, it consists of changing the weights of each neuron proportionally to their contribution to the error and with smoothing ratio, called learning rate. It can be used for both regression and classification, but according to our modeling problem, it performs well in classification. To do so, an encoding method was established to transform a floating value into one hot binary string. Which is a string of zeros and one in one spot, this spot indicate the class of the value.

For instance, assuming that a temperature variable is within a range of 10 to 50°C, the value of 25°C can be represented as: 0 1 0 0 , with a bin of 10°C. To define a deep neural net, the following arguments are required: The number of layers, the number of nodes per layer, the learning rate, the feed forward batch size, the number of epochs, the cost function and the optimizer.

In our case, a neural network of two terminal layers (input and output) was used. In addition to that we defined 3 hidden layers. The numbers of nodes per layer are respectively

3, 350, 400, 350, 30. The dataset size is 27 000 record. 10% of this data is used for testing. The number of runned epochs in a training session is 100 000 epoch. AdamOptimizer was used to change the weights of the nodes with a learning rate of 0.001. In order to avoid the overfitting problem, the data was shuffled every epoch. The implementation of the neural network model was done with tensorflow running on a CPU. The algorithm was written in Python. The average training time was about 72 hours on a machine of the following specifications: 8Gb of memory, Intel i7 Quad Core processor of a processing frequency of 3.40GHz.

### 3. Results and discussion

The proposed method consists of generating data using CFD simulation along with experimental results to train a neural network model. The generated data was validated against the experimental data, the reached accuracy level was about 95%. The size of the dataset collected is 27000, with 7 columns: solar radiation, electric power, gas power, absolute error on the temperature inside the dryer, the t95% response time, and the electric and gas energy invested.

The generated data is then transformed in order to train a classification model based on the neural networks method, the method allowed us to predict the performance output data in any control point in a few hundred milliseconds with an accuracy of 95%. The generated data is then transformed in order to train a classification model based on the neural networks method, the method allowed us to predict the performance output data in any control point in a few hundred milliseconds with an accuracy of 95%. Fig 3 shows the evolution of the accuracy during the training session. The accuracy in the beginning of the training is very low, but as the steps increase the accuracy increases but at a decelerating rate.

The predictive model was exported and served to the genetic algorithm written in MatLab to execute the optimization code, the Table 2 shows the results for 4 cases using the sum of the objectives as fitness function which yielded the best results.

The average gain on the cases studied is about 20%. it is calculated assuming that the electric energy cost approximately twice as the gas energy. The following formula is used to evaluate the gain on the cost after optimization:

$$G_{cost} = 0.6 \times \frac{E_{Opt,Elec}}{E_{Elec}} + 0.3 \times \frac{E_{Opt,gas}}{E_{gas}} \quad (5)$$

Fig. 3 cost and accuracy of the predictive model during a training session.

Table 2. results of the optimization

Solar radiation	Electric Power (W)	Gas power (W)	Absolute Error (°C)	Response Time (min)	Electric energy (Wh)	Gas Energy (Wh)
900	2543.0	5000.0	0.5	2.0	607.5	1803.75
500	3982.0	5000.0	0.5	2.3	948.0	1470.0
200	4000.0	4152.0	2.0	4.0	3199.0	2963.0
0	2411.0	5000.0	1.2	6.0	2015.0	3946.0

#### 4. Conclusions

In this paper an optimization method of a solar dryer performance is proposed. A predictive model was built with artificial neural networks technique. In order to generate the training dataset for the learning session of the model, several CFD simulations were conducted to determine the gas and electric consumptions, and the 95% response time of the dryer while its drying chamber temperature is controlled at 60°C. After the training session, the predictive model reached an admissible level of accuracy about 95%, in about 50000 epochs. Then a genetic algorithm was performed in order to optimize two main goals that were defined as follow: The energy consumption and the t95% response time in which the drying chamber temperature reaches its set point (60°C). The size of the population is 500, with a mutation chance of 2%. ANN model was used to calculate the fitness function. After 150 generations, we obtained a 30% decrease of the t95% response time, and 20% decrease of the energy consumption.

#### 5. Nomenclature

$q$	Quality ratio
$t$	Reponse time ratio
$c$	Energy cost ratio
$G_{cost}$	Gain on the energy cost after optimization

$E_{Opt,Elec}$	Consumed electric energy after optimization	(Wh)
$E_{Elec}$	Consumed electric energy before optimization	(Wh)
$E_{Opt,Gas}$	Consumed gas energy after optimization	(Wh)
$E_{Gas}$	Consumed gas energy before optimization	(Wh)

### **Abstract**

*The main goal of this paper, is to propose a multivariable control model (MM) issued from CFD study of an innovative hybrid solar-gas dryer to simulate the drying chamber temperature in three modes of operation: Solar mode, Gas mode and hybrid mode. There is an indirect heating of drying air instead of direct heating inside the drying chamber. The air temperature obtained by CFD is still closed to one obtained by multivariable model (MM) with an RMSE under 2.31. the proposed multivariable model leads to a quick output parameters estimation related to each climate conditions and so, to an easy control of a hybrid solar dryer.*

## **1. Introduction**

Currently, solar energy is an important alternative source of energy. It is free, abundant, inexhaustible and non-pollutant in comparison with higher price and shortage of fossil fuels [1]. Solar drying of agriculture products is one of the most important potential applications in the countries in development [2]. Actually, framers and citizens dry crops such as (date, grapes, tea, menth and tomato) by spreading them in thin layers, on mats, paved ground or in the field, exposing them directly to the sun radiation. The drying by his archaic way affect strongly the quality of dried product and leads to a large post-harvest deterioration [3]. Indirect solar dryer can easily overcome these issues while using solar radiation as energy source for drying process [4].

In the other hand, the solar dryers are still limited by the intermittent fact and it could not be effective without the presence of another source. However, to enhance the quality of dried products and to optimize energy consumption, many works were carried out to design a dryer where the hot air is produced regularly and where the drying parameters (temperature, humidity and airflow) are under control.

In contrast, hybrid solar-gas dryers are widly used for drying a variety of products. They operate with solar energy in addition to an other energy source which is gas power. According to the literature survey, many works used an external boiler where the gas is burned and the hot air is produced and conducted to the drying chamber [5]. This technique requires a huge operational space and regular maintenance which make the drying system more complex. In other works [6,7], conceived a hybrid solar-gas dryer using a gas burner inside the drying chamber where the dried product adsorb many gaseous species resulting from the combustion of the gas.

Some reaserchers have already employed CFD to simulate the temperature, air velocity and relative humidity at various locations inside the drying chamber [8,9,10]. However, due to the complexity in the drying chamber, obtaining accurate results by CFD study requires a high level of grid density so a performing computational ressources [11].

This paper is proposed to design and simulate a hybrid indirect solar-gas dryer to best controlling drying process. The indirect heating of air inside the drying chamber guarantees the safety and improves the quality of the dried product. CFD modeling of the hybrid dryer is established in order to investigate its thermal performances in term of the threshold of drying temperature. A multivariable model issued from CFD simulation was developed based on non linear least square methods. The developed model leads to predict the drying temperature inside the drying chamber with a huge reduction in simulation time and leads also to easily synthesise a control system of the drying temperature.

## 2. Materials and Methods

The hybrid solar-gas dryer was designed and simulated using Solidworks Flow simulation developed by Dassault systems Solidworks crops. The dryer consists of a cubic drying chamber of (1m \* 1m \* 1m), fitted with perforated plate trays of stainless steel. The drying chamber is combined with a solar-gas collector used to generate regularly the hot air. The solar part of the collector is a finned plate solar air heater, the absorber's length is  $L=2\text{m}$  and its width is  $W=0.95\text{m}$  and it is made from aluminium. The top side of the absorber is painted with matt black glycerpphtalic lacquer. The absorber contains 24 fins made from 1 mm thick aluminium. The top side of the absorber is covered by 3mm glass with a separation of 0.05m with the absorber. The solar collector is fitted with a heat exchanger (metallic sheet) placed under the absorber. The back up heating system is a set of 9 burners located under the exchanger and monitored by a valve. The drying air passes through the flat plate collector between the absorber and the exchanger. The synoptic of the hybrid dryer is presented in Fig. 1.

*Fig. 1 Synoptic of the hybrid solar-gas dryer*

## 3. Simulation approach

CFD is used for air temperature and airflow distribution inside the drying chamber accomplished by 3-dimensional governing equation (mass, momentum and energy equation) along with initial and boundary conditions under transient and turbulent flow assumptions. Since the small temperature variations, the hot air is considered as incompressible flow.

### 3.1 Simulation model

Fig. 2 demonstrates the 3-D solar-gas hybrid dryer simulation model. This model used single component model with assumptions of incompressible and unsteady-state flow. Simulations were conducted using a grid density of (1,906,000).

Fig. 2 CFD conception of the hybrid dryer

### 3.2 Initial and boundry conditions.

The initial temperatures of chamber walls, surface of tubular burners and inside air were taken equal to 25°C. The inlet air velocity was 0.025kg s<sup>-1</sup> calculated from the flow rate of the ventilating fan while the inlet temperature and the relative humidity were assumed to be at 25°C and 50% respectively. These values are typical average ambient ones in Marrakesh at Morocco. The flames of the burners are modeled as volume heat sources located under a metallic sheet. The flames' diameter is 1cm and their number is 216 (24 flames for each burner). Hence, the power of each flame is  $P_g/216$ , with  $P_g$  is the total gas power (W). The solar-gas collector is fitted with apertures in the both sides and in the outlet allowing the natural circulation of the necessary air for total combustion.

## 4. Multivariable model of the hybrid solar-gas dryer

In this paper, a hybrid solar-gas dryer designed in SolidWorks is consedred as a non linear multivariable system. Solar radiation ( $G$ ), gas power ( $P_g$ ) and airflow ( $\dot{m}$ ) are considered as the main inputs of the dryer and the drying chamber temperature ( $T_{ch}$ ) is considered as output parameter.

### 4.1 Static characteristics

The static characteristics of the dryer are necessary for a description of the behavior of the system. It consists on measuring the output on the basis of inputs in steady state. Statics characteristics of the dryer lead to easily identify the linear zones and operating points which help for shapping the input signals for modeling the system.

The average drying temperature ( $T_{ch}$ ) was measured on the basis of solar radiation, gas power and airflow. The measurements were carried out in the steady state.

The static characteristic of ( $T_{ch}$ ) on basis of ( $G$ ) was built varying the solar radiation in a range of 0-1200W m<sup>-2</sup> while considering gas power and airflow constant ( $P_g = 2\text{kW}$  and  $\dot{m} = 0.025\text{kg s}^{-1}$ ). wherease, the static characteristic of ( $T_{ch}$ ) on basis of ( $P_g$ ) was built varying

the gas power in a range of (0-5 kW) while considering solar radiation and airflow constant ( $G = 700 \text{ W m}^{-2}$  and  $\dot{m} = 0.025 \text{ kg s}^{-1}$ ). The static characteristic of ( $T_{ch}$ ) on basis of ( $\dot{m}$ ) was built varying the airflow in a range of (0.005-0.07  $\text{kg s}^{-1}$ ) while considering solar radiation and gas power constant ( $G = 700 \text{ W m}^{-2}$  and  $P_g = 3 \text{ kW}$ ) (Fig. 3).

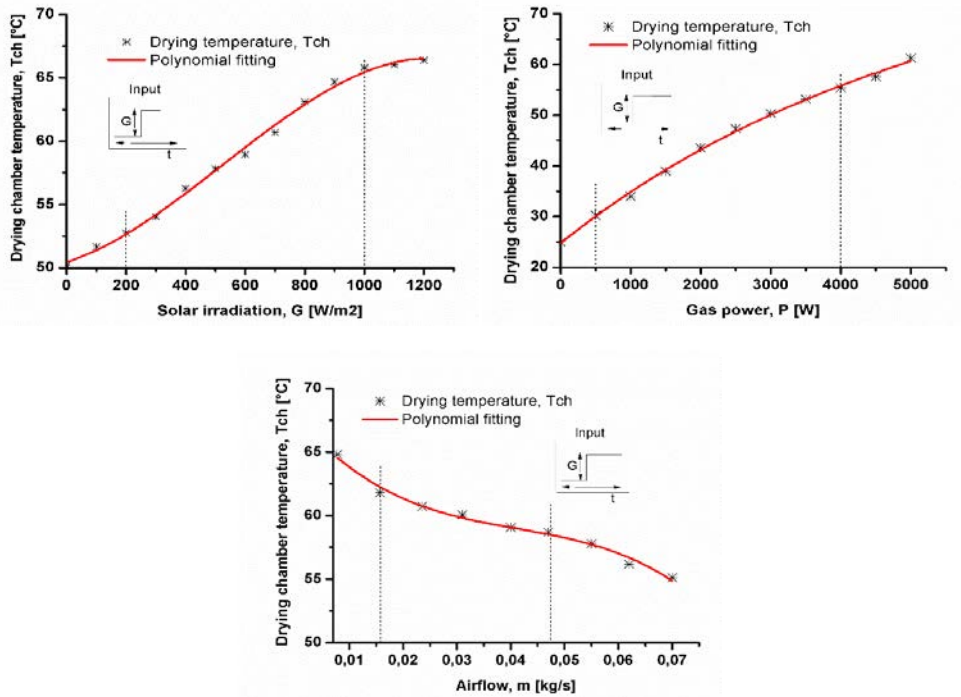

Fig. 3 Static characteristics of the hybrid dryer

## 4.2. Generation of input signals

The used input test signals for modeling the dryer are Pseudo Random Binary Sequences (PRBS). The PRBS is a two state signal varying between the maximum and the minimum points of each linear zone. In addition, at least one of the PRSB pulses should be greater than the system rise time [12].

The measurements were conducted in transitory state. The time simulation was set to 20 hours of operation.

The obtained input/output were loaded into the system identification Toolbox of Matlab environment using (Ident) in order to identify the linear model of the hybrid dryer. The system identification provided using Matlab allows building mathematical models of a dynamic system based on non-linear least squares estimation method.

The simulation result of the identified linear multivariable model fitted the CFD simulation with 90% of accuracy. for control purpose, this is an accurate model.

The hybrid dryer state space multivariable model is represented by:

$$A = \begin{bmatrix} -0.0030 & -0.0202 \\ -0.0141 & -0.1701 \end{bmatrix}; B = \begin{bmatrix} -0.00046 & 6.87e^{-6} & 4.959e^{-6} \\ -0.00180 & 2.66e^{-5} & -0.00039 \end{bmatrix}; C = [238.4 \quad -0.56]$$

To verify the validity and the effectiveness of the proposed multivariable model. The temperature profile inside the drying chamber obtained by CFD simulation is compared with the temperature predicted by multivariable model. The CFD average drying chamber temperature at three operating modes of the solar dryer (solar mode (900W m<sup>-2</sup>), gas mode (3kW) and hybrid mode (600W m<sup>-2</sup>; 2kW)) was considered for comparison with the multivariable model simulation. CFD and Multivariable model simulation results were plotted against clock time as shown in Figs. (4a-4b-4c). The temperature profile of CFD simulation was almost similar to that of Multivariable model. The root main square error RMSE remains under 2.31.

Fig. 4 Comparison between the simulated CFD and MM output; a. solar mode; b. hybrid mode; c. gas mode

## 5. Conclusion

A multivariable model of the hybrid dryer for predicting the drying temperature was developed based on nonlinear least square methods taking into account solar radiation, gas power and airflow as the main input parameters. The predicted temperatures by multivariable model were compared with the CFD ones based on mean root square error (RMSE). From the values of RMSE (0.91-2.38), it is inferred that the predicted values by multivariable model are in harmony with the observed values by CFD. The multivariable model leads to predict the temperature with a remarkable reduction in simulation time. The threshold of drying temperature has been investigated in three operating modes of the dryer: solar mode, gas mode and hybrid mode. The range of the reached temperature ( 45.2°C, 53.4°C and 62.4°C) is suitable for drying a wide variety of products. The developed multivariable model will be useful to synthesize a temperature controller in order to control the drying temperature in a suitable range for the product to be dried and improves their quality.

### **Abstract**

*Gypsum is a popular building material. Drying and rewetting of gypsum is a process of practical importance. This work presents the experimental results of kinetic of drying, heating and internal pressure development in rewetted gypsum cylinders. Analysis of the observed changes is presented. Additionally sorption isotherms, permeability and dependence of Young's modulus on moisture content were measured. These data will be used in the model of the process under development.*

**Keywords:** *internal pressure, permeability, Young's modulus*

---

## **1. Introduction**

Gypsum is commonly used as a building material in the form of gypsum blocks, plasterboards, fillers and renders. It is also used by other industries e.g. ceramic industry for making molds. In buildings moisture in gypsum materials is present both during setting and normal use due to its hygroscopicity. It influences energy consumption, air quality in houses and durability of the material. It is therefore important to know more about the mechanism of heat and moisture exchange with surroundings and their transfer in the gypsum materials. Literature of the subject is abundant in models which serve for prediction of spatial and temporal variations of temperature and moisture content in building materials. The models usually require performing experimental determination of model parameters like specific heat, heat conductivity, moisture diffusivity [1,2] and permeability [3,4]. The knowledge of microstructural changes and interactions of water and the material of crystalline structure like gypsum, especially in heat and mass transfer processes is one of key issues influencing mechanical properties of the gypsum products. Gypsum materials change their mechanical properties depending on their wetness and the reason are weak bonds of crystalline adhesions. Repeating cycles of humidification-dehumidification may lead to shrinkage, deformations and cracks as described in numerous publications [5]. Several works concentrate on heat and mass transfer during drying of building materials like plasterboard, and wood [6], brick and render including determination of moisture content profiles [7], analysis of external parameters as pressure [8], wind speed [9] and analysis of the determination of the influence of drying kinetics [10] on distribution of stresses in the material.

The aim of this work is to experimentally analyse the drying process of gypsum by measuring its kinetics of mass, temperature and internal pressure in drying and measure necessary parameters i.e. sorption/desorption isotherms, Darcy permeability and Young's modulus of wet gypsum. These observations will be used in the model of drying including stress development in the solid (under construction).

## **2. Materials and Methods**

Commercial gypsum powder of building grade produced by Piotrowice company under a brand name Alpol. It is destined for using as building material and filler as well as for casting of prefabricates. The powder was mixed with recommended water/gypsum ratio equal to 0.65. Cast gypsum is a material that doesn't shrink during drying.

### **2.1 Sorptional equilibrium**

Desorption isotherms at low temperature were measured by a standard method of saturated salt solutions at 20°C and 50°C and atmospheric pressure. Additionally experiments were

made in superheated steam in the range of temperatures of 120°C to 200°C in a separate set-up also at atmospheric pressure

**2.1 Drying kinetics**

Drying experiments were performed in a drying tunnel described elsewhere [18]. Cylindrical samples 28 mm in diameter and 54 mm high were used. Drying was performed at 50°C and air velocity of 1 m/s. Air humidity was not controlled.

**2.1 Permeability**

Permeability was measured by hydraulic method described elsewhere [12] using compressed air permeation. Gypsum disks 13 mm in diameter and 2 mm thick were used. Experiments were made on dry gypsum which was then soaked. Measurements were made in duplicate.

**2.1 Mechanical properties**

For modeling of drying stresses the dependence of Young’s modulus on moisture content is required. The dependence was measured using seasoned gypsum samples of given moisture content and standard Instron testing machine. The experiments were made in duplicate.

**3. Results**

**3.1 Sorptional equilibrium**

The results are shown in Fig. 1 in the form of 3D dependence of moisture content X on water activity  $a_w$  and temperature T. Two isotherms for 20°C and 50°C and an isobar in the range 120°C-200°C are shown. It is visible that equilibrium moisture content rapidly increases with water activity and slowly decreases with temperature. This indicates that gypsum is only slightly hygroscopic.

The data points were fitted with Chen and Clayton equation (1) with coefficients available in Table 1. The fit is of satisfactory quality.

$$a_w = \exp(a_1 T^{a_2} \exp(a_3 T^{a_4} X)) \tag{1}$$

*Table 1. Coefficients of equation (1)*

1-isotherms 20°C and 50°C, 2-isobar.

#### 4.1 Drying kinetics

An exemplary test run results are shown in Fig. 2. Fig. 2a shows how air parameters: atmospheric pressure, temperature and water activity vary during the process.

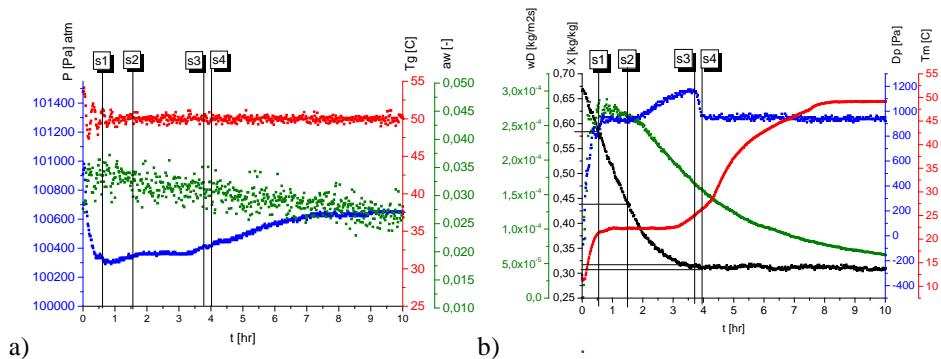

Fig.2. a) Air parameters, b) Drying kinetics at 50°C

A sample of initial  $MC=0.67 \text{ kgkg}^{-1}_{dm}$  and temperature  $12^{\circ}\text{C}$  is dried with air of temperature  $50^{\circ}\text{C}$  and  $RH=3.5\%$ . In the time range from 0 to S1 the solid heats up to the wet-bulb temperature. During that time MC decreases to  $0.57 \text{ kgkg}^{-1}_{dm+}$  and internal pressure rapidly decreases to  $-400 \text{ Pa}$  and then rises to  $+900 \text{ Pa}$ . The initial pressure drop may be a result of fast evaporation at still initial axial temperature. The mass flux “drags” water from the inside creating underpressure. When the axial temperature increases thermal expansion of liquid causes pressure to rise. At the end of this time drying rate reaches  $2.75e-4 \text{ kgm}^{-2}\text{s}^{-1}$ .

In this phase of the process the solid is saturated and the dominating mechanism is Darcy flow. It is worth noticing that while the axial pressure is negative, the inner part of the

sample is compressed and when positive it is stretched. If the resulting stress should exceed material strength the solid would crack.

The time range from S1 to S2 corresponds to CRP where MC decreases from initial value 0.57 kgkg<sup>-1</sup><sub>dm</sub> down to 0.47 kgkg<sup>-1</sup><sub>dm</sub>, The dominating mechanism is Darcy flow in liquid phase. From S2 to S3 we have the FRP - drying rate decreases, the temperature increases to 25°C and internal pressure increases to +1200 Pa, reaching maximum. In this range mass transport takes place in liquid phase, vapor phase and gas phase of water vapor and air, and a penetration of the evaporation front is observed. As proposed in [11] the transport fluxes are: water in liquid phase where the driving force is pressure gradient in liquid phase, flux in vapor-gas phase driven by pressure gradient, diffusional flux in gas phase driven by vapor concentration gradient and finally flux of bound water with MC as the driving force. The last two fluxes govern the range from S3 to S4 where MC decreases to the equilibrium value, pressure decreases to +900 Pa and temperature increases. In the remaining time all parameters remain constant except temperature which increase further reaching the external air temperature.

### 5.1 Permeability

Permeability was measured according to the Polish National Standard PN-EN 993-4. The governing Darcy equation has the form:

$$k_g = Q\eta_G \frac{h}{A} \frac{1}{(p_1 - p_2)} \frac{2p_1}{(p_1 + p_2)} k \tag{2}$$

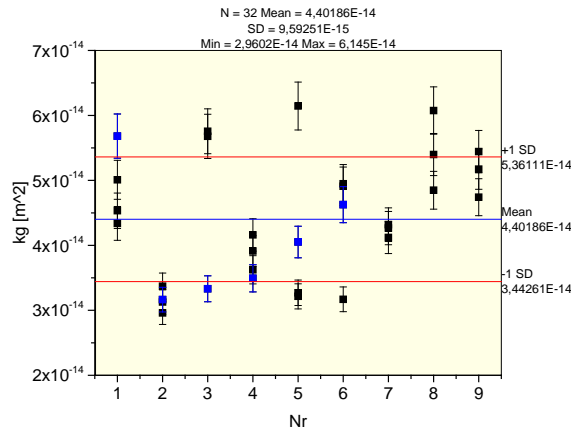

Fig.3. Permeability of samples (black - dry, blue - wet)

In this work actual pressure varies in time while in PN-EN 993-4 is steady. Another difference is that the quoted standard requires samples of cylindrical shape 50x50 mm

while in our experiments samples were much smaller. Experimental error was estimated as less than 6 %. The results are shown in Fig. 3 both for dry and wet samples of MC=0.65 kg/kg. The straight blue line is the mean value of  $4.40 \cdot 10^{-14} \text{ m}^2$  and the red lines are at 1 standard deviation off this value. The entire range of results for wet sample was  $3 \cdot 10^{-14} \text{ m}^2$  to  $6 \cdot 10^{-14} \text{ m}^2$ . Similar values were obtained in [13] by the method of PN-EN 993-4 [3,14]. The values for wet samples were in the range  $3 \cdot 10^{-14} \text{ m}^2$  to  $5 \cdot 10^{-14} \text{ m}^2$ .

### 6.1 Mechanical properties

Strength of plaster is a results of bonds between the forms of gypsum (anhydrite, semihydrate and dihydrate), sulfur compounds, water and residuals [15]. Typically compression and bending strength are measured, rarely the Young’s modulus [16]. Mechanical characteristics of plaster depend mainly on porosity, placement and structure of gypsum crystals formed during hydration of calcined gypsum [17]. On the other hand they also depend on the actual condition of plaster resulting from ambient conditions like temperature and humidity. Although gypsum sets in ca 25 min after mixing with water it reaches full mechanical strength after 28 days according to ASTM C215, 1991. Only then the mechanical tests can be performed. The results of this work are shown in Fig. 4.

Fig.4. Young’s modulus dependence on moisture content of rewetted gypsum

The approximating equation has the form:

$$E = [0.89332 + 31.13157(\exp(-6.32736X))] \cdot 10^8 \quad (3)$$

### 3. Conclusions

Results of this work indicate that hardened gypsum is slightly hygroscopic as sorption isotherms indicate and bound water range at room temperature is below MC of ca. 0.03 kg/kg. It also shows negligible shrinkage in drying. Yet MC significantly influences the Young’s modulus, which exponentially decreases with increasing MC.

During convective drying gypsum exhibits the initial drying period (IDP), constant-rate period (CRP) and falling drying period (FRP). However the internal pressure is only partly related to these periods. In the IDP pressure first rapidly decreases to ca. -400 Pa and then increases to +900 Pa. In CRP the pressure first stabilizes and at the final stage of CRP begins to increase. It continues to increase in FRP reaching the maximum of +1200 Pa and at the end of the FRP it falls again to +900 Pa. These variations cause changes in internal stresses. The observed changes of pressure shed some light on moisture transport in the solid which only can be explained with a suitable model. The work on the model is in progress.

### ***Abstract***

*The results of experimental and theoretical research of heat and mass transfer in polycaproamide granules during convective drying are presented.*

***Keywords:*** *convective drying, mathematical modeling, polycaproamide.*

---

## 1. Introduction

Drying process of polycapraamide granules is one of the stages of technological chain during production of polyamide fiber caprone. Rather high level of dehydration of granules during drying process should be provide to obtain high quality fiber. Average final moisture content of the material should be not more than 0.1%. We know that at low values of moisture content drying process of polycapraamide is sharply slows down and the distribution of moisture content is substantially nonuniform. In this case calculation of kinetics of granules dehydration should be provide using local coefficient values of mass transfer (diffusion of moisture). Results of calculations which illustrate features of heat and mass transfer processes during convective drying of cylindrical granules are presented. Two local parameters of mass transfer are using for calculation – coefficient of moisture diffusion in polycapraamide (in the form of a liquid)  $a_m$  and criteria of phase transfer  $\varepsilon$ . These parametres are depends on material moisture content and temperature in given point of material at certain point in time.

## 2. Materials and Methods

The object of drying is polycapraamide. Average degree of polymerization is 130-200, average molecular weight is 15000-23000. The structure of samples was research by three independent methods. Method of mercury porosimetry, electron microscopy and sorption method were used.

The predominant pore radius is 1000 Å. Such pores are filled only at direct contact with liquid phase but not during sortion process and its presence in polycapraamide associated probably with mechanical impact during preparation of a substance but not with supramolecular structures. Photos of fracture of polycapraamide crumb obtained using an electron microscope confirm the presence of large pores in the material.

The specific volume of pores is 0.022 cm<sup>3</sup>/g. Isotherm of sorption of moisture vapor by polycapraamide was obtain using vacuum sorption installation with weights of Mac-Ben-Bakr. Maximum hygroscopic humidity at 22°C is about 8%. The existence of a loop of sorption hysteresis the appearance of which indirectly indicates partial swelling of polycapraamide in water is established.

Drying kinetics curves for samples of polycapraamide received in convective dryer equipped with devices for monitoring and controlling the parameters of the drying agent The radius of the granule was  $R_{gr}=1.375 \cdot 10^{-3}$  m, length -  $L_{gr}=4 \cdot 10^{-2}$  m. The relative humidity of the environment was maintained equal to  $\varphi_c \sim 3\%$ . The speed of drying agent was 25 m/s. Kinetic curves at different temperatures in the range from 90 to 150°C are rpresented on Fig.

1. The set air temperature was maintained with accuracy 0,1°C. The weighing accuracy was 10<sup>-6</sup> kg/m<sup>3</sup>.

Character of experimental kinetics curves allow to draw a conclusion about essential nonlinearity of effective coefficient moisture conductivity in the granule of polycapramide which is associated with the specific nature of phase transitions in macromolecular systems. The intensity of vaporization here depends not only on the amount of heat supplied but also on the rate of arrival of the volatile component to the evaporation surface (the outer surface of the granule and the interphase boundary of liquid-vapor in microcracks and pores). Diffusion transfer in polymer systems at low solvent contents is limiting for interfacial mass transfer [1].

### 3. Mathematical model

Nonstationary nonlinear axisymmetric 2D model similar [2] which generalizes the well-known mathematical model of the diffusion-filtration heat and moisture transfer of A.V. Lykov [3] using for description of heat and mass transfer processes during drying. It is constructed as the limiting case of models based on the mechanics of multiphase systems [4-5]. The mathematical model includes transfer equations averaged over the microvolume of the material:

- liquid phase transfer equation

$$\frac{\partial u}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left[ r a_m(u, T) \frac{\partial u}{\partial r} \right] + \frac{\partial}{\partial z} \left[ a_m(u, T) \frac{\partial u}{\partial z} \right] - \frac{s_{12} j}{\alpha_3 \rho_3^0}; \quad (1)$$

- heat transfer equation

$$c\rho \frac{\partial T}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left[ r \lambda(u, T) \frac{\partial T}{\partial r} \right] + \frac{\partial}{\partial z} \left[ \lambda(u, T) \frac{\partial T}{\partial z} \right] - L_{12} \varepsilon \rho \frac{\partial u}{\partial t}; \quad (2)$$

$$\lambda = \alpha_1 \lambda_1 + \alpha_2 \lambda_2 + \alpha_3 \lambda_3; \quad c\rho = \alpha_1 c_{p1} \rho_1 + \alpha_2 c_{p2} \rho_2 + \alpha_3 c_{p3} \rho_3;$$

- equation for vapor-gas phase pressure

$$c\rho \frac{\partial p_1}{\partial t} = p_1 \frac{K_{13}}{\mu_1} \left[ \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial p_1}{\partial r} \right) + \frac{\partial^2 p_1}{\partial z^2} \right] + \frac{p_1}{c\rho T} \frac{\partial T}{\partial t} + \frac{p_1 L_{12} \varepsilon}{cT} \frac{\partial u}{\partial t} + \frac{p_1}{B_1} \frac{\partial B_1}{\partial t} - \frac{p_1}{\alpha_1} \frac{\partial \alpha_1}{\partial t} + \frac{s_{12} j T B_1}{\alpha_1} - \frac{p_1 L_{12} \varepsilon}{cT} \cdot \frac{s_{12} j}{\alpha_3 \rho_3}; \quad (3)$$

- equation for the concentration of the vapor component.

$$\frac{\partial(\alpha_1 \rho_1 (1-\chi))}{\partial t} = \frac{1}{r} \frac{\partial}{\partial r} \left[ r (\alpha_1 \rho_1 (1-\chi)) (v_1^r + w_{1g}^r) \right] + \frac{\partial}{\partial z} \left[ \alpha_1 \rho_1 (1-\chi) (v_1^z + w_{1g}^z) \right] = 0; \chi = \frac{\rho_{1v}}{\rho_1}; 1-\chi = \frac{\rho_{1g}}{\rho_1}. \quad (4)$$

Where:  $a_m$  - water diffusion coefficient,  $m^2/s$ ;  $B$  - individual gas constant,  $J/(kg \cdot K)$ ;  $c$  - thermal capacity,  $J/(kg \cdot K)$ ;  $j$  - rate of evaporation,  $kg/(m^2 \cdot s)$ ;  $K_{ij}$  - coefficient of  $i$ -phase penetrability in  $j$ - phase  $m^2$ ;  $L_{12}$  - latent heat of evaporating water,  $J/kg$ ;  $t$  - time,  $s$ ;  $p$  - pressure,  $Pa$ ;  $T$  - temperature,  $K$ ;  $r$  - radial coordinate,  $m$ ;  $R$  - universal gas constant,  $J/(mol \cdot K)$ ;  $s_{12}$  - specific surface area of the section of phases,  $m^{-1}$ ;  $u$  - moisture content,  $kg/kg$ ;  $v$  - velocity,  $m/s$ ;  $w$  - diffusive velocity,  $m/s$ ;  $z$  - axial coordinate,  $m$ ;  $\alpha$  - volumetric content,  $m^3/m^3$ ;  $\varepsilon$  - criterion of phase transitions;  $\varphi$  - relative humidity;  $\lambda$  - thermal conductivity,  $W/(m^2 \cdot K)$ ;  $\rho$  - density,  $kg/m^3$ ;  $\chi$  - concentration of steam in a gas mixture,  $kg/kg$ . Subscripts: 1 - gas vapour mixture; 2 - fluid phase; 3 - solid phase; g - gas; v - vapor; 0 - initial state. Superscripts: r, z - components of vectors.

The transfer equations (1-4) are supplemented by the equation of the sorption polytherm, the equations of state for the vapor and gas components, the Fick diffusion law, the Darcy filtration law, the Dalton law for calculating the intensity of phase transitions, the Antoine formula for determining the saturated vapor pressure at a defined temperature:

$$u = f(T, \varphi); p_1 = \rho_1 T B_1; p_{1g} = \rho_{1g} T B_{1g}; p_{1v} = \rho_{1v} T B_{1v}; \rho_1 = \rho_{1v} + \rho_{1g}; B_1 = B_{1v} + (1-\chi) B_{1g}; w_{1g}^r = \frac{\rho_1}{\rho_{1g}} D \frac{\partial \chi}{\partial r}; w_{1g}^z = \frac{\rho_1}{\rho_{1g}} D \frac{\partial \chi}{\partial z}; v_1^r = -\frac{K_{13}}{\mu_1} \frac{\partial p_1}{\partial r}; v_1^z = -\frac{K_{13}}{\mu_1} \frac{\partial p_1}{\partial z}; j = \kappa_2 \frac{p_{sat}(T) - p_{1v}(T)}{p_{atm}}; p_{sat} = \exp\left(A_s - \frac{B_s}{T + C_s}\right); \quad (5)$$

where:  $D$  - diffusion coefficient  $m^2/s$ ;  $\mu$  - dynamic viscosity,  $Pa \cdot s$ ;  $\bar{v}$  - fluid molar volume,  $m^3/mol$ ;  $A_s, B_s, C_s$  - empirical coefficients. Subscripts: atm - atmospheric; sat - saturation.

The initial and boundary conditions have the form:

$$T(0, r, z) = T_0; u(0, r, z) = u_0; p_1(0, r, z) = p_{10}; \chi(0, r, z) = \chi_0; \quad (6)$$

$$-\lambda \frac{\partial T}{\partial n} \Big|_{\Gamma} = \alpha^h (T|_{\Gamma} - T_c); u|_{\Gamma} = u_{eq}; \chi|_{\Gamma} = \chi_c; p_1|_{\Gamma} = p_c. \quad (7)$$

Subscripts: eq – equilibrium; 0 - initial state; c - surrounding medium;  $\Gamma$  - external boundary of a granule; n – normal. Parameter  $\alpha^h$  - coefficient of heat transfer, W/(m<sup>2</sup>K).

Important elements of the model are the original computational formulas for calculating the time-varying local diffusion coefficients of liquid  $a_m$  and the values of the phase transition criterion  $\varepsilon$ . These formulas were obtained by analyzing a more general mathematical model of heat and mass transport of transport constructed on the basis of the mechanics of multiphase systems [4-5]:

$$a_m = -\frac{K_{23}}{\mu_2} \frac{RTu}{\bar{v}} \frac{1}{\phi} \frac{\partial \phi}{\partial u}; \quad \varepsilon = \frac{c_{v1}}{L_{12}} \frac{T - T_{sat}}{1 + u}. \quad (8)$$

The nonstationary nonlinear mathematical model (1-8) has been researched numerically. The equations are solved by an implicit method of finite differences using the control volume approach as described by [6].

#### 4. Results of experiments and numerical analysis

Calculations were carried out at the values of the thermophysical parameters of water, water vapor, air according to [7]. For other parameters, the values are:  $\rho_3=1150$  ;  $K_{13}=1.0 \cdot 10^{-16}$  m<sup>2</sup>;  $K_{23}=1.5 \cdot 10^{-23}$  m<sup>2</sup>;  $\kappa_2=1.7 \cdot 10^{-12}$  kg/(m<sup>2</sup>s);  $s_{12}=6.6 \cdot 10^6$  m<sup>-1</sup>;  $\lambda_3=0.25$  W/(m<sup>2</sup>K);  $c_{p3}=2100$  J/(kgK). The heat transfer coefficient  $\alpha^h$  was determined taking into account the drying agent's speed according to known empirical relationships. The polytherm of sorption of polycapromamide was obtained on the basis of experimental data:

$$u = u_{max}(T) \phi^{a_0 k^{\phi}}; \quad u_{max}(T) = u(T_0) - \alpha_T (T - T_0).$$

The values of the parameters of the sorption polytherm are determined as follows:  $a_0=0.9567$ ;  $k=4.796$ ;  $T_0=295$  K;  $u(T_0)=0.08891$ ;  $\alpha_T=0.0002517$  K<sup>-1</sup>.

The results of numerical calculations of drying kinetics of the polycapromamide granule satisfactorily coincide with the experimental curves of high-temperature drying (Fig. 1). By increasing the temperature of the air in the drying chamber, the duration of the process of dehydrating granules of polycapromamide can be significantly reduced. The drying of the granules at the temperature of the drying agent  $T_c=423$  K is approximately 4 times faster than at  $T_c=383$  K. The influence of the ratio  $R_{gr}/L_{gr}$  on the dewatering intensity of the granule is shown in Fig. 2. It should be noted that the main contribution to slowing down the drying process with increasing  $R_{gr}/L_{gr}$  is not the shape of the granule (tablet or elongated cylinder), but its volume, which also increases.

**Fig. 1.** The change in time with the average volume of moisture content of the polycaproamide granule with  $R_{gr} = 1.375 \cdot 10^{-3} m$ ,  $L_{gr} = 0.04 m$  at  $\varphi_c = 0.03$  for  $T_c = 373 K - 1, 383 - 2, 403 - 3, 423 - 4$ .

**Fig. 2.** The change in time with the average volume of moisture content of the polycaproamide granule at  $T_c = 423 K$ ,  $\varphi_c = 0.03$ ,  $L_{gr} = 0.04 m$  for  $R_{gr}/L_{gr} = 5 - 1, 1 - 2, 0.5 - 3, 0.1 - 4, 0.005 - 5$ .

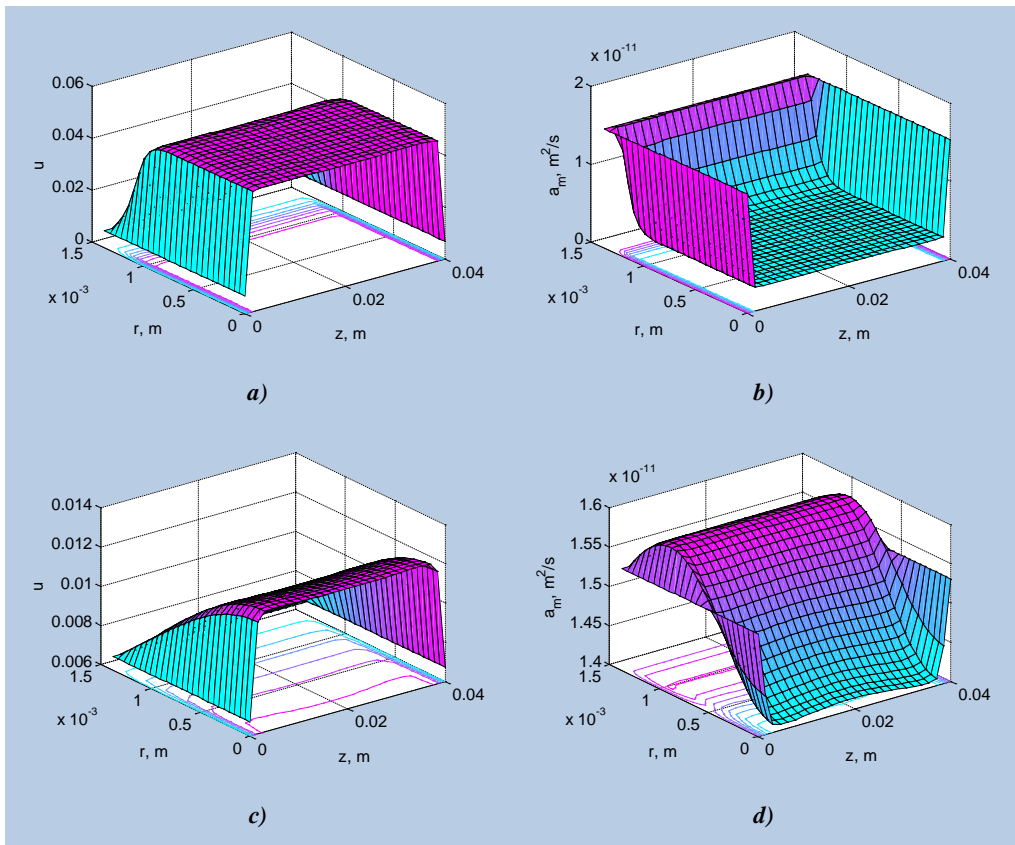

**Fig. 3.** The change with time of the local values of the diffusion coefficient (a) and the intensity of vaporization (b) in the cross section of the polycaproamide at  $T_c = 423 K$ ,  $\varphi_c = 0.03\%$  for  $R_{gr}/L_{gr} = 0.1$ ,  $t_{xap} = 15456 s$ ,  $a_{m,xap} = 1.63 \cdot 10^{-11} m^2/s$ ,  $j_{xap} = 3.06 \cdot 10^{-6} kg/(m^2 \cdot s)$ .

The moisture transfer in this process is carried out as a transfer of the liquid phase due to the gradient of the disjoining pressure in the boundary layers of water, if the moisture content of the material is below the maximum hygroscopic humidity, and also as the transfer of the vapor component, the production of which occurs throughout the volume of

the granule. Fig. 3 illustrates how the contribution of different moisture transfer mechanisms at individual points of the cross section of the granule varies with time. The motion of the liquid phase, characterized by the value  $a_m > 0$ , begins after the stage of material heating and intensive removal of moisture in the form of vapor. After a decrease in the value of  $u$  below the maximum hygroscopic moisture content, a flow of liquid from the region with a higher saturation to a region of lower saturation begins at this temperature, with the diffusion coefficient  $a_m$  increasing, reaching a maximum (Fig. 3a). The intensity of vaporization decreases (Fig.3b), which is associated with a decrease in saturated vapor pressure above the interphase surface and a decrease in its activity.

**Fig. 4. The distribution in the plane  $r$ - $z$  moisture content (a,c) and local diffusion coefficient of liquid phase (b,d) at the instants  $t = 13138$  s – (a,b), 19722 – (c,d) during drying the granules with  $R_{gr} = 1.375 \cdot 10^{-3}$  m,  $L_{gr} = 0.04$  m at  $T_c = 383$  K,  $\varphi_c = 0.15$ ,  $T_0 = 295$  K,  $u_0 = 0.013$ .**

The distribution of the water diffusion coefficient over the granule cross-section and the corresponding moisture content distribution during drying are shown in Fig. 4 for different

instants of time. In the early stages of dehydration in the central zone of the granule, the moisture content exceeds the maximum hygroscopic humidity. Mass transfer occurs here due to evaporation, the coefficient of diffusion transfer of water is practically zero (Fig. 4a). Over time, this area is reduced (Fig. 4c), and at the end of the process it disappears. The distribution of the water diffusion coefficient across the cross-section of the granule  $a_m$  transforms with time (Fig. 4b, d) and gradually equalizes at low moisture content.

## 5. Conclusions

Comparison of the results of mathematical modeling of heat and mass transfer in the granule and data from the laboratory experiment on the kinetics of drying granules of polycapramide showed good agreement between the calculated and experimental data. The constructed mathematical model allows to form energy-efficient regimes of granule polycapramide drying.

### **Abstract**

*Self-sustained fluctuating airflow behaviour in spray drying chambers is in essence an unsteady phenomenon requiring the transient CFD simulation framework. There is currently, however, a mixture of steady state and transient CFD simulations of spray dryers practised and reported in the literature. The choice between steady state and transient approach significantly affects the computation time of the simulation and subsequently the adoption of this approach by industry. This paper firstly examines in detail the bottleneck in computation time of the transient simulation approach. Based on past reports, this review paper then presents a discussion and provides several recommendations on the use of steady state and transient simulation approach for spray dryers.*

**Keywords:** CFD simulation, spray drying, transient, steady state, fluctuations

## **1. Introduction**

The start-up of an industrial spray drying operation typically involves an initial heating of the chamber with hot air, followed by the spray of water to mimic the evaporation rate of the intended product feed. Once the outlet air conditions are approximately achieved, the product feed spray is introduced. This is then followed by a short period of operation, during which the product is diverted and operation adjustments are made, until stable outlet air and product conditions are achieved. These stable conditions are called the steady state operating condition. Examining the overall spray drying process from such a macro plant-wide view, beyond the initial start-up phase, the a spray drying process is typically operated indeed in a steady state mode.

There are experimental evidences to suggest that even if the overall operation is steady state, the airflow pattern within the spray drying chamber may exhibit significant transient fluctuations [1][2]. Such transient air flow behaviour manifests in form of a self-sustained flapping from side to side. Such self-sustained transient behaviour was experimentally observed even for spray dryers fitted with nozzle and rotating disc atomizers (the latter would have significant swirl in the airflow pattern) and in large scale dryers with an internal static fluidized bed [3]. It is noteworthy that the self-sustained fluctuations were observed on relatively long time scales and were spatially coherent fluctuations; in contrast to small time scale and small length scale turbulent fluctuations.

Against the backdrop of a steady state spray drying operation, one may naturally raise the following question: Is it important for us to account for the self-sustained transient airflow behaviour in the analysis of spray dryers? Answering this question with a straightforward “yes” or “no” would naturally instigate a long debate and legitimate dispute, since it always boils down to the purpose of the simulation. However, if the interest is on the overall process i.e. mass and energy balance of the process, the answer is most likely “no”. On the other hand, for specific studies such as those on detailed drying behaviour, wall deposition, agglomeration etc. particularly with the development in the application of the Computational Fluid Dynamics (CFD) technique for spray drying analysis, which currently allows detailed analysis of the flow field within the chamber to be performed, accounting for the self-sustained transient behaviour may become crucial. Reports available in the literature, however, are not conclusive on whether or not this phenomenon should be accounted for. The former, in essence, is unable to capture the self-sustained behaviour. This review paper provides a discussion and analysis based on these reports with the aim of providing a guideline for future works in selecting a suitable approach for CFD modelling of spray dryers.

## **2. Steady versus transient CFD analysis and its implications**

It is important to firstly define the structure of a steady and a transient CFD analysis of spray dryer, so that the subsequent discussion can be made on the same benchmark. This review

paper centres around the Euler-Lagrangian framework. Within this framework, the hot dehydrating air is computed in the Eulerian framework as a continuous medium while the particles are numerically injected into the simulated flow field as discrete Lagrangian phase. In this review, the term ‘particles’ refers to droplet or solid particles interchangeably. Two-way coupling is normally used in the simulation framework where the air imparts momentum, mass (moisture content) and energy change to the particles and vice versa; the latter two parameters are due to the drying process that the droplets are subjected to. Details on this aspects of a CFD simulation of spray dryers can be found in other publications [4].

Adopting the Euler-Lagrangian framework, Figure 1 shows two different numerical approaches in which a steady and a transient spray dryer simulation can be undertaken. Solutions with the transient framework will certainly involve higher computational requirements and longer computation time. From the authors’ experience, however, given the computing power available nowadays, such differences may not be the significant factor affecting the potential selection between the steady and the transient framework. As a comparison, a steady state flow field simulation may take several hours while a transient flow field simulation may take a few days. The key difference lies in how the particles are injected into the flow field and in the way the two-way coupling is incorporated in both frameworks.

In the steady state framework, each particle is introduced into the flow field and tracked throughout the flow field until it leaves the simulation domain. This is then repeated depending on the number of particles specified to be injected to capture the stochastic behaviour of the particle movement and the particle size distribution of the spray. In essence, even though the source terms determined from the tracking of particles are accumulated for the subsequent incorporation into the steady state solution, there is only one particle numerically present in the simulation at any point. Therefore, the number of numerical loops required to achieve a converged solutions (Figure 1) is only dependent on the number of particle injection specified (which is fixed) and the ‘numerical’ speed at which the source terms are incorporated into the flow field solution. This ‘numerical’ speed is certainly dependent on the two-way coupling algorithm used and it is not the intention of this review paper to focus on any particular scheme.

Conversely, in the transient framework, particles are injected continuously at each discrete time step. During this time step, the particles injected into the simulation domain are only tracked and moved by one spatial step size. As opposed to steady state simulations, they are not tracked throughout the domain until those leave the chamber. Hence, as the simulation progresses in time, denoted by the loop in Figure 1, the number of particles within the chamber progressively increases leading to a further increase in the computational requirements at each time step. A fully developed flow field in this case, needs to account for not only the development of the temperature, momentum and humidity profile within the chamber, but also the development of the number of particles within the chamber. A well developed flow field should have a relatively stable number of particles indicating that the system has ‘truly’ entered the steady state operation behaviour. The simulation time required to achieve such fully developed simulation is, therefore, significantly determined by the physical characteristics and the size of the spray dryer (larger drying chamber will expect to have more particle accumulation and vice versa) and not merely by the coupling algorithm, as in the steady state simulations. From the authors’ experience, this takes significantly longer

time, in the order of weeks for large scale industrial dryers, when compared to the steady state simulations.

The transient simulation framework also warrants significantly different approach to the post-processing analysis of the particle drying history, which is one of the primary results from the CFD simulations. In the steady state approach, as each particle is tracked throughout the simulation domain until it leaves the domain, it is straightforward and easy to track and monitor the drying history of each particle. Determination of the particle conditions at the outlet of the dryer will only require collating the conditions of all the injected particle (those that leave the domain via the outlet) tracked one-by-one in the simulation. On the other hand, similar tracking and monitoring of the particle history in the transient framework will require large and simultaneous storage of all the particles within the simulation domain. For comparison, in a steady state simulation, an injection of hundreds or thousands of particles will normally be sufficient to account for the size distribution of the feed spray [5]. In a transient simulation, depending on the size of the dryer, the number of accumulated particles may be in the range of tens of thousands or hundreds of thousands of particles [6][7]. Determination of the particle conditions at the outlet will then require further time averaged sampling of particles leaving the system [6][7]. Even though the implemented parcel tracking method in the Eulerian-Lagrangian framework, which allows a parcel representing a group of identical particles having the same fate to be tracked in lieu of tracking each individual particle, eases the conundrum of tracking and storing information about so many particles, the remaining computational and postprocessing effort required still is far from negligible.

In order to overcome these limitations in transient simulation post-processing, a pseudo-steady analysis method was developed in which the flow field is developed with fully transient airflow computation accompanied by transient particle tracking for a low velocity spray dryer. Particle history is then analysed and obtained by adopting an instantaneous snapshot of the developed flow field and undertaking steady state particle tracking through the flow field [8][9]. The premise of this post-processing approach assumes that, in view of the self sustained fluctuating behaviour, a snap shot at any particular flow time is representative of the overall flow behaviour in the system. Comparison on using snapshots at different flow time provided compelling evidence to support this assumption. Further comparison is, however, required with full transient analysis and with dryers of different configurations to better validate this technique. Even if this could be fully resolved or verified, the transient simulation framework would still need long computation time to fully develop the flow field incorporating transient simulation tracking (Figure 1). An earlier report can also be found adopting this approach excluding the two-way coupling [10] i.e. no build-up of humidity or reduction of the air temperature due to droplet evaporation could be predicted and fed back to the solution.

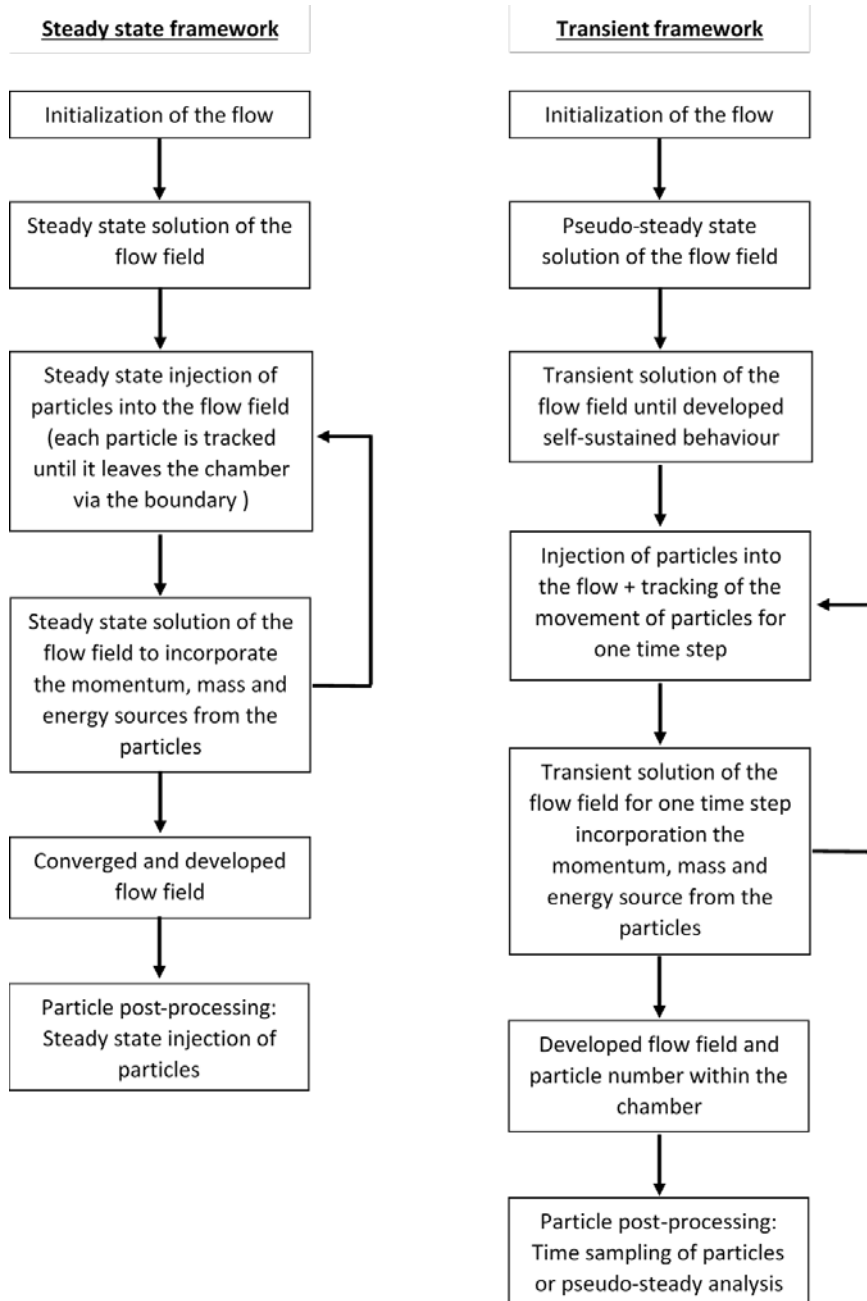

Fig. 1 Numerical approaches to undertaking steady or transient CFD simulations of spray dryers

Based on the comparison presented above, it can be concluded that it is obviously more attractive to adopt the steady state simulation approach. This will then allow the CFD simulation technique to be used in a more routine-manner, which will be particularly important for the adoption of this technique by industry. Nevertheless, the same question still prevails: How accurately do steady state simulations capture the reality of a potentially fluctuating flow field in spray dryers? At any rate, the ensuing question will be: in what situation can we employ a steady state simulation? In an attempt to answer these important questions, detailed comparison were undertaken based on past reports in the literature. However, this part of the review was not included here due to page limitation.

### **3. Understanding the numerical source of self-sustained fluctuation**

The fact that self-sustained fluctuations discussed in this review may occur even in symmetrical geometries suggests that it must be initiated from some ‘imbalance’ in the system. There is a series of numerically based reports elucidating the self-sustained fluctuation behaviour based on the sudden flow expansion theory. The premise of this theory is that a certain flow regime characterized by the Reynolds or Swirl number and the expansion ratio will have the propensity to exhibit self-sustained flow behavior [11][12][13][14]. The jet feedback mechanism was proposed later on, expanding on the theory of expansion to elucidate the potential unbalanced pressure within the chamber, leading to the self-sustained fluctuation behavior [15].

In a real physical system, there are many factors which may contribute to such imbalance such as slight asymmetry in the drying chamber or in the inlet flow of air (no perfect system in reality). These imbalances are then sustained or propagated and consequently reflected by the inherent propensity of the system for self-sustained fluctuations, as discussed in the preceding section. For a numerical system, however, where the geometry and the input parameters for a CFD simulation can be perfectly symmetrical, such asymmetric physical seed for the initiation of self-sustained fluctuation will not be available. One may argue that even though the geometry and the inputs are symmetrical, the meshing of the system, particularly if tetrahedral meshes are used, may lead to numerically asymmetric solution to the flow field. However, it must be noted that self-sustained fluctuations were predicted even when very structured symmetrical hexahedral meshes were used [14]. Basing our discussion on the solution of the turbulent flow field with the Reynolds Averaged Navier Stokes (RANS) equations and its subsequent closure models, there is no stochastic element in the mathematical framework. Hence, if the mesh used is symmetrical, the RANS framework should theoretically provide a symmetrical solution. What is then the source of asymmetry, which provides the seed for the occurrence of self-sustained fluctuation behaviour in a numerical model?

Eliminating the possible influence of the physical geometry, meshing and mathematical model as discussed, the seed for or the instigation of ‘numerical’ self-sustained fluctuation

must then be attributed to numerical imbalance during the solution of the flow field. Such numerical imbalance may propagate into imbalances predicted in the physical flow field, building up the potential for self-sustained fluctuations. If this argument is to be further extended, it can be noted that perhaps, the numerical coupling with particles introduced into the simulation may also contribute to such instability, as was reported by Jubaer et al. [16]. Whether or not such imbalances propagate into self-sustained flow behaviour will certainly depend on the propensity of the spray drying chamber for ‘dampening’ such physical or numerical imbalances. The understanding on the numerical source of self-sustained fluctuation is important in guiding the numerical approach employed in the CFD simulation of spray dryers. Perhaps, as a ‘robust’ approach to encompass all the possibilities to capturing the self-sustained fluctuation, there may be a need for an element of numerical imbalance in the simulation domain; a system which inherently is not self-sustained in fluctuation would damp the imbalance anyway and vice versa.

## **5. Conclusions**

A key numerical bottleneck in transient CFD simulation of self-sustained fluctuating flows in spray dryers is the long computation time required for two-way coupling during flow development. There is a strong need for future numerical development to overcome this limitation so that the CFD technique can be used in a more routine manner. From the reports available in the literature, there is currently no clear guidelines on the use of steady or transient simulation approach when analysing pilot or industrial scale spray dryers. This paper recommends to ascertain the significance of the fluctuating behaviour with the transient simulation framework, on a case-by-case basis. This is particularly important if an asymmetric flow field was predicted for a symmetrical simulation domain. A few numerical guidelines are proposed. It was further reasoned that numerical imbalance may be the seed for self-sustained fluctuations observed in CFD simulations of spray dryers. Whether or not this numerical imbalance propagates into physical imbalances leading to flow fluctuation behaviours, depends on the characteristics of the spray drying geometry relative to its operating conditions, which may or may not contribute to dampening these imbalances.

### **Abstract**

*We compared a semi empirical and an empirical model. The empirical model is a multilayer ANN. The semi empirical model is a custom multilayer ANN. It is a structured model, and we define the structure by hand before the training of the network. The influence of the neuron numbers on the accuracy of the models was also investigated by statistical approach.*

*We found that the custom multilayer ANNs developed like this, are suitable for modelling the drying process of agricultural materials. They also provide the ability to improve the applicability of the empirical models. Furthermore, the semi empirical model has a higher sensitivity on neuron number applied.*

**Keywords:** *drying; energetics; artificial neural network; semi-empirical model.*

---

## **1. Introduction**

The complexity of the water removal process, and the inhomogenities of the process variables both in time and space make the modelling of the drying process of agricultural products difficult. The usability of theoretical models is limited due to the stochastic material properties. [4] In these cases, the application of empirical models is essential. [5] However, in the most cases we have theoretical information about the process. Applying this information to the model it will became semi-empirical and possibly improve the usability compared to the pure empirical. [3]

Artificial intelligence techniques are also found in drying. [6] They are used for process variable prediction [10][12][15], process control [9][11][13] or for soft sensors[14]. Artificial neural networks (ANN) are sucsefully applied on all these fiels on their own, or combined with other AI or conventional techniques. [8] The use of ANN requires attention and awareness as the structure, the training and data preparation have significant effect on usability of the model. [7]

Earlier we found that artificial neural networks (ANN) are suitable to model the drying of agricultural products. [1] They are empirical models, but can be turned into semi-empirical when we use the combination of smaller ANNs in a suitable structure instead of one unstructured model. [2]

It can happen that we have a priori information about the structure of the system (to be modelled), but don't have the data to train the subsequent ANNs that make up the semi-empirical model as a combination of smaller individually trained networks. In this case a single, but structured ANN can be created. The ANN can be defined by hand. It is called a custom artificial neural network. It can have a structure like the combination of smaller ANNs have, but the model can be trained without having any data for the internal connection.

The statistical approach that we used earlier [1] can help us to find the optimal structure of the network. The models' performance can be highly influenced by the applied number of the layers, and the number of the neurons in the layers. There are structures and neuron numbers that will never ever provide us an accurate model. On the other hand, there are structures what provide us accurate model with a high probability.

This paper is about the semi-empirical ANN models made from structured analytical neural networks and it is looking for answers to the following questions: Is it possible to construct such a model? Is it possible to find an optimal model? Is it better than the pure empirical?

## 2. Materials and Methods

The measurement data is taken from an experimental drying of tomato pomace in a laboratory dryer. The drying apparatus is a convective batch dryer. The dried material is placed into the drying chamber on perforated sheet metal trays in three layers. The psychrometric properties of the drying air are measured before and after each layer, the flow rate is measured with an orifice at the duct inlet. The water removal is measured with gravimetric method. For data acquisition five-minute sampling rate was used.

*Fig. 1. Schematic of the dryer. (T-temperature, H-humidity, F-flow rate, m-mass, q-heat flow)*

The wet-base moisture content of the raw material was about 80% at the beginning and 6% at the end of the drying experiment. The flowrate of the drying air was 370m<sup>3</sup>/h and the temperature was set according to table 1. 2 kg tomato pomes was put on each tray in a 40 mm thick layer.

<b>experiment</b>	<b>temperature [°C]</b>
1	40
3	110
5	75
6	55

From the preliminary data analysis four data sets have been chosen for the models: experiment 1, 3, 5 and 6. From these data sets experiment 1 has systematic error, and not

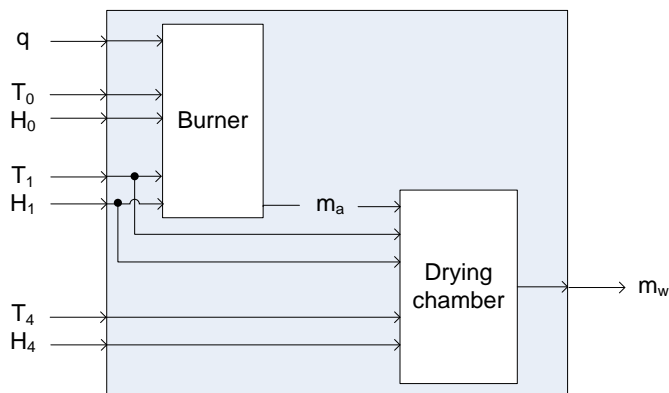

used for training the models but for test. It is required that the model shall approximate experiment 1 with a significantly higher error.

The first model constructed is purely empirical. According to the earlier works on this topic [1], a two-layer ANN has been chosen. Two such models were defined and we use the simpler one as it can be found on figure 2 below. The simplified model does not deal with the layers; it is like a one-layer dryer.

**Fig. 2. Empirical model of deep bed dryer.** ( $m_w$ -water removal rate,  $T_0$ -ambient air temperature,  $T_1$ -air temperature at drying chamber inlet,  $T_4$ -air temperature at drying chamber outlet,  $H_0$ -ambient air humidity,  $H_1$ -humidity at drying chamber inlet,  $H_4$ -air humidity at drying chamber outlet)

The semi-empirical model is considering that the dryer consists of a burner and a drying chamber. The connection of the two components is the flow rate of the drying media.

**Fig. 3. Semi-empirical model of the deep bed dryer.** ( $m_a$ -flow rate of the drying air)

For the burner a one-layer ANN was used. For the drying chamber and the simplified empirical model, a two-layer structure was used. For the determination of the optimal neuron numbers in each layer the statistical approach was used. [1] We compared several networks with different neuron numbers in each. Table 2 contains the neuron numbers we used.

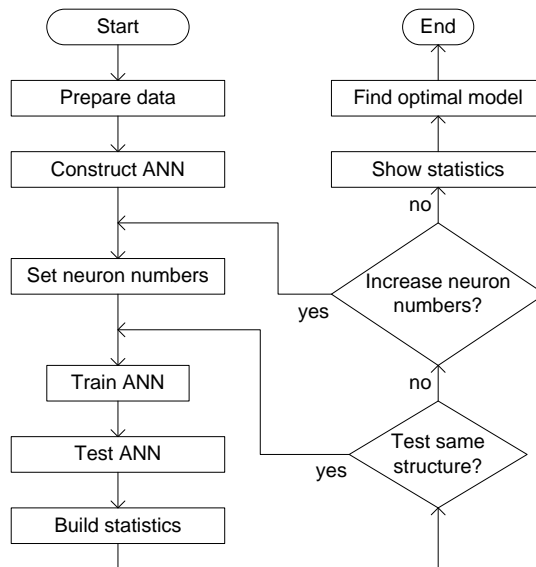

After the training of the ANN models, we tested them. All the experiment data was given to the model inputs and the model output was compared to the measured data. For each simulation the cumulated squared error was calculated as the measure of model performance.

$$\text{Cumulated\_squared\_error} = \sum (\text{measured} - \text{simulated})^2 \quad (1)$$

*Table 2. Neuron numbers per layer*

model	layer	neurons
empirical	1 <sup>st</sup>	1-15
	2 <sup>nd</sup>	1-15
semi empirical	burner	1-10
	drying chamber 1 <sup>st</sup>	1-15
	drying chamber 2 <sup>nd</sup>	1-15

We also checked the correlation of the model output with the measured data. Figure 4 shows the algorithm of the whole process. Each structure was trained and tested 5 times. At the end, the results were shown in diagrams and the optimal model structure was chosen. The optimal model is the model with the smallest expected value and little standard deviation of cumulated squared error. The optimal models output should also have a good correlation with the measurement data.

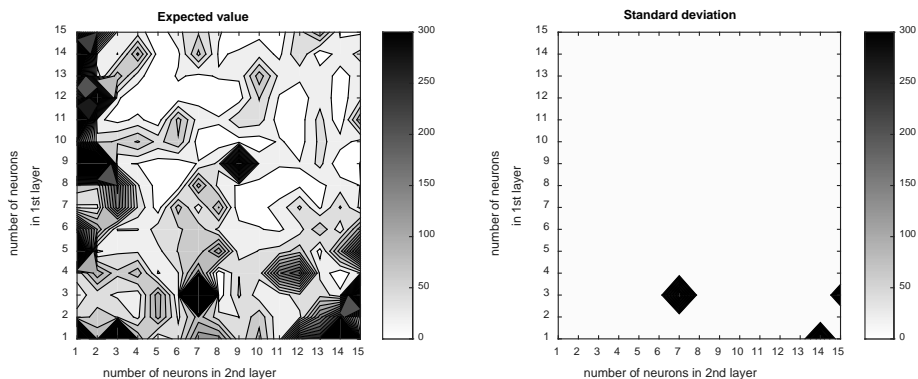

*Fig. 4. Workflow of finding the optimal model*

### 3. Results and Discussion

The empirical model has 2 hidden layers. We used the method on Figure 4 to construct empirical models with different neuron numbers according to Table 2. The results can be observed on Figure 5. The structure of the optimal empirical model and its performance is shown in Table 3.

*Table 3. Optimal models*

model	layer	neurons	error
empirical	1 <sup>st</sup>	7	0.862
	2 <sup>nd</sup>	9	
semi empirical	burner	1	2.6
	drying chamber 1 <sup>st</sup>	13	
	drying chamber 2 <sup>nd</sup>	11	

*Fig. 5. Performance of the empirical model with different neuron numbers.*

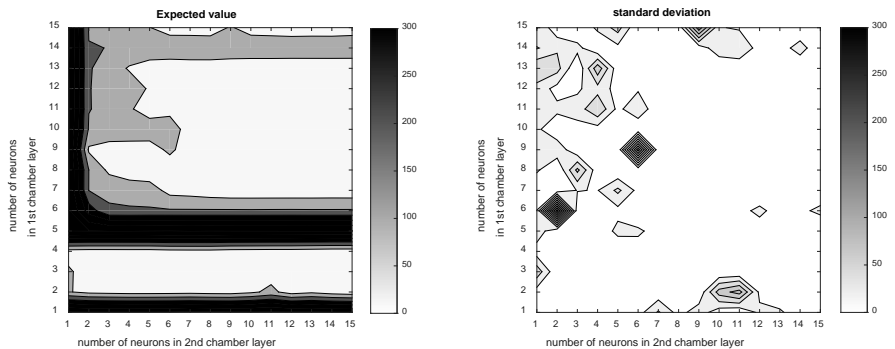

The semi empirical model always has 3 hidden layers: one for the burner and two for the drying chamber. We used the same method as for the empirical model thus on Figure 4. The results cannot be shown on one diagram as the 3 layers of neurons span a 3-dimensional space rather than a 2-dimensional. But it is possible to show on several diagrams. We need as many diagrams, as many neurons we have in a chosen layer. We choose the burner layer, because it has less possible number of neurons than the others. This way we got the smallest number of diagrams. Figure 6 contains the optimal structure. The structure of the optimal semi empirical model and its performance can be found in Table 3.

**Fig. 6. Performance of the semi empirical model with a single neuron in the burner layer.**

There are several near optimal structures on figure 6. On the other hand there are structures with significantly higher error what probably make the model unusable. If the burner has one neuron the 1<sup>st</sup> chamber layer should have at least 3 or 4 neurons. The diagrams with higher neuron numbers for the burner show significantly higher error. Because of the limited space we did not include in this paper all the diagrams but they are very similar to Figure 7 in the aspect that the model with all those neuron numbers has significantly higher error.

**Fig. 7. Performance of the semi empirical model with 2 neuron in the burner layer.**

#### 4. Conclusions

Empirical and semi empirical models both approximated the measurement data with acceptable error.

It was possible to construct a semi empirical model with a custom ANN that is suitable for modelling the drying process of tomato pomace.

There are significant differences in model performance depending on the model structure and the number of neurons used in its layers.

The statistical method we used can highlight the unusable and potentially usable structures.

With the statistical method we used it was possible to find the optimal model structure.

### **Abstract**

*In a freeze drying process, the freezing step determines the pore size distribution within the product, which, in turn, affects the sublimation rate. Traditionally, pore analysis is carried out on SEM images by means of a manual, time-consuming approach. Here, an image segmentation technique was used to automatize this process and improve its reliability. A 3D structure of the cake was then reconstructed from the distribution of the super-pixels. We show that the approach herein proposed can remarkably improve prediction of the sublimation rate with respect to traditional methods.*

**Keywords:** *Freezing; Freeze-Drying; Image Segmentation; 3D Reconstruction*

## 1. Introduction

During freeze drying, water is removed by sublimation and desorption from a previously frozen product. When designing a freeze drying process, it is well-known that the freezing step is extremely relevant for both process performance and product quality [1]. In fact, different freezing protocols result in different pore size distributions within the product, affecting both sublimation and desorption rates. More specifically, the nucleation event, and, in particular, the temperature at which the first ice crystal nuclei are formed, is of major importance in the freezing process, as it determines the pore size distribution which will then be formed in the dried sample. In particular, a low nucleation temperature will result in the formation of small pores. These small pores will then offer a large resistance to water vapor flow during primary drying, thus decreasing the sublimation rate. From this viewpoint, a problem with the traditional freezing approaches, such as shelf ramped freezing, is that they do not allow control of the nucleation temperature, which will therefore be stochastically distributed. However, some techniques have been developed to overcome this problem [1,2]. Among them, vacuum induced surface freezing (VISF) was demonstrated to be beneficial for both product homogeneity and process performance [3,4]. In fact, VISF can be used to induce nucleation at a higher temperature in all the vials being processed. This higher nucleation temperature results in the formation of larger pores within the dried samples, boosting the sublimation rate. For instance, in Figure 1 two Scanning Electron Microscopy (SEM) images are shown, representing a 5% w/w mannitol sample after freeze drying. In the case of Figure 1a, VISF was used, while the sample in Figure 1b was processed using the conventional shelf-ramped freezing protocol.

*Fig. 1 SEM images of 5% w/w mannitol samples obtained using VISF (a) or shelf ramped freezing (b).*

The huge difference in sample morphology which can be observed translates into remarkably different cycle performance; it is therefore clear that the information on the pore size distribution is crucial for the proper design of a freeze-drying process. Although many other

approaches have been proposed in the past, such as X-ray tomography [5], the most common technique remains off-line SEM analysis. This is generally achieved by means of a manual analysis of the resulting images. The manual approach is, however, highly time consuming, and the results obtained are subjective and, therefore, poorly reliable. Therefore, we recently proposed a method based on the segmentation of SEM images to automatically determine the pore size distribution [6]. In the above-mentioned work, we showed that image segmentation could quickly and reliably allow resolution of the porous structure of the sample under investigation. Here we propose a further improvement of this technique, which combines the analysis of the levels of grey-tones to the detection of edges between different domains. Moreover, we will show that, from the super-pixels distribution obtained as a result of segmentation, a 3D structure of the cake may be reconstructed by means of a stochastic approach. We will prove that the reconstruction obtained can fairly well represent the main features of the real dried cake. This result is important, since the generated structure may then be used within a computational fluid dynamics (CFD) simulation, to estimate the tortuosity of the sample [7]. Since both the pore size distribution and the tortuosity factor enter into the definition of the mass transfer resistance to vapor flow, the approach herein proposed could remarkably improve prediction of the sublimation rate, which is at the basis of any model for the freeze-drying process.

## 2. Materials and Methods

### 2.1 Freeze drying cycles and SEM analysis

The formulation investigated in this work was a 5% w/w mannitol solution, prepared from distilled water and mannitol powder (Sigma Aldrich). The vials employed (type 1, 10R, 45x24 mm, Schott AG, Germany), were filled in with 3 ml of sample solution, and loaded onto the shelves of a freeze-dryer LyoBeta 25 (Telstar, Terrassa, Spain). For the conventional (shelf ramped) freezing tests, the refrigerating fluid temperature was decreased to  $-45^{\circ}\text{C}$  at  $0.7^{\circ}\text{C}/\text{min}$ .

As regards VISF, the product was first equilibrated at  $-5^{\circ}\text{C}$  for 45 min and, then, the chamber pressure was reduced to 130 Pa until nucleation was observed. The pressure was then quickly released to the atmospheric value, and the product was equilibrated at  $-10^{\circ}\text{C}$  for 1 h. To complete the freezing of the product, the refrigerating fluid temperature was subsequently decreased to  $-45^{\circ}\text{C}$  at  $0.7^{\circ}\text{C}/\text{min}$  and held for 1 h. Finally, drying was performed at 10 Pa, and  $-10^{\circ}\text{C}$ . The internal structure of the resulting cake was analyzed by means of a Scanning Electron Microscope (SEM, FEI type, Quanta Inspect 200, Eindhoven, the Netherlands).

## 2.2 Image Segmentation for the processing of SEM images

In [6], we described a segmentation approach, based on the analysis of the levels of grey-tones, for the determination of the pore size distribution in freeze dried samples. Here, we propose an improved version of this technique, in which the detection of the edges between the pores and the surrounding scaffold is included in the analysis. First, the SEM image is processed to enhance the edges in it, that is processed to detect the regions where we have a large gradient in the topography. Among the methods for edge detection, the Retinex filter, which is available in GIMP (the GNU Image Manipulation Program [8]), was chosen. Then, this information is merged to that concerning the topography itself and the image converted into a binary black and white map (Figures 2a and 2b). From the resulting map, the pores are automatically selected, as described in [6], and as shown in Figures 2c and 2d.

*Fig. 2 (a) SEM and (b) binary images corresponding to mannitol 5% w/w, freeze dried using VISF. (c) Segmentation of the original SEM image, where the domains are represented by different colors. (d) Distribution of the super-pixels (in logarithmic scales), obtained by counting them according to their area (in pixels).*

## 2.3 Prediction of the resistance to mass transfer

The resistance to mass transfer,  $R_p$ , was calculated from the average pore dimension  $D_p$ , as calculated using either the manual approach, or the image segmentation technique, by means of the following equation,

$$R_p = \frac{3 \tau^2 L_d}{2 \varepsilon D_p} \sqrt{\frac{\pi R T}{2 M_w}} \quad (1)$$

where  $R$  and  $M_w$  are the universal gas constant and water molecular weight, respectively. As can be seen,  $R_p$  is a function of the dried layer thickness  $L_d$ , and depends on the product temperature  $T$ , and on the dried product tortuosity factor  $\tau$  and porosity  $\varepsilon$ , as well.

## 2.4 Stochastic reconstruction of 3D structures

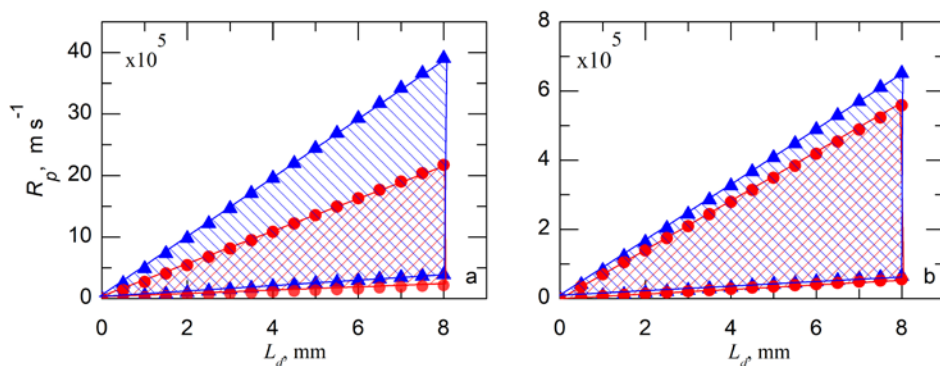

Using the information obtained from image analysis, a 3D structure of the dried cake was then reconstructed, for the case of the product obtained by VISF (Figure 1a). To do this, spherical pores were stochastically built into an 800 x 800 x 800  $\mu\text{m}$  original bulky cube. The dimension of the spheres was chosen so as to reproduce the pore size distribution obtained from image segmentation (Figure 2d). As shown in Figure 3 this procedure was iterated until the desired value of porosity was reached. No constraints were imposed on the position of the sphere centers, so that interpenetration of the pores was possible, as illustrated in Figure 3. This was done in order to better reproduce the real structure of a freeze-dried product, where the porous structure is, generally, highly interconnected.

**Fig. 3** Reconstruction of a lyophilized cake with different void fraction.

### 3. Results and Discussion

The image segmentation technique described in section 2.2 was applied to the SEM images shown in Figure 1. As illustrated in a previous work [6], this technique allows calculation of the super-pixels distribution within the SEM image, from which an average pore size can be extracted. For instance, using segmentation, average pore dimensions of  $140 \pm 30 \mu\text{m}$  and  $36 \pm 6 \mu\text{m}$  were obtained for VISF (Figure 1a) and shelf ramped freezing (Figure 1b), respectively. By contrast, using the traditional approach, that is, manually selecting and measuring a sufficiently large number of pores, the conventional freezing protocol and VISF resulted in an average diameter of  $20 \pm 8 \mu\text{m}$  and  $120 \pm 36 \mu\text{m}$ , respectively. As can be seen, both techniques measured a larger average pore size in the case of VISF, which was expected, because of the higher nucleation temperature in the case of controlled nucleation. However, the pore dimension is not sufficient for an accurate estimation of the resistance to mass transfer  $R_p$ , since another required parameter is the tortuosity factor  $\tau$ , whose value is generally only roughly hypothesized. Typically used values span between 1.2 and 3.8 [9], and this range translates into a large uncertainty in the value of  $R_p$ , as shown in Figure 4.

**Fig. 4** Uncertainty in the value of  $R_p$  as function of the dried layer thickness  $L_d$ , due to the uncertainty on  $\tau$ . The range 1.2–3.8 was considered for  $\tau$ . (a) conventional freezing, and (b) VISF. ●: Values calculated using Eq. 1, in which the pore dimension  $D_p$  was obtained by the image segmentation approach; ▲: Values calculated using Eq. 1, in which the pore dimension  $D_p$  was obtained by the traditional manual approach.

A possible solution to this problem can be found combining image analysis and CFD simulations. In fact, as described in section 2.4, a 3D structure of the dried cake might be reconstructed using the super-pixels distribution obtained from image segmentation. An example of reconstructed structure, for varying values of porosity, is shown in Figure 3. The stochastic approach used for the 3D reconstruction was validated against the original SEM image, as outlined in Figure 5. A  $800 \times 800 \times 400 \mu\text{m}$  slice was isolated from the reconstructed cube, and a 2D section (Figure 5b) was obtained from this slice, using a grey-

tone scale ranging from white to black to represent perspective. This was done in order to simulate the same type of representation obtained in a typical SEM analysis. As can be seen comparing Figures 5a and 5b, there was a striking similarity between the original SEM image and the 2D section obtained from the 3D reconstruction. To further confirm this similarity, Figure 5b was analyzed using image segmentation, and the super-pixels distribution was calculated (Figure 5c). Remarkably, the resulting distribution compares fairly well with that obtained for the original SEM image (Figure 2d). This means that the 3D reconstruction preserves most of the features of the original sample, and could therefore allow an easier analysis of the properties which influence the sublimation rate; for instance, by a CFD simulation of water vapor flow through the reconstructed 3D structure.

**Fig. 5** Validation of the 3D reconstruction approach: a) SEM image, b) upper view of a slice of the 3D structure and c) super-pixels distribution in Fig. 5b.

#### 4. Conclusions

In the present work, a new approach has been proposed for the estimation of both the pore size distribution and the tortuosity factor within a freeze dried sample. Work is in progress to simulate the fluid dynamics in the 3D reconstructed matrix. Subsequently, analysis of the velocity vectors for the water vapor during the simulation would make it possible to estimate the tortuosity of the sample, and, thus, to calculate a more accurate value for the mass transfer resistance; the same procedure discussed in [7] for granular beds obtained by spray-freezing can be adopted. The described method may allow a significantly improved fitting of experimental data with respect to other traditional modeling techniques. We are therefore convinced that the approach herein outlined could be extremely beneficial, paving the way for a more robust design of the freeze drying process.

### Abstract

*Cellular and non-cellular-solid food systems were used to obtain experimental data of  $a_w$  and  $T_g$  as a function of moisture content during drying. GAB, Gordon-Taylor, and Khalloufi-Ratti models were used to obtain the state diagrams of the four food systems investigated. The results suggest that the GAB and Khalloufi-Ratti models can successfully be used to capture the experimental data. In terms of plasticizing effect, it seems that cellular and non-cellular systems have comparable values. Although the number of food samples explored in this study was limited, it is suggested that the chemical composition could have more impact on  $T_g$  and stability than the presence of cell structures.*

**Keywords:** *Isotherms; Glass Transition; Cellular and Non-Cellular Food Systems; Modeling.*

## 1. Introduction

Several mathematical models are available for describing sorption isotherms. The widely used model for food matrices is Guggenheim-Anderson-de Boer (GAB) [1]. This model is based on the monolayer moisture concept, and may be used to provide estimative values of critical moisture content and relative humidity for safe storage of dried foods [2]. With respect to bio-material, the Flory-Huggins model has been also able to properly describe sorption isotherms [3, 4].

The concept of glass transition has been widely applied to food, polymer, material and pharmaceutical sciences to relate physical, chemical and structural changes to the physical state of the material [2]. In general, the  $T_g$  value depends on the thermal history of the material, the molecular weight of the polymer chains, the presence of a plasticizer, the degree of crystallinity and sample composition [5]. Water, with low molecular weight and low  $T_g$  (-135°C) [6], is the most important plasticizing agent in foodstuffs, increasing the flexibility of matrix and decreasing  $T_g$ . Water plasticization effect may be well represented in foods by the Gordon-Taylor (G-T) equation [7] and, for polymer blends, by the Couchman and Karasz (C-K) equation [8]. Khalloufi et al. (2000) developed an equation to represent glass transition temperature of fruit powders as a function of water activity, which proposes a sigmoid rather than linear representation of  $T_g$  in the whole range of water activity [9].

Both water activity and glass transition have been used extensively in the literature to evaluate storage stability [10, 11]. The combination of these two parameters can be used to obtain the state diagram. [12] which can help to select packaging material and optimizing ingredient in food formulation. Furthermore, the state diagram can be used to design and optimize drying equipment, as well as to model and control processing, i.e. determination of the end-point of drying or assessing the energy requirement by choosing optimum temperature and moisture content to avoid undesirable effects [13]. So far, the state diagrams for various foodstuffs have been reported in literature [2, 14, 15, 16]. However, none of this data compared cellular to non cellular systems. In addition, state diagrams for maltodextrins, carrots and potatoes are rare in the open littertaure [17].

The objective of the current study was to develop the state diagrams for potato, carrot and two agar-maltodextrin model systems (AM DE19 and AM DE36), by measuring the glass transition temperature and water sorption isotherms. The GAB and Flory-Huggins equations were used to describe the sorption isotherms, while the G-T equation, for the glass transition temperature. The relationship between  $T_g$  and  $a_w$  was established from Khalloufi-Ratti model [9]. State diagrams for the four products were built from mathematical representations for  $T_g$ ,  $a_w$  and moisture content and compared with experimental data.

## 2. Materials and Methods

### 2.1. Material and processing

Maltodextrin was provided by Laboratory Mat (Quebec city, Canada). Agar was delivered by Becton Dickinson and Company (Sparks, MD 21152 USA). White potatoes (W1386 variety) were provided by Gosselin G2 Inc. (Quebec City, Canada). Carrots were purchased directly from a local market in Quebec, Canada (ATV farms, Quebec). Two cellular systems (potato and carrot) and two non-cellular systems (water-agar-maltodextrin: AM DE19 and AM DE36) were used in this study. The non-cellular models were prepared in a mass proportion of water/agar/maltodextrin of 1/0.015/0.15. Cylindrical samples were made and cut from random positions within the sample with a hollow punch in 1cm-diameter by 4cm-long cylinders. Samples were dried by convection in an Armfield tunnel dryer (Model UOP8-G, Hampshire, UK) with air at 55°C and air speed of 1.6m/s, until constant weight.

### 2.2. Sorption Isotherms

Materials with various moisture contents and water activities were obtained by re-humidification of powdered air-dried samples at various relative humidity levels over saturated salt solutions in desiccators at 25°C. Relative humidity of the saturated solutions was checked by measuring their water activity with an Aqualab (model series 3, Decagon Devices Inc, USA).

### 2.3. Glass transition temperature ( $T_g$ )

The glass transition temperature of equilibrated samples was measured with a Differential Scanning Calorimeter DSC Pyris 1 (Perkin Elmer, Shelton, CT, USA).

### 2.4. Mathematical modeling

The mathematical relationships used in this contribution are presented in Table 1.

*Table 1. Mathematical relationships between moisture content ( $X$ ), water activity ( $a_w$ ), and/or glass transition temperature ( $T_g$ )*

Model & Reference	Mathematical expression	Eq.
GAB [1]	$X = \frac{(X_m Y K a_w)}{(1 - K a_w)(1 - K a_w + Y K a_w)}$	(1)
Flory-Huggins [3]	$\ln a_w = \ln(1 - \phi_p) + \phi_p - \frac{\phi_p}{N} + \chi \phi_p^2$	(2)
Gordon-Taylor [7]	$T_g = \frac{(1 - w) T_{g_s} + k w T_{g_w}}{(1 - w) + k w}$	(3)
Khalloufi-Ratti [9]	$T_g = \frac{A a_w^2 + B a_w + C}{D a_w^2 + E a_w + 1}$	(4)

### 3. Results and discussion

Figure 1 shows the results obtained by using the Flory-Huggins model to describe water activity as a function of volume fraction. The Flory-Huggins model was satisfactory for carrot, but not for other food systems investigated in this contribution (e.g. AM DE19, AM DE36 and potato). According to Kocherbitov (2016), the Flory-Huggins equation is not able to describe the glassy part of water sorption isotherms of some polymers [4]. As the Flory-Huggins model was not suitable for all the four food systems, the GAB model will be used for the next steps of this study (Figure 2 and Table2).

Figure 1. Comparison between experimental data and predictions of Flory-Huggins model

The  $T_g$  values for carrots and potatoes, obtained in this investigation, are close to those reported by Karmas et al. (1992). Georget et al. (1999) detected two glass transition temperatures for carrot material associated with two phases: a sugar-rich phase and a cell wall-rich phase. The  $T_g$  value found in the current study is considered to be in agreement with those of the sugar-rich phase but lower than those of the cell wall rich phase [17]. Three main saccharides occurring commonly in carrot roots are glucose, fructose and sucrose [18], thus the glass transition temperature in carrots are related to  $T_g$  for those three types of sugars. The  $T_g$  value of carrots is also similar to the one of rich glucose-fructose fruit such as raspberry ( $T_{g_s} = 42.62^\circ\text{C}$ ) [2]. In the case of potato, the  $T_g$  value in both native or non-native potato starch reported in literature ( $120^\circ\text{C}$ ) is much higher than the experimental data found in the present study ( $49.8 \pm 12.3^\circ\text{C}$ ) for dry potato [5, 19]. Significant differences between  $T_g$

values of dried potato tuber and potato starch was also observed by Chirife et al. (1996). According to Biliaderis et al. (1986), the absence of a clearly detectible glass transition in native starch is due to the amorphous chains locked by crystalline domains, the decrease of mobility of the amorphous chain by physical crosslinks and the presence of inter-crystalline phases that do not follow normal thermal behavior. The constants  $Tg_s$  and  $k$  of the Gordon-Taylor model (Eq. 3) were estimated by non-linear regression for the four types of sample materials, which results are shown in Table 2. The  $k$  values of the four products studied in the present work were in the range reported for fruits and vegetables such as onion ( $k = 4.3$ ), raspberry ( $k = 4.7$ ), strawberry ( $k = 4.3$ ), mango ( $k = 4.5$ ), kiwifruit ( $k = 4.9$ ), gooseberry ( $k = 5.7$ ) and banana ( $k = 6.1$ ) [2, 14, 15, 16, 20, 21]. The  $k$  value is an estimate of the plasticization effect of water, which means the strength of interaction between water and the food solids. Higher values indicate a greater plasticizing effect of water on solids [12]. From Table 2, it can be observed that water has a greater plasticizing effect on potato than on carrot. For carrot, this plasticizing effect of water was the lowest among the four products.

**Table 2. Parameters involved in the Gordon-Taylor model (Eq. 3, Table 1)**

	$Tg$ (°C)	$k$	$r^2$
AM DE19	108.4	4.9	0.97
AM DE36	81.9	5.2	0.99
Potato	76.2	6.8	0.99
Carrot	35.2	4.3	0.96

State diagrams (Figure 2) was built by using experimental data and the predictions obtained from the mathematical model of GAB expression (for water sorption) and from Khalloufi-Ratti model (for glass transition temperature). As it can be seen, the predictions obtained by both models are in agreement with the experimental data. The monolayer water content ( $X_m$ ) obtained from the GAB equation is an important parameter for stability of foods, which depends on chemical composition and temperature of the material. A product is most stable below  $X_m$  where rates of deteriorative reactions are minimal [22]. At temperature of 25°C, the estimated values of the parameter  $X_m$  is 0.049 kg/kg (db) for AM DE19, 0.065 kg/kg (db) for AM DE36, 0.056 kg/kg (db) for potato. These values were found to be lower than the one

for carrot, which was 0.195 kg/kg (db). These results are close to those reported by Kiranoudis et al. (1993) which found that the  $X_m$  value of potato was 0.087 and that of carrot was 0.21 kg/kg (db).

Figure 2. State diagram of cellular and non-cellular food materials. Lines are predicted data obtained by using GAB and Khalloufi-Ratti models

The relationship between  $a_w$  and  $T_g$  has been reported to be sigmoid [11]. The Khalloufi-Ratti model [9] allows capturing this sigmoidal profile for all the food systems investigated in this study (Figure 2). This model is a combination of parameters obtained previously from Gordon-Taylor and GAB models (Table 1).

Table 2 shows the critical water content and critical water activity of four products at 4°C and 25°C obtained from state diagram (Figure 2). The critical water content (CWC) and critical water activity (CWA) are the value at which the glass transition occurs, at a determined storage temperature of the product. These values are helpful to show the dependence of  $T_g$  of product on moisture content or water activity. For example, if the AM DE19 is conserved at 25°C, the CWC and CWA at which the glassy system AMDE19 transformed to a rubbery state is 0.096 kg/kg dm and 0.536, respectively. According to the water activity concept, foods are most stable at their monolayer moisture content. While the glass transition concept proposes that amorphous matrix are more stable at or below the corresponding  $T_g$  [10, 13].

**Table 3. Critical water activity ( $a_{wc}$ ) and Critical water content ( $X_c$ )**

	4°C		25°C	
	$a_{wc}$	$X_c$	$a_{wc}$	$X_c$
AM DE19	0.6765	0.1336	0.5389	0.0966
AM DE36	0.4883	0.0865	0.3439	0.0567
Potato	0.3416	0.0711	0.1453	0.0450
Carrot	0.3303	0.0493	0.1105	0.0145

#### 4. Conclusions

Water activity ( $a_w$ ) and glass transition temperature ( $T_g$ ) are relevant concepts to predict the stability of food products. The Flory-Huggins model was able to describe the sorption isotherm of carrot but not for other food systems investigated in this study. GAB and Khalloufi-Ratti models were successfully able to capture the experimental profile of cellular and non cellular food systems. These two mathematical models can be used to construct the state diagrams which describes the physical states as a function of water activity and water content of foods. This state diagram can be used as a significant tool to help food scientists, food engineers and food-packaging researchers to develop processing protocols and selecting storage conditions. In terms of plasticizing effect of water, it seems that cellular and non-cellular systems have comparable values. Although the number of food samples used in this study was limited, this contribution suggests that the chemical composition of food systems could have more impact on their  $T_g$  and stability than the presence of cell structures. Further investigations with diverse food systems are required to confirm this preliminary finding.

### Abstract

*The aim of this work was determine the sorption isotherms in roasted beans of specialty coffee at temperatures of 25, 30 and 40 °C and water activities between 0.1 and 0.8 using the dynamic dew point method. The experimental sorption data were modeled using 12 different equations to represent the dependence of equilibrium moisture content with  $a_w$  and temperature. The net isosteric heat of sorption was determined from the experimental sorption data using the Clausius-Clapeyron equation. The Weibull model satisfactorily modeled the effect of the temperature on the hygroscopic equilibrium in roasted coffee beans ( $R^2_{adj}=0.902$  and  $RMSE = 0.005 \text{ kg}\cdot\text{kg}^{-1}\cdot\text{d}\cdot\text{b}$ ). The net isosteric heat of sorption increase with increased moisture content.*

**Keywords:** water activity; sorption properties; equilibrium moisture content; hygroscopicity.

---

## 1. Introduction

Coffee beans are a highly hygroscopic matrix and could readily take up moisture when exposed to the environment during storage [8], this condition may affect the coffee bean freshness. For proper handling of roasted coffee beans, it is necessary to know, among other properties, the water sorption isotherms, which describe the relationship between the equilibrium moisture content and the water activity at constant temperature and pressure [2]. There are many sorption models proposed in literature to represent the water sorption in foods [16], some models are empirical or semi-empirical equations. Due to the complex in the food matrices, there are not a unique model to describe entirely of the agri-food products [3]; therefore, is necessary to validate from experimental data the best model for both the material and the air conditions.

The objective of this work was to determine and model the moisture isotherms of roasted coffee beans at temperatures of 25, 30 and 40 °C and water activities between 0.1 and 0.8 using the dynamic dew point method.

## 2. Materials and Methods

### 2.1 Coffee samples

Nine samples of wet processed coffee (*Coffea arabica* L.) from Huila region (Colombia) were sensory analyzed to SCAA (Specialty Coffee Association of America) methodology in the South Colombian Coffee Research Center (CESURCAFÉ) by four experts panelists [12]. The coffee beans were roasted in a laboratory equipment (TC-150R, Quantik, Colombia).

### 2.2. Experimental determination of the sorption isotherms

Sorption isotherms were determined at water activities between 0.1 and 0.8 and temperatures of 25, 30 and 40 °C by the dynamic dew point method (DDI). The measurements were carried out in a Vapor Sorption Analyzer (VSA Aqualab Decagon Device, Inc. Pullman, WA) at water-activity intervals of 0.01 and 0.05 for adsorption and desorption, respectively, and a flow rate of 100 ml·min<sup>-1</sup>.

### 2.3 Modeling sorption isotherms

The sorption isotherms of roasted coffee beans were represented mathematically using the 12 models shown in Table 1, where  $X_e$  is the equilibrium moisture content (kg·kg<sup>-1</sup>, dry basis),  $a_w$  is the water activity,  $K$ ,  $C$ ,  $C_0$  and  $K_0$  are GAB model parameters,  $H_m$  is the monolayer sorption heat (kJ·mol<sup>-1</sup>),  $H_n$  is the multilayer sorption heat (kJ·mol<sup>-1</sup>),  $\lambda$  is the evaporation enthalpy of water (kJ·mol<sup>-1</sup>),  $T$  is the absolute temperature (K),  $R$  is the universal gas constant (kJ·mol<sup>-1</sup>·K<sup>-1</sup>) and  $b_i$  are empirical model parameters.

**Table 1. Mathematical model to define roasted coffee beans isotherms**

Model	Reference	Mathematical expression	Equation
		$X_e = \frac{X_m CK a_w}{[(1 - K a_w)(1 - K a_w + CK a_w)]}$	(1)
GAB	[6, 10]	$C = C_o \exp\left(\frac{H_m - H_n}{RT}\right)$	(2)
		$K = K_0 \exp\left(\frac{\lambda - H_n}{RT}\right)$	(3)
Oswin	[1]	$X_e = b_1 \left(\frac{a_w}{1 - a_w}\right)^{b_2}$	(4)
Smith	[13]	$X_e = b_1 + b_2 \ln(1 - a_w)$	(5)
Chung-Pfost	[11]	$X_e = b_1 + b_2 \ln(-\ln a_w)$	(6)
Kunh	[15]	$X_e = \left(\frac{b_1}{\ln a_w}\right) + b_2$	(7)
Caurie	[9]	$X_e = \exp(b_1 + b_2 a_w)$	(8)
Iglesias and Chirife	[5]	$X_e = b_1 + b_2 \left(\frac{a_w}{1 - a_w}\right)$	(9)
White and Eiring	[15]	$X_e = \frac{1}{(b_1 + b_2 a_w)}$	(10)
Peleg	[14]	$X_e = b_0 a_w^{b_1} + b_2 a_w^{b_3}$	(11)
DLP	[14]	$X_e = b_0 + b_1 x + b_2 x^2 + b_3 x^3$ $x = \ln(-\ln a_w)$	(12)
Polynomial	[11]	$X_e = b_0 + b_1 a_w + b_2 a_w^2 + b_3 a_w^3$	(13)
Weibull	[17]	$X_e = b_1 + \exp^{b_2(1-a_w)^{b_3}}$	(14)

\*It has been considered that the parameters of the empirical equations have a linear dependence with the temperature ( $b_i T_{abs} + b_{i,1}$ ).

### 2.3.1 Parameter estimation and statistical analysis

The tool Curve Fitting of Matlab® R2017b (The MathWorks Inc., Natick, MA, USA) was used to identify the model parameters and calculate the 95% confidence intervals of parameters. The adjusted determination coefficient ( $R^2_{adj}$ ) and the root mean square error ( $RMSE$ ) were used as goodness-of-fit statistics.

### 2.4 Determination of the net isosteric heat of sorption

Sorption heats were calculated through the direct use of moisture sorption isotherms by applying the Clausius–Clapeyron equation (15). Estimations of net isosteric heat of sorption have been found in literature integrating Equation (15) between two temperatures (Eq.(16)). It is reported in literature that Riedel equation (17) adequately describes the influence of temperature on water activity. By combining Equations (16) and (17), another expression to estimate net isosteric heat of sorption may be considered (Eq. (18)) [7].

$$q_{sn} = -R \left[ \frac{\partial(\ln a_w)}{\partial\left(\frac{1}{T}\right)} \right]_x \quad (15)$$

$$q_{sn} = R \left[ \frac{T_1 T_2}{T_2 - T_1} \ln \frac{a_{w2}}{a_{w1}} \right] \quad (16)$$

$$\ln\left(\frac{a_{w2}}{a_{w1}}\right) = A_r \exp(-B_t W) \left(\frac{1}{T_1} - \frac{1}{T_2}\right) \quad (17)$$

$$q_{sn} = C_r \exp(-B_r W) \quad (18)$$

When  $A_r$ ,  $B_r$  are constants of the riedel equation and  $C_r$  being  $A_r \cdot R$ .

## 3. Results and Discussion

The Table 2 presents the four mathematical models with the best fit of the experimental data, considering the effect of temperature; the Weibull model could be considered the which best represent experimental data, since reached high value of the  $R^2_{ajs}$  coefficient 0.902 and  $RMSE$  lower than 0.01 kg·kg<sup>-1</sup> d.b; the others eight mathematical models (Smith, Chung pfof, White and Eiring, Caurie, Iglesias and Chirife, Kunh, Oswin y Peleg) they resulted with values of the  $R^2_{ajs}$  coefficient below 0.8 and  $RMSE$  higher than 0.1 kg·kg<sup>-1</sup> d.b.

**Table 2. Estimated model parameters and statist**

Models	Parameters	Confidence Intervals 95%	$R^2_{adj}$	RMSE
Polynomial	$b_3 = 0.677$	[0.596, 0.757]	0.881	0.006
	$b_{2.1} = 7.201 \times 10^{-3} \text{ K}^{-1}$	[ $4.972 \times 10^{-3}$ , $9.43 \times 10^{-3}$ ]

The figure 1 presents the experimental isotherms and the values obtained with the Weibull model at 25, 30 and 40 °C. The resulting isotherms are of the type III form, according with classification of Brunauer [4]. The type III Isotherms obtained for roasted coffee beans, could be due to Maillard reactions in the roasting coffee process.

Fig 2. Variation of net isosteric heat of sorption differential and integrated in roasted coffee beans

#### 4. Conclusions

The equilibrium moisture content increases when temperature increases at constant water activity. The Weibull model was considered the best equation for describing sorption isotherms of roasted coffee beans. The isotherms behaved in a way typical of food rich in soluble components. The net isosteric heat of sorption increases with increments of equilibrium moisture content, indicating a strong bond energy. The trends of the sorption isotherms were similar to those reported for roasted coffee beans of others cultivars.

### Abstract

*The hygroscopic equilibrium of Warionia saharae was studied, which allowed getting an idea of the equilibrium water content relative to a given humidity. The results of this study made it possible to have the sorption curves. The results of this study made it possible to obtain the sorption curves necessary for know the storage conditions of the plant and the study of its drying kinetics. The static gravimetric method was used to determine sorption isotherms of Warionia saharae leaves at 30 and 40 °C and in the range of water activity varying from 0.063 to 0.898. The Gab, Peleg models was found to be the most suitable for describing the sorption curves. The isosteric heat calculated by applying the Clausius–Clapeyron equation. The desorption isosteric heat was higher than the isosteric heat of adsorption and both decreased continuously with increasing of the equilibrium moisture content. The experimental results obtained allowed us to determine the temporal evolution of the drying kinetics as a function of the moisture content. The curve of the evolution of the water content as a function of time shows the absence of the phases product temperature and constant drying rate*

## 1. Introduction

The *Warionia saharae*, which belongs to the important composite's family, is an endemic species of North Africa, characterized by a discerning odour [1]. The leaves of *Warionia saharae* are used in traditional medicine to treat inflammatory diseases, gastrointestinal disorders and against epileptic crisis [2,3]. Crude extracts of this plant showed anti-inflammatory and cytotoxic activities against a cancer cell line (KB cells) [4,5]. The methanolic soluble fraction of the dichloromethane extract of *Warionia saharae* afforded cytotoxic and anti-inflammatory sesquiterpene lactones [3-6], while hexanoic extract showed the presence of several hydrocar bon acid derivatives [7]. Like many other herbs, is highly seasonal in nature. In order to preserve this seasonal and highly perishable plant and make them available to consumers all year round at low prices, it is subjected to post harvest technological treatments [8]. Several process technologies have been employed on an industrial scale to preserve food products; the major ones are canning, freezing, and dehydration. Among these, drying is especially suited for developing countries with poorly established low-temperature and thermal processing facilities. It offers a highly effective and practical means of preservation to reduce postharvest losses and offset the shortages in supply. Drying is a simple process of moisture removal from a product in order to reach the desired moisture content and is an energy intensive operation. The prime objective of drying apart from extended storage life can also be quality enhancement, ease of handling, further processing and sanitation and is probably the oldest method of food preservation practiced by humankind [9]. In the literature several methods are mentioned to analyze the drying of hygroscopic products (theoretical, empirical and semiempirical). The empirical models of drying show a direct relationship between average moisture content and drying time.

## 2. Materials and Methods

The leaves of *Warionia saharae*, used for the drying experiments were collected from the region of southwest Algeria (Jebel Anter, wilaya of Bechar). In the period of May 2012. The moisture content was measured and the equilibrium moisture contents of *Warionia* were determined at temperatures of 30 and 40 °C over a water activity range of 0.063–0.89 using the static gravimetric method. For prevent destroy plant chemical components like essential oils, the leaves of *Warionia saharae*, were drying in shade.

### 2.1. Equilibrium moisture content determination

The desorption equilibrium moisture contents of *Warionia saharae* leaves were determined at temperatures of 30 and 40 °C over using the static gravimetric method. This method

involves the use of saturated salt solutions to maintain constant relative humidity ( $a_w$ ) in enclosed still moist air at a certain temperature to obtain the complete sorption isotherms. The mass transfer between the product and the ambient atmosphere was assured by natural diffusion of the water vapor and the water activity of the product equals the relative humidity of the atmosphere at equilibrium conditions. Seven saturated salt solutions (KOH, KF, K<sub>2</sub>CO<sub>3</sub>, NaNO<sub>3</sub>, NaCl, KCl and BaCl<sub>2</sub>).

### 3. Modeling of the drying curves

Four models were used to describe the sorption isotherms (table.1). The goodness of fit for each model can be evaluated based on the relative percent error (P), which compares the absolute difference between the predicted moisture contents with the experimental moisture contents. Relative percent errors values lower than 10 % indicate a good fit [11].

**Table 1 .Mathematical models applied to drying curve**

<i>Model name</i>	<i>Formula</i>
<i>Peleg</i>	$X_{eq} = A(a_w)^C + B(a_w)^D$
<i>Gab</i>	$X_{eq} = \frac{ABC a_w}{(1 - Ca_w)(1 - Ca_w + CBa_w)}$
<i>Caurie</i>	$X_{eq} = \exp(a + b \cdot x)$
<i>Bet modifie</i>	$X_{eq} = \frac{(A + B \cdot T)Ca_w}{(1 - a_w)(1 - a_w + Ca_w)}$

*X<sub>eq</sub>, moisture content, % (kg/kg d.b.); a<sub>w</sub>, water activity (decimal); t, absolute temperature a,b,c and d constants specific to individual equations [12].*

## 4. Result and discussion

### 4.1. Sorption isotherms

In this study, models were used in predicting the sorption isotherms of *Warionia leaves*. Based on the statistical analysis, average relative error and standard error estimation were used to select the best model describing the shade drying curves of *Warionia saharae* leaves. Peleg and Gab models has a correlation coefficient value of 0.998, which is higher than Bet and Caurie. This means that Peleg and Gab models are the most suitable models for describing the relation between equilibrium moisture content and water activity. It was observed also that the moisture content decreases with time and drying rate increases with increasing temperature.

$$SEE = \sqrt{\frac{\sum_{i=1}^N (X_{e_{i,exp}} - X_{e_{i,pre}})^2}{N - n_p}} \quad (2)$$

#### 4.2. Net isosteric heat of sorption

The isosteric heat of sorption, were calculated from the equilibrium data at different temperatures using The Clausius –Clapyron equation .The curve shows that the heat of desorption decreased with increase in moisture content. The decrease in the isosteric heat with the increase in sorbed water content may be attributed to the fact that sorption initially occurs on the most active sites such as hydrophilic polar groups giving rise to the greatest interaction energy. With increase in the moisture content, as these sites become occupied, sorption occurs on the less active sites viz., peptide bonds or hydrophobic hydration sites resulting in lower heats of sorption [13,14].The heat of desorption is greater than that of

adsorption at low moisture contents for all the samples studied. This indicates that energy required in the desorption process is greater than that in the adsorption process [15]. The isosteric heats of desorption and adsorption of water in *Warionia saharae* leaves can be expressed mathematically as a power function of moisture content(3and 4):

$$Q_{st(adsorption)} = 137,48 - 17,839X_{eq} + 78,138X_{eq}^2 - 0,111X_{eq}^3 \quad (3)$$

$$Q_{st(desorption)} = 236,98 - 29,312X_{eq} + 1,226X_{eq}^2 - 0,016X_{eq}^3 \quad (4)$$

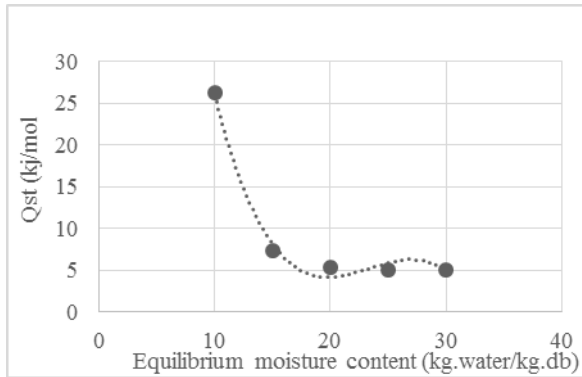

Fig.1 Adsorption isosteric heat

Fig .2 Desorption isosteric heat

### 4.3. Drying rate:

As seen in figure 5 the drying rate decrease rapidly in the first period of drying and slowly as drying progresses .The constant rate period is absent in the drying curves of *Warionia saharae*. Similar results were obtained for all agricultures and medicinal products [16]. These results can be explained by diffusion phenomena in the solid. This is a complex mechanism involving water in both liquid and vapour states, which is very often characterised by a so-called "effective diffusivity" [17].

The dimensionless drying rate was determined by the relation (3) :

$$f = \frac{-\left(\frac{dX}{dt}\right)_t}{\left(\frac{dX}{dt}\right)_0} \quad (3)$$

Where,  $\left(\frac{dX}{dt}\right)_0$ , the initial drying rate .

The figure 3 and 4 illustrate the variation of moisture ratio as a function of drying time. It is clear from these figures that the moisture content has an exponential decrease; it decreases continuously with the drying time. To determine the ratios of moisture during drying we used the following expression (4):

$$X^* = \frac{X(t) - X_{eq}}{X_i - X_{eq}} \quad (4)$$

Where

$X^*$ : moisture ratio;  $X(t)$  : water content of product (% d.b.);  $X_i$ : initial water content of the product (% d.b.);  $X_{eq}$  : equilibrium water content of the product (%d.b.).

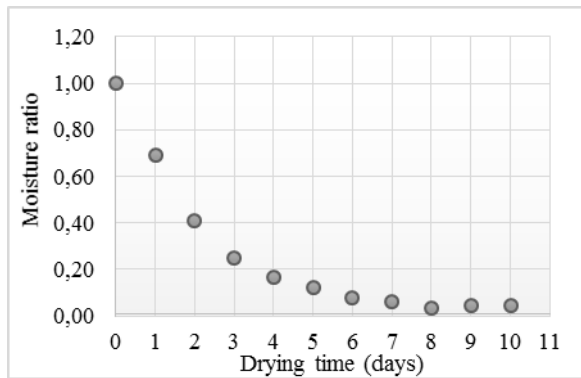

Fig.3 moisture ratio as a function of drying time

Fig. 4 moisture ratio as a function of moisture content

*Fig.5 Drying rate as a function of drying time*

*Fig.6 Drying rate as a function of moisture content*

## 5. Conclusions

The sorption isotherms of *Warionia saharae* leaves were determined with the static gravimetric method. Peleg and Gab models were found the most suitable to describe the relationship between equilibrium moisture content and water activity. The isosteric heat of sorption were using the Clausius–Clapeyron equation. The heats of sorption increased with decreasing moisture content. The drying rate was characterized by the absence of the period (0) and (1) which corresponds to the period of drying at increasing rate and at a constant rate respectively and the presence of the single period of the decreasing rate. That have been observed in the drying of different fruits and vegetables. The modelling of kinetics curves will be established in our next paper.

### Abstract

*In this paper, we introduce a novel energy-efficient dryer that uses hot air as a combined heating method of heat conduction and convection heat transfer. The dryer consisting of rotary cylinders and arched jackets is structurally different from conventional dryers. We designed and built a hybrid 4-cylinder dryer for sheet-form materials. The energy consumption to evaporate unit water is about 930 kcal/kg moisture from the experimental results of a hybrid 4-cylinder dryer. The hybrid 4-cylinders dryer has a compact structure with about 1/3 of the size of a conventional dryer for the drying of sheet-form materials.*

**Keywords:** *Dryer; Hot Air; Sheet-form; Energy Efficiency; Hybrid*

---

## **1. Introduction**

Research and development (R&D) in industrial drying systems has been focused primarily on technological advances that improve drying efficiency and lower energy costs. According to the survey, the annual energy consumption of domestic industrial dryers is about 7% of the total industrial energy consumption. Since the energy consumed in the drying process for textile/paper is about 30% to 50% of the total energy consumption, it is urgent to increase the energy efficiency of dryers for textile/paper. Domestic fabrication technology for dryers is at the level of advanced countries, but the domestic core technologies such as system design, control technology, and post-processing are about 70% compared to advanced countries and still depend on advanced technology. It is expected that the development of high energy efficiency and commercialization technology in the domestic drying field have a significant effect from the viewpoint of energy saving.

This study proposes a new type of a dryer with high energy efficiency using hot air. The dryer consisting of rotary cylinders and arched jackets is structurally different from conventional textile/paper dryers. The rotary cylinder in contact with the sheet-form materials is thermally optimized through numerical methods. The arched jacket allows the hot air coming from the rotary cylinder to come into contact with the sheet-form materials. The energy consumption to evaporate unit moisture for the proposed dryer is about 930 kcal/kg water from the experimental results of a hybrid 4-cylinder dryer.

## **2. Drying wet materials and numerical analysis**

### **2.1. Drying wet materials**

The drying characteristics of drying wet materials may be determined by a drying curve. Figure 1 shows the drying curves of various textile samples. As shown in Fig. 1, the change in the moisture content of the textile is apparent, but the first and second falling drying-rate period are not clearly distinguished. The feature of the drying curves of the textiles in which the falling drying-rate period is not clearly shown is important in the design of a dryer.

### **2.2. Thermal design of a rotary cylinder**

A rotary cylinder in this study uses hot air differently from a conventional cylinder using steam and has fins on the cylinder inner surface for the purpose of improving the heat transfer. Heat flowing into the center of the cylinder is conducted to the cylinder outer surface, and the heat is transferred to the drying wet material in contact with the cylinder outer surface. In this study, numerical analysis is used to calculate the heat transfer

according to the number and shape of fins. For the shape design of fins, case studies are carried out under the same conditions as Table 1. The optimal shape of the cylinder selected in this study is shown in Fig. 3. The cross-sectional area of the cylinder decreases along the direction of hot air flow and the fin is wavy shape.

Fig. 1 Drying curves of textile samples.

Fig. 2 Rotary cylinder and simulation domain.

Table 1. Constraints for simulation of a rotary cylinder

Inlet temperature of hot air	180 °C
Outer radius of cylinder	0.25 m
Inner radius of cylinder	0.125 m
Length of cylinder	2.0 m
Hot air velocity	4.5 m/s
Fin material	Aluminium 6063-T5

Fig. 3 Temperature variation according to the flow direction of hot air in single fin.

### 2.3. Arched jacket

The hot air exhausted through the cylinder is brought into contact with the drying wet material in the arched jacket. When designing an arched jacket, it is important to have uniform velocity distribution in the direction perpendicular to the flow in terms of drying quality. The numerical analysis approach is used to design the arched jacket. Figure 4 (a) shows that the flow tends to lean toward one side of the jacket in the original design. In order to make the flow of hot air uniform, numerical analysis is conducted to introduce guide vanes and flow analysis according to the change of guide vane shape. The numerical results are shown in Fig. 4 (b).

Fig. 4 Velocity distribution in the arched jacket.

## 3. Results and discussion

### 3.1. Dryer with 4-cylinders

Based on the results from numerical analysis, the dryer with 4-cylinders is fabricated as shown in Fig 5. The dryer has four rotary cylinders, a burner, blowers and other elements. In addition, the dryer is configured to facilitate the management of the apparatus. The hot

air flow was controlled for the purpose of minimizing the moisture content deviation of drying products in the horizontal direction after drying, and the active control tensioner was installed to reduce the tension acting on the drying wet materials due to the cylinders.

*Fig. 5 Dryer with 4-cylinders*

### **3.2. Temperature deviation of the drying system**

In this study, the deviation of hot air temperature means the difference between the values of the measured temperature over a certain period of time. The temperature deviation is to confirm the temperature uniformity of the hot air supplied to the drying system and the basic system stability such as the energy efficiency evaluation of the dryer and the temperature stability of the system. The test is performed by measuring the temperature at the inlet of the cylinder for 1 hour, and checking whether the temperature deviation between the maximum temperature and the minimum temperature is within  $\pm 5^\circ\text{C}$ . In the test results, since the temperature deviation is  $\pm 2.9^\circ\text{C}$ , it can be judged that the temperature stability of the system is excellent.

### **3.3. Drying efficiency**

Drying efficiency is used to evaluate the energy savings of a dryer. The energy saving of the dryer is compared with the energy consumption of a conventional dryer and the developed dryer. a conventional dryer is a through-flow drying method in which hot air hits onto the surface of textiles. Table 2 shows experimental conditions and drying efficiency. The initial moisture content of the textiles is about 55 w.t% and the drying capacity is 200 kg/hr. Energy consumption is measured using an integrating wattmeter and a gas meter. The drying efficiency is defined as Eq. (1).

**Table 2. Comparison of drying efficiency**

	Existing dryer	Novel dryer
Initial M.C	55 w.t%(w.b)	
Final M.C	3 w.t%(w.b)	
Hot air temp.	180 °C	
Drying capacity	200 kg/hr	
Drying efficiency	30.4 %	58.1 %

$$\varepsilon = \frac{\text{Latent heat of evaporated moisture}}{\text{Total energy of heat and electricity}} \times 100 [\%] \quad (1)$$

As shown in Table 2, the drying efficiency of the developed dryer compared to the conventional dryer shows a great difference. It can be seen that the developed dryer in this study has a drying efficiency twice as high as that of the conventional dryer. The energy consumption to evaporate unit moisture is about 930 kcal/kg water from the experimental results of the hybrid dryer. The dryer has a compact structure with about 1/3 of the size of the conventional hot air dryer.

#### 4. Conclusions

The purpose of this study is to develop a dryer for sheet-form materials with high energy efficiency. The novel dryer is a cylinder type using hot air. While a conventional dryer using only direct heating or indirect heating, the proposed dryer adopts a multiple heating system. The developed dryer dramatically increased the drying efficiency and is a unique device that differentiates from the conventional dryer in the usage of the heat source. In order to utilize a combined heating method of direct heating and indirect heating, precise analysis and complicated design should be performed. We have successfully developed the 200kg/hr dryer with 4-cylinders through R&D. The energy consumption to evaporate unit water is about 930 kcal/kg water from the experimental results of a hybrid dryer.

### Abstract

*This investigation examines and compares the water sorption isotherms and the thermodynamic properties of two pharmaceutical preparations (Hypril and Azix) intended to be manufactured with the same process plant and equipment. The moisture equilibrium isotherms were determined at 50, 60 and 70 °C using a gravimetric technique. Five isotherm models were explored for their fitting to the experimental data. Azix showed sigmoid type II isotherms while Hypril showed type III isotherms according to the BET classification. All investigated models fitted well the water sorption isotherms of Hypril. By contrast, only GAB and Adam and Shove equations gave appropriate fit to the experimental data of Azix. For both formulations, the isosteric heat and the differential entropy decreased sharply with the increase of equilibrium moisture content to minimum values and thereafter remain constant. In the case of Azix, the integral enthalpy decreased with equilibrium moisture content while the integral entropy increased until reaching a constant value. Contrariwise, Hypril showed decreasing of the integral enthalpy and entropy with the equilibrium moisture content.*

## **1. Introduction**

Tablets are the most popular advantageous drug dosage form used today. They ensure best protection to the drug against temperature, humidity, oxygen, light and stress during transportation. They present also the best-combined properties of chemical, mechanical and microbiological stability of all the oral form. The manufacture of tablets involved several steps: mixing of therapeutic agents with excipients, granulation of the mixed powders, mixing the obtained granules with other excipients such as lubricants and finally compression into tablets. Wet granulation is a widely applied process in the pharmaceutical industry used to improve powder flow characteristics thereby enhancing the compressibility of the drug. In a typical wet granulation, the water is initially added to the mixed powders to form large agglomerates which will be dehydrated in order to remove water. The drying operation is a crucial step, usually accomplished in fluid-bed dryers, whereby a warmed and low humidity air passed through the agglomerates via a gill plate. Water interacts with pharmaceutical solids not only at this level but also at all stages of manufacture. Therefore, water–powder interaction is a major factor in the formulation, processing, and performance of solid dosage forms. Determination of sorption isotherms of pharmaceutical preparations and deduced thermodynamic properties allows the control of corresponding drying process and modeling of their drying kinetics.

## **1. Material and Methods**

Azix (Azithromycine- 500 mg, Anhydrous Dibasic Calcium Phosphate, Pregelatinised starch, Sodium starch glycolate, Magnesium stearate) and Hypril (Enalapril maleate-20 mg, Hydrochlorothiazid -12, 5 mg , Sodium bicarbonate, Lactose Monohydrate, Maize starch, Microcrystalline cellulose, Sodium starch glycolate, Magnesium stearate) preparations are provided from Pharmaghreb® company (Tunisia).

### **2.1. Determination of sorption isotherms**

The experimental sorption isotherms of Azix and Hypril preparations were established using the static gravimetric method. The experimental setup consisted of 11 air-sealed glass jars provided with perforated supports in which triplicate samples weighing 0.1 g ( $\pm 0.0001$ g) were exposed to the humid atmospheres. Sulfuric acid solutions of known concentration were used to reach 0.06 to 0.95 water activity values. The prepared glass jars were then placed in temperature controlled cabinets maintained at 50, 60 and 70 °C  $\pm 1$  C. Each sample was weighed at the beginning of experiment and at intervals of 24 h until constant mass was reached. The equilibrium moisture content was determined according to the AOAC official method [1].

## 2.2. Sorption models and statistical analyses

The equilibrium moisture data were fitted with five mathematical models shown in Table 1. The nonlinear regression analysis (MATLAB®) was used to estimate the constants of the models from the experimental results. To evaluate the goodness of fit of each equation, the coefficient of determination  $R^2$ , the adjusted  $R^2$ , the roots mean squared error (RMSE) and the sum of squares due to error (SSE) were determined by using the following equations [2] (Eqs 1 to 6):

The coefficient of determination  $R^2$  measures the model adequacy, ( $0 \leq R^2 \leq 1$ ):

$$R^2 = \frac{\text{explained variation of } y}{\text{total variation of } y} = \frac{SSR}{SST} \quad (1)$$

SSR is the regression sum of squares which reflects the amount of variation in y explained by the model:

$$SSR = \sum_{i=1}^n (\hat{y}_i - \bar{y})^2 \quad (2)$$

SST is the total sum of squares:

$$SST = \sum_{i=1}^n (y_i - \bar{y})^2 \quad (3)$$

Where  $y_i$  is the equilibrium moisture content at observation  $i$ ,  $\bar{y}$  is the mean value of  $y_i$  of the  $n$  observations and  $\hat{y}_i$  is the value of  $y$  estimated from the regression model for observation  $i$ .

The corrected or adjusted  $\bar{R}^2$ :

$$\bar{R}^2 = 1 - (1 - R^2) \frac{(n-1)}{(n-k)} \quad (4)$$

Where  $n$  is the total number of observations and  $k$  is the number of model parameters.

$$RMSE = \left( \frac{SSE}{n-k} \right)^{1/2} \quad (5)$$

Where SSE is the error sum of squares or sum of the residuals which reflects the variation about the regression line:

$$SSE = \sum_{i=1}^n (y_i - \hat{y}_i)^2 \quad (6)$$

## 2.3. Calculation of thermodynamic properties

The net isosteric heat (net enthalpy) of sorption ( $q_{st}$ ) was obtained from the moisture sorption data using the Clausius-Clapeyron equation [3]:

$$\frac{d(\ln a_w)}{d\left(\frac{1}{T}\right)} = -\left(\frac{q_{st}}{R}\right) \quad (7)$$

In which  $q_{st} = Q_s - \Delta H_{vap}$  where  $a_w$  is the water activity,  $q_{st}$  is the net isosteric heat of sorption ( $\text{kJ mol}^{-1}$ ),  $Q_s$  is the isosteric heat of sorption ( $\text{kJ mol}^{-1}$ ),  $\Delta H_{vap}$  is the heat of

vaporisation ( $\text{kJ mol}^{-1}$  water),  $R$  is the universal gas constant ( $8.314 \text{ J mol}^{-1} \text{ K}^{-1}$ ) and  $T$  is the absolute temperature (K). The value of  $q_{st}$  was calculated from the slope of the plot between values of  $\ln(a_w)$  and  $1/T$  at constant moisture content. The differential entropy ( $S_d$ ) of sorption can be calculated from Gibbs–Helmholtz equation as follows:

$$S_d = \frac{q_{st} - G}{T} \quad (8)$$

Where  $G$  is the Free Gibbs energy calculated as:

$$G = RT \ln(a_w) \quad (9)$$

Substituting Eq. (9) into Eq. (8), and after rearranging, the final form is :

$$-\ln(a_w)|_W = \frac{-q_{st}}{RT} + \frac{S_d}{R} \quad (10)$$

By plotting  $\ln(a_w)$  versus  $1/T$ , for a constant moisture content ( $W$ ), the  $S_d$  can be determined from the intercept ( $S_d/R$ ). The  $S_d$  values at different moisture contents are found from the determination of the relation between  $S_d$  and moisture content. The net integral enthalpy,  $q_{eq}$  is an integral molar quantity and is calculated in a similar manner to the isosteric heat of sorption but at constant spreading pressure instead of constant moisture content .

$$q_{eq} = -R \left[ \frac{d(\ln a_w)}{d(1/T)} \right]_{\phi} \quad (11)$$

$\ln(a_w)$  was plotted against  $1/T$  at constant spreading pressure. The net integral enthalpy was determined from the slope of the straight line and plotted against moisture content. The net integral entropy of sorbed water,  $\Delta S_{eq}$ , is given as:

$$\Delta S_{eq} = -q_{eq}/T - R \ln(a_w)^* \quad (12)$$

$(a_w)^*$  is the geometric mean water activity obtained at different temperatures and at constant spreading pressures.

### 3. Results and Discussion

#### 3.1. Water sorption isotherms

The moisture sorption isotherms of Azix and Hypril at different temperatures are displayed in Fig. 1.

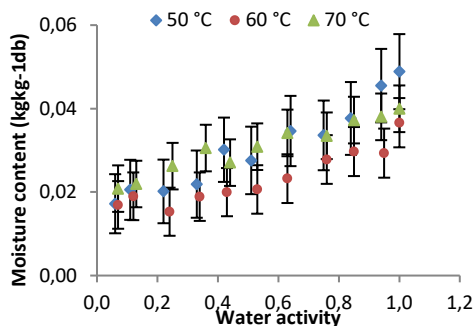

Fig. 1a Experimental moisture sorption isotherms of Azix at 50 °C, 60 °C, 70 °C

Fig. 1b Experimental moisture sorption isotherms of Hypril at 50 °C, 60 °C, 70 °C

The moisture sorption isotherms of Azix showed moisture levels from 1.5% to approximately 5% over water activity range from 0.06 to 0.95 at the examined temperatures (Fig 1.a). These findings are in line with those of [4] who reported the same trend for spray-dried pure azithromycin, the active ingredient of Azix preparation. Indeed, the moisture behavior of pure azithromycin determined using a dynamic vapour sorption system showed 6 % of water absorbed at relative humidity of 90%. Hypril exhibited the same moisture levels as Azix over water activity range from 0.06 to 0.44. Thereafter, the level of adsorbed water increased sharply from 7% to approximately 50% (Fig1.b) . This behavior could be ascribed to the degradation of Enalapril maleate in the presence of lactose and magnesium stearate at very high humidities and temperatures. Enalapril maleate powder is stable under moderate heat and humidity (40°C - 75% RH) [5]. However, when it is prepared in tablet formulations by wet granulation with lactose, starch and magnesium stearate enalapril maleate would degrade to form a diketopiperazine by dehydration and the diacid by hydrolysis. These degradates increase with temperature.

Inspection of Fig. 1a and Fig. 1b indicates that there is no significant effect of temperature on the sorption isotherms of Azix and Hypril formulations. The same behavior was observed on the moisture isotherms of crystalline, amorphous and predominantly crystalline lactose powders established at 12, 20, 30 and 40 °C [6].

### 3.2. Mathematical modelling

The results of nonlinear fitting of sorption models are shown in Table 1. All the examined models provided a good description of the isotherms of Hypril, the optimal one is the Oswin model which presented the most suitable fitting. As to Azix formulation, only GAB and Adam and Shove models gave appropriate fit between the experimental and the predicted data.

### 3.3. Isotheric heat of sorption and sorption entropy

The results in Fig. 2 illustrate a progressive decrease in the net isotheric heat of sorption (net enthalpy) with increasing moisture content for both formulations. The values of net isotheric heat of sorption are high for equilibrium moisture content < 0.10 kg/kg and then decreased rapidly until equilibrium moisture contents reach respective values of 0.15 and 2 kg/kg d.b for Azix and Hypril, and then they decreased smoothly with increasing moisture content. Azix showed higher values of net isotheric heat than Hypril. This suggests that the energy to be supplied to dehydrate Azix would be higher than the energy needed to dehydrate Hypril. The differential entropy as a function of moisture content, illustrated by Fig. 3, shows the same tendency as the net isotheric heat. The sorption entropy of Azix exhibited higher magnitude than that of Hypril.

Fig. 2a Net isosteric heat of Azix and Hypril formulations

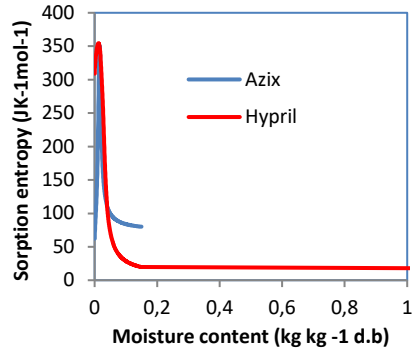

Fig. 2b Sorption entropy of Azix and Hypril formulations

### 3.4. Integral enthalpy and entropy

The variations in net integral enthalpy with the moisture content for Azix and Hypril are shown in Fig. 3. On the whole range of equilibrium moisture content, the integral enthalpy of both products decreases as a function of equilibrium moisture content until reaching minimum values then they remains constant.

Fig. 3a Net integral enthalpy of Azix formulation

Fig. 3b Net integral enthalpy of Hypril Formulation

Variations of the net integral entropy (Fig.4) of Azix and Hypril showed different trends. Values decreased with equilibrium moisture content for Hypril and increased for Azix. The better conditions to assure stability to the powders during storage [7] are those corresponding to lower entropy values.

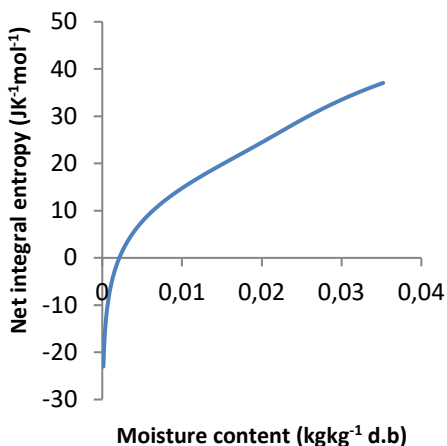

Fig. 4a Net integral entropy of Azix formulation

Fig. 4b Net integral entropy of Hypril formulation

#### 4. Conclusions

This study affords an understanding of the sorption isotherms and the thermodynamic properties of two powders with different compositions. The obtained results suggest that the two products could be dehydrated at lower temperature (50°C) since the isotherms of sorption are independent of temperature. Azix preparation seems to be less hygroscopic and more stable than Hypril preparation which requires less energy to be dehydrated.

### **Abstract**

*The two-phase theory has been frequently used to model fluidised bed drying. At high air velocities, a transition from the bubbling regime to the turbulent regime may occur. In this work, we compare a bubbling model and a turbulent model for the simulation of a two pharmaceutical powders drying in a pilot plant and an industrial plant fluidised bed. The bubbling model was based on a discrete variable bubble size. Heat and mass transfer coefficients were based on the Kunii and Levenspiel correlation [1]. Flow regime was supposed to be completely mixed for the emulsion phase. For the turbulent model, the bubble size is not anymore discrete but continuous and bubble phase is less distinguishable than in the bubbling regime. Heat and mass transfer were those proposed by Foka[2]. In addition, the freeboard section was considered since high entrainment is specific of this regime. Gas backmixing was taken into account by considering a plug flow with axial dispersion for the interstitial gas flow. The bubble phase being dilute, was modeled by a plug flow. A plug flow was also considered for the freeboard gas. The solid phase was supposed to be completely mixed. The bubbling regime simulation gave good agreement with experiment in the case of the pilot plant experiment, while the turbulent model better simulated the industrial scale experiment.*

---

## **1. Introduction**

Drying of pharmaceutical products is frequently carried in batch fluidized bed dryers. Fluidisation offers the advantage of high heat and mass transfer rates due to the elevated specific surface area created. Generally, the drying end is determined by analyzing the moisture content at different times. Several works [3-4] proved that more rigorous control could be obtained by mathematical modeling. Models proposed considered either bubbling regime or turbulent regime fluidisation. The transition between these two regimes, at high air velocities, should be better experimentally determined. Correlations proposed to determine the transition velocity depend generally on experimental system used. In this work, a bubbling regime model based on the two phase theory is compared to a turbulent regime model for the simulation of the drying kinetics of an A type particles and a B type particles pharmaceutical powders. Sorption isotherms determined experimentally were used to describe the falling drying rate period.

## **2. Experimental study**

### **2.1. Material properties**

The drying experiments were carried with two pharmaceutical products supplied by Pharmaghreb industry (Tunisia), an A type particles (Hypril) and a B type particles (Azix).

### **2.2. Equilibrium sorption study**

Sorption isotherms of the two products were determined by contacting the solid samples with air at a variety of relative humidity at a fixed temperature. Equilibrium water sorption was measured, at different temperatures, by static gravimetric method with sulfuric acid solutions at different concentrations.

### **2.3. Drying kinetic study**

Fluidized bed-drying experiments for group A type particles were carried in a Diosna MinilabXP (Germany). conical laboratory scale bed. Drying kinetics for group B type particles were obtained from a Glatt WSD-CD-30(USA) conical industrial scale fluidized bed . Experimental conditions are listed in table 1. Air heated at the desired temperature was supplied at the bottom of the conical chamber. The bed temperature was on line measured. The solid moisture content was determined by a moisture analyser (Mettler Toledo, Switzerland).

At the beginning of the fluidized bed experiments, the A type powder was initially very cohesive showing a Geldart C powder characteristics. The entire bed mass rose as plug when hot air was blown into the bed. After a short time of drying, the moisture content decreased, the Geldart C type cohesive powder shifts to a Geldart A powder. The plug was broken manually and a fluidization state was attained. The same trend was obtained for B type particles.

**Table 1. Experimental conditions and physical material properties**

<b>Geldart group</b>	<b>A</b>	<b>B</b>
Mean diameter( $\mu\text{m}$ )	48.8	384.72
Density( $\text{kg}/\text{m}^3$ )	649.35	702
Superficial air velocity (m/s)	0.97	2.26
Inlet air temperature ( $^{\circ}\text{C}$ )	47	50
Initial air temperature ( $^{\circ}\text{C}$ )	24	18.4
Relative humidity(%)	60	60
Initial solid moisture ( dry basis,% )	29.55	19.74
Critical moisture (dry basis,% )	13,00	4.00
Solid mass (wet basis, kg)	1	36.9
Column diameter(m)	0.16	0.5
Column height (m)	0.5	2.0

### 3. Mathematical modeling

#### 3.1. Bubbling regime model

The behaviour of the fluidized bed dryer is based on the two-phase theory: a bubble phase and an emulsion phase [1, 3]. The emulsion phase is at minimum fluidisation conditions and consists of interstitial gas and solid phase. Due to the buoyancy force, all the gas in excess of minimum fluidisation by passes the particles and rises through the bed as bubbles containing very small amount of solids. The governing equations are the equations of mass and heat conservation for bubble phase, interstitial gas and solid emulsion phase. These equations are detailed in [3,4]. The bubble diameter is a key parameter in the modeling of a bubbling fluidised bed and have a great importance on its performance. Several correlations were proposed to calculate the bubble diameter. For B type particles, the Darton's [5] correlation is largely used, it takes account of bubbles coalescing as they rise in the bed.

For A type particles, the correlation proposed by Horio and Nonaka [6] is selected. The authors proved that, for fine particles, a stable equilibrium bubble size could be obtained due to their successive coalescence and splitting.

### 3.2. Turbulent regime model

The turbulent regime is characterised by a breakup of coalesced bubbles to smaller ones. The large bubble renewal frequency caused by coalescing and splitting leads to a better interchange between bubbles and interstitial gas. The bubble size decrease reduces the short cut leading so to less gas back mixing and an increase in the gas solid contact. At the same time, the solids back mixing is also violent in turbulent fluidization. Experimental evidence [7] proved that gas flow is intermediate between an ideal plug flow and ideal agitated flow. As the bubbles erupt at the bed surface, they burst and particles splash into freeboard above the bed. At high velocities, high entrainment is produced. The particles are carried over in the freeboard. Two regions coexist in the bed:

- A bottom dense bed region with a high solid concentration and overall voidage  $\epsilon$
- An upper dilute freeboard region with an axial variable voidage  $\epsilon_z$

#### 3.2.1. Dense bed balance equations

The equations for the bubbling regime can be extended to the turbulent fluidization with no distinct bubble phase, but rather low and high-density phases with a different bubble phase voidage.

Dense phase interstitial gas mass balance

The dense phase is no longer at the minimum fluidisation conditions and voidage  $\epsilon_d$  is greater than  $\epsilon_{mf}$  because of solid entrainment. Axial dispersion is considered and mass and heat transfer coefficients between the low and high density phases are different than those used for discrete bubbles.

$$\rho_G u_d \frac{\partial x_e}{\partial z} + D_{ax} \rho_G \epsilon_d (1 - \delta_b) \frac{\partial^2 x_e}{\partial z^2} - K_{be} \rho_G \delta_b (x_e - x_b) + (1 - \epsilon_d)(1 - \delta_b) \frac{6}{d_p} \sigma (x_p^* - x_e) = \epsilon_d (1 - \delta_b) \rho_G \frac{\partial x_e}{\partial t} \quad (1)$$

Where  $x_e$  is the moisture content of the dense phase interstitial gas on dry basis (kg/kg) and  $x_p^*$  is the moisture content of drying gas on particle surface.  $\sigma$  is evaporation coefficient ( $\text{kg m}^{-2} \text{s}^{-1}$ ).  $\epsilon_d$  is the dense phase voidage and  $\delta_b$  is the lean phase voidage.  $D_{ax}$  is the axial dispersion coefficient ( $\text{m}^2/\text{s}$ ).

At the bed entrance and exit the Danckwerts Boundary conditions were used for the axial dispersed low.

Dense phase interstitial gas energy balance

$$\begin{aligned}
 -\rho_G u_d (c_G + x_o c_v) \frac{\partial T_e}{\partial Z} + k_g \varepsilon_d (1 - \delta_b) \frac{\partial^2 T_e}{\partial Z^2} - H_{be} \rho_G \delta_b (T_e - T_b) \\
 - (1 - \varepsilon_d) (1 - \delta_b) \frac{6}{d_p} (T_e - T_p) [c_v \sigma (x_p^* - x_e) \\
 + h_p] - \frac{1}{A_c dz} h_w S_w (T_e - T_w) = \varepsilon_d (1 - \delta_b) \rho_G (c_G + x_e c_v) \frac{\partial T_e}{\partial t}
 \end{aligned} \quad (2)$$

The interphase mass transfer coefficient ( $s^{-1}$ ) is given by a correlation proposed by [2]

$$K_{be} = 1.631 S_c^{0.37} u_o \quad (3)$$

The heat transfer coefficient  $H_{be}$  ( $w/m^3.K$ ) determined by the Chilton-Colburn analogy.

The dense bed voidage and Peclet number are correlated as proposed by [7]:

Dense phase solid mass balance

The axial dispersion in the turbulent regime increases largely with the gas velocity giving up an homogeneous solid phase in the bed. The following equations describe mass and heat transfer between solid and interstitial gas.

$$-\frac{\rho_s}{1 + \frac{\rho_s}{\rho_w} x_c} \frac{\partial x_p}{\partial t} = \frac{6}{d_p} \sigma (x_p^* - x_e) + \frac{\rho_s}{1 + \frac{\rho_s}{\rho_w} x_c} D_s \frac{\partial^2 x_p}{\partial Z^2} \quad (4)$$

$$\begin{aligned}
 \frac{6}{d_p} h_p (T_e - T_p) - \frac{6}{d_p} \sigma (x_p^* - x_e) [\gamma_o + c_v (T_e - T_{ref}) - c_w (T_e - T_{ref})] + k_s \frac{\partial^2 T_p}{\partial Z^2} \\
 = \frac{\rho_s}{1 + \frac{\rho_s}{\rho_w} x_c} (c_p + x_p c_w) \frac{\partial T_p}{\partial t}
 \end{aligned} \quad (5)$$

### 3.2.2. Freeboard balance equations

The plug flow model is used to describe the drying upper dilute region or freeboard. The mass and heat balance for the gas phase are:

$$-\rho_G u_o \frac{\partial x_f}{\partial Z} + (1 - \varepsilon_z) \frac{6}{d_p} \sigma (x_p^* - x_f) = \varepsilon_z \rho_G \frac{\partial x_f}{\partial t} \quad (6)$$

$$-\rho_G u_o (c_G + x_o c_v) - (1 - \varepsilon_z) \frac{6}{d_p} (T_f - T_p) [c_v \sigma (x_p^* - x_f) + h_p] \quad (7)$$

$$-\frac{1}{A_c dz} h_w S_w (T_f - T_w) = \varepsilon_z \rho_G (c_G + x_e c_v) \frac{\partial T_f}{\partial t}$$

Several correlations were proposed to determine solid decay in the freeboard, but they give predictions that differs each from others. However, it is largely accepted that concentration in the freeboard decreases exponentially with height.

$$\frac{\varepsilon^* - \varepsilon_z}{\varepsilon^* - \varepsilon} = \exp(-a_z * (z - h_i)) \quad (8)$$

$\varepsilon$  is the dense bed voidage.  $\varepsilon_z$  is the freeboard voidage at  $z$ .  $\varepsilon^*$  is the asymptotic voidage at  $z \rightarrow \infty$  in the dilute region.

$$\varepsilon_z = \varepsilon^* - (\varepsilon^* - \varepsilon) \exp(-a_z * (z - h_i)) \quad (9)$$

The position of the point of inflexion  $h_i$  separating the dilute and dense bed regions can be calculated in a trial manner using the solids inventory in the dryer.

#### 4. Results and discussion

The set of ordinary derivatives thus obtained was solved with Matlab solver (MALAB R2012b). For the group A type particles and B type particles, the moisture sorption isotherms obtained experimentally were fitted by the modified-Hendersen correlation:

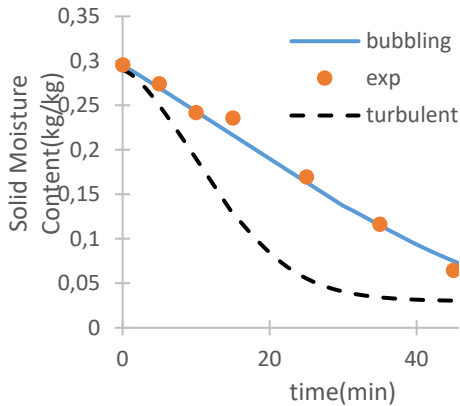

$$RH_A = \frac{P_v}{P_w} = 1 - \exp(-0.0298 * (T_p - 90.94) X_p^{0.78}) \quad (10)$$

$$RH_B = \frac{P_v}{P_w} = 1 - \exp(-465.2 * (T_p + 231.8) X_p^{3.64}) \quad (11)$$

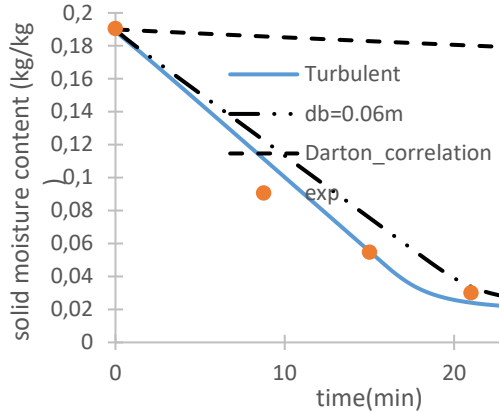

RH is the relative humidity,  $T_p$  is the particle temperature and  $X_p$  is solid moisture content on dry basis (kg/kg).

The comparison between solid moisture content simulations as function of time for bubbling and turbulent regime models to experimental results is illustrated in **Fig.1 and Fig.2**. For A type particles, bubbling regime gives better fitting of experimental results than turbulent one. The latter regime overestimates the drying rate. The completely mixed flow is more realistic than the axially dispersed flow. For B type particles, the bubble diameter was calculated by Darton correlation. [1] suggested that a constant bubble diameter value of 0.05 m could be convenient for the simulations. [4] obtained good predictions with a constant bubble diameter of 0.06m and an air superficial velocity of 2.4m/s. The equivalent bubble diameter value obtained with (2) for A type particles was also 0.06m. A simulation with this diameter was so tried. It is noted that Darton correlation largely underestimated the drying rate. This is due to the growth of bubble size by coalescence as they rise in the bed which causes mass and heat transfer decrease. At high superficial velocities, splitting of bubbles occur and constant equivalent bubble diameter is more realistic. However the turbulent regime is more

convenient for this powder and gives the better prediction of experimental data. This regime is characterised by considerable solid entrainment in the freeboard zone.

**Fig.1** Simulated and experimental solid moisture as function of time (A type particles)

**Fig.2** Simulated and experimental solid moisture content as function of time (B type particles)

While the solid concentration in this section is very dilute relatively to the dense region (**Fig. 3**), drying continues in the freeboard region. From **Fig.4**, it can be noted that air moisture content in the dense bed is higher than that in the freeboard zone. Moisture is driven more efficiently to air in the dense bed but freeboard contributes also to performing drying kinetics. Freeboard contribution becomes more important as the product is dried in the falling rate period where there is no more surface water. The same trend was found by [8].

To ensure homogenous solid moisture content in the bed, axial dispersion was added to solid mass and heat balances. To test the influence of axial solid dispersion coefficient, four values were assigned to  $D_s$ : 10, 1, 0.1 and 0.01  $m^2/s$ . The simulation results of solid moisture content variation with time and with axial coordinates are presented in **Fig.5** and **Fig.6**. Closer inspection of these figures shows that for  $D_s$  values, 0.1, 1 and 10  $m^2/s$  solid particles are perfectly mixed and there is no influence of  $D_s$  value on solid moisture content as function of time. This is in well agreement with the results of [9] where  $D_s$  values were stated to be in the range 0.5-10  $m^2/s$ . In this work a  $D_s$  value of 1  $m^2/s$  was used for all simulation as suggested by [2]. For the lowest  $D_s$  value 0.01  $m^2/s$ , an axial solid moisture content dispersion appears and a little deviation from experimental data is obtained.

## 5. Conclusions

A comparison between bubbling regime and turbulent regime batch-fluidized bed drying of an A and a B pharmaceutical powders has been made. Simulation results show that the experimental drying kinetic is better predicted by the bubbling regime in the case of the A type particles while for the B type particles turbulent regime model is more convenient

### **Abstract**

*This study aimed at the modeling and simulation of intermittent drying to be applied to highly deformable moist foods such as apples. Mass transport modeling considered two stages: the first at 95, 85 and 75°C air temperatures, and the second at 60°C. The shrinkage was correlated with the sample moisture and included in the model that was solved by the finite differences method. The first stage temperatures affected the water diffusivity in the second stage. This model was suitable for simulating the water profiles during the two-stage intermittent drying, showing an efficient fitting to the experimental data.*

**Keywords:** *thermal intermittence; coefficient diffusion effective; shrinkage; apple drying.*

## 1. Introduction

Drying is an antique unit operation widely used by the food industry and it is based on moving of water from high to low moisture zones until reach a frontier and to be removed in the form of vapor. This operation favors the stability of the foods because it increases their shelf life due to the considerable decrease in the water activity of the material [1-3]. However, the energy demand of the drying operation is very high and besides that, can promote undesirable nutritional and organoleptic losses.

The recent literature has reported the intermittent drying processes as an alternative to decrease these negative impacts and to minimize energetic costs [4,5]. Intermittent drying consists in changing of the operational conditions during drying. In the case of the temperature variation during the process, referred as thermal intermittence, a high temperature is used in the beginning of the process favoring the evaporation. During this period the surface of the product is saturated and the water evaporation ensures its low temperature [6]. When instauration zones begin to appear on the surface, the drying air temperature is reduced.

The knowledge and control of the heat and mass transfer phenomena during drying is fundamental to establish process conditions that promote improvement in the quality of the product. In the case of variable process conditions, such as in the intermittent drying, the recent literature [4] has reported the necessity of intense investigation and understanding of the moisture and temperature evolution during the whole process. Mathematical models can be used to estimate physical and transport parameters, and to predict spatial and temporal moisture and temperature profiles. However, it is necessary that appropriate conditions be considered. In this sense, this study proposes modeling and simulation of temporal and spatial profiles of the water content in apple slices during intermittent drying in two stages.

## 2. Materials and Methods

**2.1. Sample preparation:** The Fuji cv. apples (*Malus domestica*) were sanitized with water and then sliced (5 mm thick) using a slicer (ECO, Brazil). The slices were placed between two metallic screens to avoid deformation during the drying.

**2.2. Convective dryer:** The drying experiments were carried out using two identical tray dryer with forced convection as described by Filippin et al. (2018) [5]. The air flowed parallel to the samples. Dryer 1 was kept at 75, 85 or 95 °C and dryer 2, at 60 °C.

**2.3. Drying tests:** During the first stage of intermittent dryings, the trays were placed in dryer 1. After 45 minutes, they were removed from the dryer 1 and immediately inserted into the dryer 2, where remained until the samples reached constant weight. In both dryers the drying air velocity was 2 m·s<sup>-1</sup>. The samples were weighed successively during the drying using a semi-analytical balance (Gehaka, BK 4000, Brazil).

**2.4. Experimental determination of sample shrinkage:** The shrinkage was described as a linear function of the moisture content on dry basis. The thickness was measured at each trial at the beginning and end of drying by using a micrometer screw (Mitutoyo, MDC-25SB, Japan).

**2.5. Analytical methods:** The total solids content of fresh and dried apple slices were gravimetrically determined in triplicate by drying in a vacuum oven at 60 °C and 10 kPa to constant weight. The water activity of the samples was measured in triplicate at 25 °C in a hygrometer (Aw sprint; Novasina, Switzerland).

**2.6. Mathematical modeling:** Considering that drying can be described by the falling-rate period and that liquid diffusion is the principal mass transfer mechanism, the drying kinetics were evaluated based on Fick's second law [7] presented in Eq. 1 in its modified form, in terms of the mass fractions (dry basis, d.b.). It was assumed a constant solids concentration. The slice was considered as a flat plate with mass flow along the thickness of the apple (z-axis).

$$\frac{\partial X}{\partial t} = D_{\text{eff}} \frac{\partial^2 X}{\partial z^2} \quad (1)$$

where X is the mass fraction of water on a dry weight basis ( $\text{kg} \cdot \text{kg}^{-1}$ )  $D_{\text{eff}}$  represents the effective diffusivity ( $\text{m}^2 \cdot \text{s}^{-1}$ ), z is the thickness and t is the time (s).

Initial conditions for the first and second stage of the intermittent drying are presented in Eq. 2 and 3, respectively.

$$t = 0 \quad \left\{ \begin{array}{l} X_1 = \bar{X}^0 \\ X_2 = X_2^0(z) \end{array} \right. \quad (2)$$
$$(3)$$

where the sub index 1 and 2 represent the first and the second stage, respectively, and the super index 0 represents the initial condition. At the second stage, the initial water mass fraction is a function of the distance z, because there is a spatial distribution profile of water content in the sample at the end of the first stage.

Eqs. 4 and 5 represent the spatial conditions.

$$z = \pm L/2 \quad X = X^{\text{eq}} \quad (4)$$

$$z = 0 \quad \frac{\partial X}{\partial z} = 0 \quad (5)$$

where L is the initial thickness of the apple slice and z = 0 refers to the central position on the z-axis (symmetry condition) and X<sup>eq</sup> is the water mass fraction in equilibrium. Eq. 4 and 5 were employed in both drying stages.

In this study, the thickness shrinkage was described by a linear equation as a function of moisture and, therefore, included in the Eq. 1

The parabolic partial differential equations were solved by finite differences method using MATLAB software (MathWorks Inc., Natick, Massachusetts, USA). The moisture profile generated in the first stage was the initial condition of the second stage. The effective diffusion coefficients (D<sub>eff</sub>) were determined by minimizing the (relative) deviations between predicted and observed average water contents in the slices. For this, the predicted water profiles were integrated and compared with the observed values.

The estimated parameter D<sub>eff</sub> was evaluated based on the best fit using statistical indicators as such as the coefficient of determination of the fit (R<sup>2</sup>), the mean relative error (P%) and on the root mean square error (RMSE).

$$P(\%) = \frac{100}{N} \sum_1^n \frac{|X^{\text{exp}} - X^{\text{cal}}|}{X^{\text{exp}}} \quad (6)$$

$$RMSE = \left[ \frac{1}{N} \sum_1^n (MR^{\text{cal}} - MR^{\text{exp}})^2 \right]^{\frac{1}{2}} \quad (7)$$

where X<sup>calc</sup> represents the water content on a dry basis, X<sup>exp</sup> is the experimental value, MR<sup>exp</sup> is the experimental moisture ratio, MR<sup>calc</sup> the calculated moisture ratio and N represents the number of observations or residuals.

### 3. Results and Discussion

The moisture and water activity of the samples for the treatments are shown in Table 1.

**Table 1. Moisture and water activity of the fresh and dried samples**

Treat.	Moisture			a <sub>w</sub>
	Fresh sample	Dried Sample	Equilibrium	Dried sample
T1	0.869 ± 0.002	0.047 ± 0.001	0.033 ± 0.001	0.275 ± 0.016
T2	0.860 ± 0.002	0.043 ± 0.001	0.032 ± 0.001	0.237 ± 0.013
T3	0.863 ± 0.002	0.050 ± 0.001	0.032 ± 0.002	0.248 ± 0.016

The experimental curves of the intermittent drying are shown in Fig.1.

Fig 1. Experimental curves of the intermittent drying

It was observed that the intermittent drying curves exhibit a discontinuity between the first and second stages, indicated by the vertical dashed line. The relation between the drying rate and the air temperature is evidenced by the difference between the curves in the first stages, in which higher drying air temperature promoted a more pronounced slope of the curve. In addition, after 45 min at 75°C, the sample average moisture reached 75% on wet basis (or 2.97, d.b.), while at 95°C the average moisture was 62% (1.63, d.b.).

Table 2 shows the effective diffusivity obtained at each stage of the intermittent drying treatments and the statistical parameters evaluated.

Table 2. Diffusion coefficients ( $D_{eff}$ ),  $R^2$ , P(%) and RMSE

Treatment	T (°C)	$D_{eff} \times 10^{10}$ ( $m^2 \cdot s^{-1}$ )	$R^2$	P(%)	RMSE
T1	95	7.00	0.990	3.1	0.032
	60	3.40	0.999	28.7	0.005
T2	85	5.90	0.992	2.3	0.027
	60	3.10	0.999	25.0	0.004
T3	75	4.50	0.985	2.8	0.034
	60	2.75	0.999	22.4	0.011

The P(%) values obtained in the second stage were higher than those obtained in the first stage and they were above 10%, which is considered as a reference value [8]. However, since the P(%) value is calculated as a relative residual, the error value is amplified as the moisture content decreases through the second stage of drying. The values of RMSE, a non-relative parameter, were satisfactory for both stages as well as the coefficient of determination ( $R^2$ ), indicating that the proposed model presented a good fit to the experimental data.

Experimental and simulated curves are shown in Fig. 2.

Fig. 2. Experimental (Exp) e simulated (Sim) drying curves

It is important to highlight that drive forces are not only related to mass concentration gradients, although this is the main driving force of the phenomenon [7]. Temperature gradients, which are more significant in the beginning of the process, will also influence the water transport [6]. However, in the case of a single-parameter model,  $D_{\text{eff}}$  encompasses all possible parameters that effectively influence the mass transport.

The effective diffusion coefficients of the first stage (Table 2) showed exponential temperature dependence, which was empirically represented by an Arrhenius type equation, as described in Eq. 8. This equation has been reported in the literature to describe the  $D_{\text{eff}}$  as a function of the air-drying temperature [9,10]. For the first stage, the activation energy was  $23.59 \text{ kJ}\cdot\text{mol}^{-1}$  ( $R^2 = 0.987$ ), as follows:

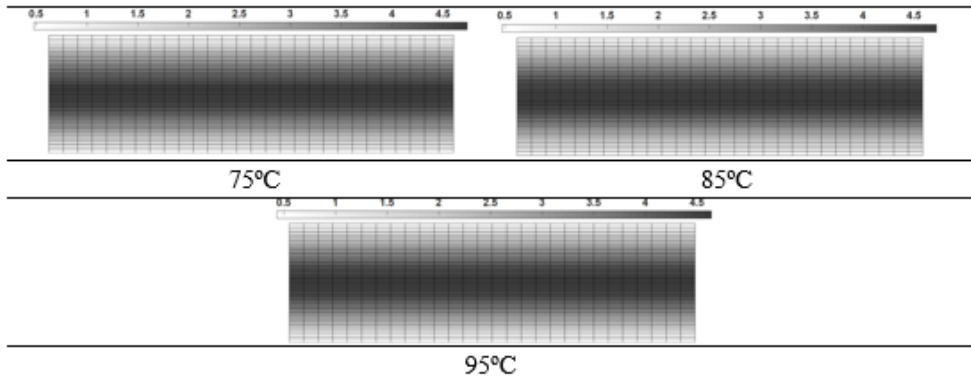

$$D_{\text{eff}} = 1.57 \times 10^{-6} \exp^{-23.59/RT} \quad (8)$$

in which  $D_{\text{eff}}$  assumes the value of  $1.57 \times 10^{-6} \text{ m}^2\cdot\text{s}^{-1}$  when the temperature ( $T$ ) tends to infinite and  $R$  is the universal gas constant in  $\text{kJ}\cdot\text{mol}^{-1}\cdot\text{K}^{-1}$ .

Although the air-drying temperatures of the second stages were the same ( $60^\circ\text{C}$ ), the  $D_{\text{eff}}$  values were different. Therefore, a dependence on the first stage air-drying temperature was found. The increase of  $10^\circ\text{C}$  in the first stage temperature led to an increase of about 11% in the  $D_{\text{eff}}$  of the second stage. This result indicates that the first stage temperature contributed to the second stage efficiency, probably because of modifying the vegetable structure that would make the water exit easier in the later stage.

The drying has been represented in the literature through empirical models such as the Peleg, Page, Handerson and Pabis and Lewis and fundamental mathematical models [4,11]. Regarding the intermittent drying, some authors model the initial condition of subsequent stages by considering a homogeneous spatial distribution of the water [9,12]. This

consideration is reasonable when tempering times are used between the stages, since this procedure provides redistribution of the water content in the solid during the holding time. Therefore, a moisture profile of the initial stage could be used to calculate the ideal tempering time required for the moisture to become homogeneous [13].

*Fig. 3. Spatial distribution of water in the apple slice at the end of the first stage at 75, 85 and 95°C.*

In the case of the thermal intermittence applied in this study, at the end of the first stage the profile of spatial water distribution was evident, as shown in Fig. 3. At the end of the first stage at 95°C, the water content was about 9 times larger at the centre of the sample than at the surface, which highlights the need to consider the moisture profile in the initial condition of the second stage. Thus, the approximation of moisture profile to experimental mean moisture would be a misconception that could underestimate the  $D_{\text{eff}}$  values.

Consideration of the shrinkage in the model also contributed to the good fit of the model. In this study, it was assumed that only the thickness dimension varied. In fact, as variation of the radial dimension of the slices was small, the mass transfer area could be neglected without considerably affecting the accuracy of the model fitting.

#### 4. Conclusions

The proposed diffusive model was appropriated to simulate water profiles during two-stage intermittent drying of deformable foods, since it presented a good fit to the experimental data. The effective diffusion coefficients found in the second stage depended on the first stage temperature.

### **Abstract**

*During hot melt fluidized bed coating, particle agglomeration leads to non-uniform particle size. In this study, Population Balance Model (PBM) is used to establish the conservation of the size of particles in the system. In order to solve the population balance model, it is discretized. The aggregation kernel of the particles can be described by the Equi-partition of Kinetic Energy (EKE) kernel based on the gas dynamics theory. The EKE kernel is incorporated into a discrete population balance (DPB) model, and the effective aggregation rate constant is obtained by fitting with the experimental data.*

**Key words:** Hot melt fluidized bed, PBM, DPB, EKE kernel, Aggregation rate constant.

---

## **1. Introduction**

Hot melt fluidized bed coating is an advanced technology for the preparation of microcapsules and it is commonly used in the food, pharmaceutical, and chemical industries. The coating process involves the agglomeration and breakage of the particles. In most studies of the model, the agglomeration model is used to describe the coating process. Tan et al (2004c) <sup>[1]</sup> showed that the agglomeration rate of the particles was much greater than the breakage rate in the melt granulation experiments. For the coating process of particle groups, particles of different sizes are transformed into each other through nucleation, growth, and breakage. Through the introduction of the particle population balance model (PBM), a conservation relationship is established between particles of various sizes in the system. Anette et al<sup>[2]</sup> established a theoretical model to quantitatively explain the agglomeration growth rate, which was in good agreement with the experiment; C.F.W. Sanders et al<sup>[3]</sup> predicting high shearing granulation behavior in the granulation process based on discrete population balance (DPB) model; Tan et al<sup>[4,5]</sup> deduced the EKE kernel based on particle growth kinetics theory to describe the net growth rate of hot melt spray fluid bed coating. In these models, the growth process of the particles is reflected from different aspects. However, the study on the constant of aggregation rate in the process of hot melt fluidized bed coating is rare.

This study only considers the agglomeration process in the coating process of hot melt fluidized bed. The main purpose is to incorporate the EKE kernel into a discrete population balance (DPB) model and use MATLAB for numerical simulation. The experimental data is fitted to a discrete population balance model to obtain an effective constant for aggregation rate.

## **2. Simulation Methods**

### **2.1 Establishment of a population balance model (PBM)**

In the process of hot melt fluidized bed coating, the agglomeration and breakage of particles resulted in non-uniform particle size. A population balance model (PBM) is introduced to establish a conservation relationship for each size particle in the system, describe the change of particle size distribution with time or space during the coating process, and reflect the process of particle growth and extinction. PBM is expressed by describing the rate of change of the particle size distribution density function. The model equation is:

$$\begin{aligned} \frac{\partial n(t, v)}{\partial t} = & B^0(t, v) - \frac{\partial}{\partial v} [G(t, v)n(t, v)] \\ & + \frac{1}{2} \int_0^v \beta(t, v - \varepsilon, \varepsilon)n(t, v - \varepsilon)d\varepsilon - n(t, v) \int_0^\infty \beta(t, v\varepsilon)n(t, \varepsilon)d\varepsilon \\ & + \int_0^\infty S(t, \varepsilon)b(v, \varepsilon)n(t, \varepsilon)d\varepsilon - S(t, v)n(t, v) \\ & - O(t, v)n(t, v) \end{aligned} \quad (1)$$

where  $n(t, v)$  is a number density function,  $v$  and  $\varepsilon$  are the mass of particles or granules,  $B$  is the nucleation rate,  $G$  is the growth rate,  $\beta$  is an aggregation kernel,  $S$  is a selection function,  $b$  is a breakage function.

The aggregation kernel uses the EKE kernel described by Hounslow (1998)<sup>[6]</sup> based on the theory of gas dynamics. Expressed as:

$$\beta_{i,j} = \beta_0(t)(l_i + l_j)^2 \sqrt{\frac{1}{l_i^3} + \frac{1}{l_j^3}} \quad (2)$$

where  $\beta_0$  is the second-order rate constant, and  $l_i$  and  $l_j$  represent particles of size  $i$  and  $j$ . This model uses the particle flow dynamics theory described by Goldschmidt et al<sup>[7]</sup> to provide a theoretical basis for the particle collision frequency in a fluidized bed.  $\beta_0$  can be expressed as:

$$\beta_0(t) = \psi g_{ij} \sqrt{\frac{3\theta_s}{\rho}} \quad (3)$$

where  $\psi$  is defined as the ratio of the aggregation rate to the collision rate,  $g_{ij}$  is the particle radial distribution function,  $\rho$  is the particle density,  $\theta_s$  is the particle temperature. Based on this work, it is considered that  $\beta_0$  should be a constant for any set of experimental conditions, so in all the work here,  $\beta_0$  can be described by the value of a single time-independent parameter.

## 2.2 Solution to the population balance equation

In order to solve the equation of population balance model, this study uses the method of discretization<sup>[8]</sup>. It ensures correct prediction of particles number and volume for the aggregation terms. In the discretization scheme used, the length domain is divided into

geometric intervals where the ratio of the upper and lower limits of each size interval is  $r = \sqrt[3]{2}$ . By assuming that the system is well-mixed, the discrete equation that gives the rate of change of the number of particles in the  $i$  th interval is:

$$\begin{aligned} \frac{dN_i}{dt} = & N_{i-1} \sum_{j=1}^{i-2} 2^{j-i+1} \beta_{i-1,j} N_j + \frac{1}{2} \beta_{i-1,j-1} N_{i-1}^2 \\ & - N_i \sum_{j=1}^{i-1} 2^{j-1} \beta_{i,j} N_j - N_i \sum_{j=1}^{n_{eq}} \beta_{i,j} N_j \end{aligned} \quad (4)$$

$N$  is the number of particles in a particular size class. Use MATLAB to solve the discretized numerical model.

### 2.3 Calculation of the aggregation rate constant $\beta_0$

The rate extraction problem is treated as a simple chi-square minimization process in the manner of Press et al<sup>[9]</sup>. In considering only the aggregation model, assuming that the aggregation rate is independent of time, the equation (2), (4) is simultaneously fitted with the mass-based experimental data to obtain the aggregated rate constant  $\beta_0$  for the entire experiment. Using the integral fitting technique to minimize the chi-square method  $\chi^2$ :

$$\chi^2(p) = \sum_i \sum_k \{ [\hat{W}_i(t_k) - \tilde{W}_i(t_k, p)]^2 \} \quad (5)$$

Where  $P$  is the fitting parameter vector,  $\hat{W}_i$  is the mass-weighted particle size distribution of the experiment, and  $\tilde{W}_i$  is the predicted particle size distribution.

## 3. Experimental

Using the method of spray cooling granulation, the citric acid is subjected to granulation experiments using a fluidized spray granulation device. Experimental device flow chart shown in fig 3-1:

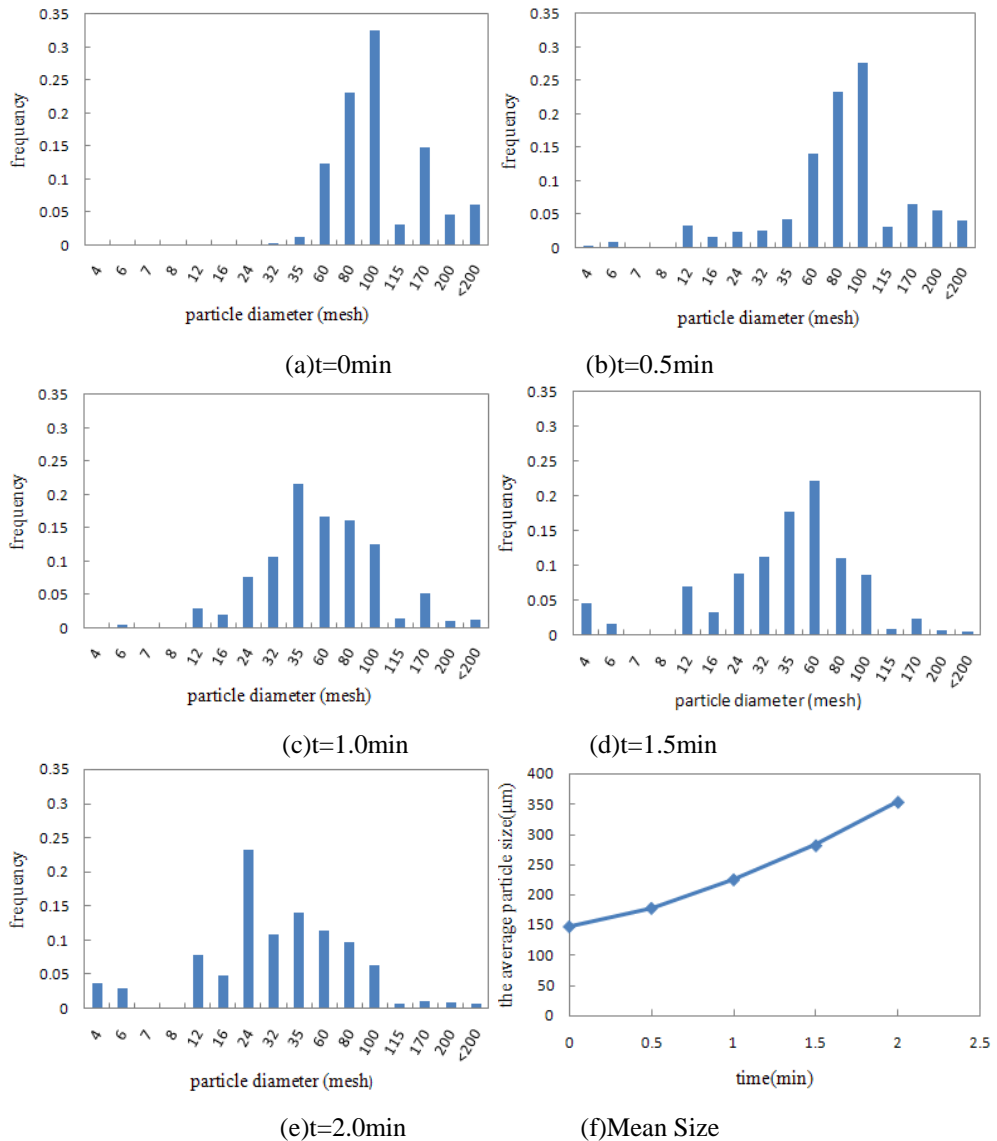

**Fig 3-1 Citric acid experiment flow chart. 1, Air compressor; 2, Water separator; 3, Air flow meter; 4, Constant temperature water bath; 5, Spray fluidized bed; 6, Lipid; 7, Fan.**

The experimental materials selected citric acid particles and lipid (butter), citric acid particles as the core material, and lipid as the wall material. 150 g of citric acid particles are weighed and frozen in a freezer at  $-30^{\circ}\text{C}$  for 24 hours. The lipid is heated and melted and sent to the nozzle, mixed with air in the nozzle, and then atomized into droplets. The citric acid particles are placed in a spray fluidized bed and the fluidized citric acid particles collide with the atomized droplets to wet, coat, and granulate.

The absolute pressure of atomization during the experiment is 0.6 MPa. The flow rate of citric acid particles is 0.5m/s. The experiments are divided into 4 groups. The fluidization time is 0.5min, 1.0min, 1.5min and 2.0min respectively. Each set of experiments is repeated 3 times. At the end of the experiment, the fan is turned off and the nozzle spray is stopped. The experimental sample is taken out and sieved. The percentage of mass is used as an important criterion for evaluating granulation, and the particle size distribution of each set of experimental samples is determined.

#### 4. Results and discussion

The particle size distribution of each experimental sample is shown in fig 4-1:

**Fig 4-1 Particle size distribution based on mass at different time. The last figure shows the change mean size.**

As shown in fig. 4-1, at  $t = 0\text{min}$ , that is, the citric acid particles are not embedding with lipid at the initial time. The distribution of particles is observed to be concentrated between 60 mesh and 200 mesh, with a particle size of 100 mesh particles having the highest mass percentage, accounting for 23%.

As shown in fig (b), the lipid is atomized and coated on citric acid particles. After spraying for 0.5 min, the experiment is ended and the particle size distribution is analyzed. Compared with fig (a), the particle size distribution range is larger, mainly distributed between 12 and 200 mesh, with the largest distribution of citric acid particles between 60 mesh and 100 mesh. However, the percentage of particles with a particle size of 100 mesh is still the largest, accounting for 28%. This is because the lipid is applied atomically to the fluidized citric acid particles so that the particles are coated and the diameter of the particles increases. However, when the coating is applied for 0.5 min, the percentage of the particles between 4 and 6 mesh was almost zero.

In fig (c), the experiment is performed for 1.0 min. It can be observed from the figure that the particle size distribution is mainly concentrated between 12 mesh and 100 mesh, among which the citric acid particles distributed between 24 mesh and 100 mesh are the most, and the citric acid particles with particle size 35 mesh are the most distributed, accounting for 21%. Compared to fig (b), the percentage of particles in each particle size range increased. Particles between 115 mesh and 200 mesh gradually decreased with increasing experimental time. This is due to the fact that as the experimental time increases, more lipid and citric acid particles contact and collide, so that the particles are sufficiently agglomerated, the particles in a small size range are reduced, and the particle size is increased. Relative to fig (b), the particle size distribution of fig (c) is relatively uniform, showing a normal distribution as a whole.

Fig (d) shows that the entire experiment is 1.5 minutes. Compared to (c), large granules of citric acid are present, with an increase in granule size of 4 mesh citric acid particles, and few particles between 115 mesh and 200 mesh. The particle size range of the particles is also concentrated between 12 mesh and 100 mesh. At this point, the particle size distribution is 60 mesh with the largest percentage of particles, accounting for 22%.

The particle size distribution in fig (e) is similar to that of fig (d). The particle size distribution range is basically the same and is mainly concentrated between 12 mesh and 100 mesh. However, the particle size distribution of 24 mesh particles is the largest, accounting for 23%.

With the increase of the experimental time, citric acid is embedded in lipid, and the average particle diameter increases. This is because the lipid is sprayed onto the fluidized particles after atomization and the particles are coated. When the experiment time increases, the quality of the atomized wall material increases, while the quality of the core material does not change. Then, the mass-based particle size distribution of citric acid particles at different times is fitted to a discrete population balance model. Solve using MATLAB to get  $\beta_0 = 7.5 \cdot 10^{(-6)} \text{ kg m}^{-1/2} \text{ s}^{-1}$ .

## 5. Conclusion

A hot melt fluidized bed coating experiment using lipid-citric acid as the research object. The agglomeration of particles leads to non-uniform particle size, The particle size distribution range is larger, mainly concentrated between 12 mesh and 100 mesh, and the mass-based particle size distribution as a whole shows a normal distribution.

The experimental data is fitted to a discrete population balance model, and the aggregation rate constant  $\beta_0 = 7.5 \cdot 10^{-6} \text{ kg m}^{-1/2} \text{ s}^{-1}$ .

### **Abstract**

*Food drying is one of the main unit operations for food preservation and it is based on the difference of chemical potential between the product and a fluid with lower chemical potential. The objective of this work was the development of a thermodynamic model of chicken meat drying process using infrared thermography; also the viability of using dielectric spectroscopy as a monitoring system was analyzed. A thermodynamic model has been developed to predict the expansion/contraction phenomena of poultry meat throughout the drying process. Moreover, it was demonstrated that permittivity is a non-destructive method to monitor the evolution of drying process.*

**Keywords:** *Poultry meat, hot air drying, permittivity, infrared, drying kinetics.*

---

## **1. Introduction**

Food drying is one of the main unit operations to preserve food<sup>[1]</sup>. The process is carried out by the difference of chemical potential between the product and a fluid (hot air) with lower chemical potential. Drying is based on three stages: induction period, period of constant drying speed and period of decreasing drying speed. During the first stage, the water transport occurs due to the difference of chemical potential between the food and the hot air, increasing the temperature of the surface. In the second stage, all the heat is used to evaporate the water, which comes from the inside faster than it evaporates from the surface, therefore, its temperature does not change. After this, the product is dried until the speed with which the water reaches the surface is less than the rate of evaporation and the heat received is used to evaporate the water as well as to heat the product.

Given the importance and extended use of hot air drying in the food industry, to model the behavior of the sample that occurs during dehydration is very useful to optimize the industrial process. A similar thermodynamic model was already reported for hot air drying process of pork meat<sup>[2]</sup>. Several authors have modeled the water transport of other products like red pepper<sup>[3]</sup>, salty pork meat<sup>[4,5]</sup>, apple<sup>[6]</sup> and sweet potato<sup>[7]</sup>.

The permittivity ( $\epsilon^*$ ) is the physical property that describes the interaction between a flux of photons and the medium through which photons circulate. Thus, the analysis of the electrical properties of a flux of photons when it passes through a biological system allow determining the quantity and state of the chemical species of the system. Infrared thermography is a technique that provides information about the heat transfer in meat tissues<sup>[8]</sup> and consists in the measurement of the infrared radiation emitted by a body surface getting an image of its thermal distribution. Thus, infrared thermography and the permittivity analysis, offer the possibility to analyze the process by a non-destructive way.

The objective of this work is the development of a thermodynamic model of the chicken meat drying process using infrared thermography; also the viability of using dielectric spectroscopy as a monitoring system is analyzed.

## **2. Materials and Methods**

### **2.1. Raw Material**

The experiments were carried out using boneless broiler breasts (Pectoralis major) obtained from a local supermarket. Cylinders of poultry breast were used for each analysis (2 cm of diameter and 1 cm of height); the cylinders were cut in perpendicular direction to the fibers.

### **2.2. Experimental procedure**

Two samples were placed inside the hot air dryer. The drying operation was carried out, for a period of 67 hours, at a temperature of 40 °C and an air velocity of 1.5 m·s<sup>-1</sup>. One of the

samples was hung from a Mettler Toledo PG503-S balance (precision of  $\pm 0.01$  g) in order to register the mass throughout the drying process. The other sample was placed on the right side of the dryer on a grid. This sample allow controlling continuously the surface temperature. Moreover, two needle electrodes sensor was placed on this sample to measure the permittivity by continuous radiofrequency spectrophotometry. The flat face of both cylindrical samples was located in perpendicular to the drying air. A reference material of known emissivity ( $\epsilon = 0.95$  - Optris GmbH) was placed next to the samples. Also, the temperature of the drying air, sample, reference material and environment were measured with K-thermocouples connected to an Agilent multiplexer 34901A (Agilent Technologies, Malaysia) and registered by an Agilent Data Acquisition equipment 34972A (Agilent Technologies, Malaysia). After the drying treatment, the samples were kept in aqualab® disposable sample cups, sealed with parafilm® for further analysis.

Water activity, moisture and volume were measured in fresh samples and also in dried samples. Mass, permittivity and thermal images were registered continuously as was explained above.

### **2.3. Infrared measurements**

The infrared analysis was carried out following the method described by Traffano-Schiffo et al. (2014)<sup>[9]</sup>, using an infrared camera (Optris PI® 160 thermal imager, Optris GmbH, Berlin, Germany) installed in front of the sample, at an angle of  $0^\circ$  relative to the plane in which the samples were placed. The camera uses a two-dimensional Focal Plane array with  $160 \times 120$  pixels, a spectral range of  $7.5\text{-}13 \mu\text{m}$ , resolution of  $0.05^\circ\text{C}$  and an accuracy of  $\pm 2\%$ . The camera covers at a temperature range of  $-20$  to  $900^\circ\text{C}$ . It has a field of vision of  $23^\circ \times 17^\circ$  with a minimum distance of 2 cm. The camera uses Optris PI Connect software (Optris GmbH, Berlin, Germany).

### **2.4. Radiofrequency measurements**

The sensor used was developed by the Dielectric Properties Laboratory (Instituto Universitario de Ingenieria de Alimentos para el Desarrollo IuIAD) and the Instituto de Instrumentación para Imagen Molecular (I3M) both belonging to the Universitat Politècnica de València (UPV), Valencia, Spain. It consists of two needle electrodes located on both sides of the cylindrical face of the sample. The sensor is connected to an Agilent 4294A impedance analyzer. The measuring frequency range is from 40 Hz to 1 MHz and the calibration is performed in open and short-circuit.

### **2.5. Physico-chemical measurements**

Water activity was determined with a dew point hygrometer Aqualab®, series 3 TE, with an accuracy of  $\pm 0.003$ . The mass of the samples was determined with a Mettler Toledo AB304-S balance, with an accuracy of  $\pm 0.001$  g. The volume was determined with Adobe ©

Photoshop © CS6 software by image analysis. Moisture was obtained with the ISO 1442 (1997) standard for meat products, drying the samples at 110 °C and atmospheric pressure until reaching a constant mass.

### 3. Results and discussion

The monitoring of the process with the thermographic camera need a correction in the temperature values, that made Traffano Schiffo et al., 2014<sup>[9]</sup>.

With the evolution of the real temperature obtained by the camera and the physicochemical determinations, it is possible to apply irreversible thermodynamics to model the drying process, in order to analyze the influence of the structure in the water transport during drying. For this purpose, the Gibbs free energy variation (Eq. 1)<sup>[10]</sup> was applied in the system interface described in figure 1.

$$dG = -SdT + VdP + Fdl + \psi de + \sum_i \mu_i dn_i \quad (1)$$

Where:  $SdT$  represents the entropic term related to heat fluxes;  $VdP$  represents the mechanical energies related to the variation of pressure;  $Fdl$  represents the mechanical energies related to the elongation force; and  $\psi de$  represents the effect of the electric field induced by solved ions. The term  $\sum_i \mu_i dn_i$  corresponds to the activity term and is the addition of the chemical potentials of the “*i*” component, being constant the rest of state variables.

*Fig. 1 Diagram of the interface of the chicken sample during drying.*

Considering the variation of free energy per mole of water, it is possible to define the extended chemical potential of water according to the equation 2.

$$\Delta\mu_w = \frac{\Delta G}{\Delta n_w} \quad (2)$$

Where:  $\Delta\mu_w$  = chemical potential of water ( $J \cdot mol^{-1}$ );  $\Delta G$  = variation of Gibbs free energy (J);  $\Delta n_w$  = moles of water (mol).

Combining the last two equations, the equation 3 is obtained. The terms  $F_{dl}$  and  $\psi_{de}$  of the equation 1 could be neglected, since the muscle tissue is elastic and the meat only has native ions.

$$\Delta\mu_w = -s_w (T^{air} - T^m) + v_w (P^{air} - P^m) + RT^m \ln \frac{a_w^m}{\varphi^{air}} \quad (3)$$

Where:  $s_w$  = partial molar entropy of the water ( $J \cdot K^{-1} \cdot mol^{-1}$ );  $T$  = temperature (K);  $v_w$  = partial molar volume of water ( $m^3 \cdot mol^{-1}$ );  $P$  = pressure (Pa);  $R$  = constant of ideal gases ( $8.314472 J \cdot K^{-1} \cdot mol^{-1}$ );  $a_w$  = water activity of sample;  $\varphi$  = relative ambient humidity. Being the superindexes: m = sample; air = air.

With the temperatures obtained by means of infrared thermography and the evolution of the moisture of the sample, estimated with the variation of mass during the process and the initial moisture, the entropic term can be calculated. For the activities term, a sorption isotherm of poultry was obtained and modeled by GAB ( $x_w^0 = 0.077$ ,  $C = 420$ ,  $K = 0.98$ ) (Fig. 2). Finally, the term of mechanical energies of the equation 3 (second term) can not be calculated, since the pressure variation of the sample can not be measured.

Fig. 2 Poultry sorption isotherm.

According to Onsager's relations<sup>[10]</sup>, the molar water flux is related to its chemical potential, which acts as a driving force for water transport, by means of the phenomenological coefficient (Eq. 4). The phenomenological coefficient is constant in reversible processes, but if the storage of mechanical energy produces irreversible breaks in the medium, the phenomenological coefficient will evolve as a function of the transformation suffered by the tissue.

$$J_w = L_w \cdot \Delta\mu_w \quad (4)$$

Where:  $J_w$  = molar flow of water ( $mol \cdot s^{-1} \cdot m^{-2}$ );  $L_w$  = phenomenological coefficient ( $mol^2 \cdot J^{-1} \cdot s^{-1} \cdot m^{-2}$ );  $\Delta\mu_w$  = chemical potential of water ( $J \cdot mol^{-1}$ ).

In order to obtain the phenomenological coefficient, water flux was estimated as follows (Eq. 5):

$$J_w = \frac{\Delta M_w^m \cdot M_0^m}{\Delta t \cdot S^m \cdot M_{r_w}} \quad (5)$$

Where:  $J_w$  = water flux ( $\text{mol} \cdot \text{s}^{-1} \cdot \text{m}^{-2}$ );  $\Delta M_w^m$  = variation of water mass of the sample (kg);  $M_0^m$  = initial mass of the sample (kg);  $\Delta t$  = time of the process (s),  $S^m$  = surface of the sample ( $\text{m}^2$ );  $M_{r_w}$  = molecular mass of water ( $18 \text{ g} \cdot \text{mol}^{-1}$ ).

As was explained above, it is not possible to calculate the mechanical term of the chemical potential, therefore the chemical potential of water was determined without considering the mechanical terms ( $\Delta\mu_w^*$ ). With the water flux and the chemical potential of water was determined without considering the mechanical terms, the phenomenological coefficient was estimated (Eq. 6).

$$L_w^* = \frac{J_w}{\Delta\mu_w^*} \quad (6)$$

In figure 3 it can be appreciated that there is a linear relation between  $L_w^*$  and  $J_w$  after 15 minutes of drying. Therefore, following that linear prediction of the phenomenological coefficient it is possible to estimate the mechanical terms with the equation 7 (Fig. 4).

$$v_w \Delta P = \Delta\mu_w - \Delta\mu_w^* \quad (7)$$

**Fig. 3 Relation between the phenomenological coefficient, without considering the mechanical terms, and the water flux from 15 minutes of drying until the end of the treatment.**

The evolution of the mechanical energy indicates that there is an expansion of the tissue during the first 400 minutes, followed by a contraction associated with the remaining functioning of the muscle from that time (Fig. 4).

*Fig. 4 Evolution of mechanical energy, developed from the thermodynamic model, throughout the drying treatment.*

The permittivity in radiofrequency was measured throughout the drying treatment. It was found a linear relation between the dielectric constant in  $\alpha$ -dispersion (40 Hz) and the number of water molecules when the sample still presents liquid phase, since this dispersion is fundamentally related to the mobility of the ions dissolved in meat liquid phase. With the drying time, the content of the liquid phase begins to decrease (samples with adsorbed water only) and also the mobility of the ions. The value of the dielectric constant in this dispersion becomes practically null.

#### 4. Conclusions

It has been demonstrated that infrared thermography is a good technique to monitor the process of drying in poultry meat, providing information of heat transfer in biological tissues, being possible to obtain the evolution of the emissivity of the meat. Thus, with this technique, it is possible to non-invasively obtain the surface temperature of the sample during the treatment.

A thermodynamic model has been developed to predict the expansion/contraction phenomena of poultry meat throughout the drying process, as well as to evaluate the driving forces of the drying process.

Finally, a direct relation between the permittivity in  $\alpha$ -dispersion with regard to the number of water molecules has been demonstrated. It can be concluded that the permittivity is a non-destructive and rapid method to monitor the evolution of the drying process.

### **Abstract**

*In this study, an experimental investigation was carried out on solar system consists of many main components; solar air collector, drying chamber and air blower. Manufacturing and an analysis of two active double-pass solar air collector integrated with unfinned and helical finned absorbers have been carried out. The helical fins increased the standers solar collector (unfinned) efficiency by about 6%. In five hours for 2 kg of apple slices drying, the final weight of the dried product is 1.237 kg using an unfinned solar collector, while 1.039 kg using helical finned solar collector.*

**Keywords:** solar drying, air heater, thermal performance, helical fins.

---

## **1. Introduction**

Drying is a complicated process including the transient transfer of mass and heat with several rate processes, such as physical or chemical transformations, which, in turn, may cause changes in product quality as well as the mechanisms of heat and mass transfer [1].

Air heater is the essential equipment through which solar energy is converted into heat energy. However, how to increase the thermal efficiency of solar air heaters becomes a significant challenge. In this paper, the design of different solar air heater with different absorber plate is discussed. Many parameters are affecting significantly on thermal performance of the solar collector, such as area of absorber, shape of absorber, speed of air, number of flow passes, number of glasses, material of absorber, ..., etc. The major parameters which discussed in this paper is the absorber shape and absorber area. Solar air collectors are classified basically into two types: bare plate and cover plate solar air heaters.

The bare plate solar air heaters consist simply of an air duct, the upper surface of which operates as the solar-energy absorber plate and the back surface insulated. For covered-plate solar air-heating collectors, to reduce upward heat losses from solar air heaters transparent cover materials above and usually parallel to the absorber plate are used of one or more [2]. The performance of solar collectors under low-temperature conditions measured and simulated. The experimental results showed that for temperatures below ambient and for cases without irradiance, unglazed collectors performed better than glazed ones, with considerable heat gains from condensation and frost. The glazed collectors are not suitable to operate at temperatures below the dew point as condensation and frost conditions might lead to deterioration of materials, compromising the reliability and durability of this type of collector [3].

The performance of a double pass solar air heater tested in the previous studies, and the results showed that the thermal efficiency of double pass solar air collector with the porous material is 20–25% and 30–35% higher than that of double-pass solar collector without porous material and single pass collector respectively [4]. The effect of the cross-sectional configurations on the thermal performance of the plastic solar air heater is examined. The results indicated that the highest efficiency was achieved for the circular shape about 80% at a flow rate of 0.18 kg/s and average solar radiation of 925 W/m<sup>2</sup> [5]. The solar radiation incident on solar collector has little effect on the efficiency of the collector, although it has a significant impact on the ambient air temperature around the collector. The outlet air temperature in flow channel increases almost linearly with insolation [6].

According to the above brief review for past literature, in the recent paper, manufacturing, and analysis of active double-pass solar air collector integrated with helical shaped finned absorber is done to be carried out.

## 2. Materials and Methods

In this study, an experimental investigation was carried out on solar system consists of many principal components to achieve study goals. The solar system includes mainly of solar air heater, drying cabin and inline air blower. Insulated air ducts have connected the elements. The system designed, manufactured and tested in the laboratory of the Department of Physics and Process Control, Szent István University, Gödöllő, Hungary.

### 2.1. Solar air collector

A simple double air-pass solar air collector had been manufactured with 120×50×15 cm length, width and thickness (external dimensions) respectively. The outer case of solar air collector is made from wood sheets and bars with different thicknesses with dimensions. For study purpose, two absorbing surfaces are made from copper sheet with 1.5 mm thickness and thermal conductivity 385 W/mK (see Fig. 1). A black matt paint used to enhance these surfaces properties (selective surface). A polystyrene material with thermal conductivity 0.038 W/mK is used as back insulation. Back insulation thickness is 2 cm, and dimensions are 120×50 cm length and width respectively. The sides of the body were well insulated to prevent heat loss by using self-adhesive rubber foam tape with a thickness of 3 mm. A transparent cover fixed on the top edges of the collector wood case and thermal insulation at the bottom base side of the wooden case. A 4 mm thick plastic glass sheet used to cover solar collector.

*Fig. 1. Wooden case and absorbing surface of solar air heater*

The first absorber is flat absorber (un-finned) with dimensions  $46.2 \times 121.8$  cm, while the second absorber had made with the same aspects of the first surface with helical Aluminum fins to increase its area of surface. The dimensions of attached fins are shown in Fig. 2. Fins function is expanding air streams length with the absorber surface to improve the useful heat transfer to the air. The space between every two buffers is 17 m. Areas of air heater inlet, exit and second channel entrance are the same, to avoid pressure reduction through the solar collector.

*Fig. 2. Helical extended surfaces dimensions*

The air recirculated from first to second air channel through 25 holes, which made on the absorber. Second air channel designed using many wood buffers which fixed on the back surface of a solar collector as shown in Fig. 1. Air circulates through the solar collector, inline air blower in air duct between solar heaters and surrounding has been used. According to Duffie and Beckman, flat-plate solar collector tilted in a way that it receives maximum solar radiation during the day and to be perpendicular to solar radiation rays at noon. The best stationary orientation is due South in the northern hemisphere and due North in the southern hemisphere. Therefore, the two solar air heaters in this work are oriented facing South line and tilted at  $45^\circ$  to the horizontal according to the solar chart for Budapest region (Budapest  $47.5^\circ$  N,  $19.05^\circ$  E) [7].

## 2.2. Drying cabin

The drying chamber is made with five trays where the different products items are placed. The external chamber dimensions are  $50 \times 50 \times 100$  cm length, width, and height respectively, as shown in Fig. 3. Dryer walls have been made from polystyrene with 5 cm thickness and thermal conductivity  $73 \text{ W/mK}$ , except the front wall of chamber made from

4 mm plastic glass sheet for observing. The five trays made from plastic nets and fixed with 10 cm distance between each. The chamber integrated with the solar air heater by a small duct (indirect drying) with 10 cm diameter.

All air leakages from drying space closed totally as possible. The product sample which used through this study is apple. Apple selected as a sample because of its high initial moisture content and its high maximum allowable temperature. The initial moisture content and maximum allowable temperature for an apple during drying process are 80% (wet base) and 70 °C respectively [8].

*Fig. 3. Layout of drying chamber*

### 3. Results

Two sets of results are collected, the first set shows the experimental results of the double air pass unfinned solar heater test, the second set shows the experimental results of double air pass helical finned solar heater test. Airspeed for these tests is 2.3 m/s with air duct cross-section area 0.00635 m<sup>2</sup>. Properties of air which considered for performance calculations are 1.2 kg/m<sup>3</sup> and 1000 J/kgK density and air specific heat at constant pressure respectively. The tests carried out on 2<sup>nd</sup> and 9<sup>th</sup> of October 2017. The daily efficiency for unfinned solar collector was 54.8%. The helical fins increased the standers solar collector

efficiency by about 6%. Fig. 4 and Fig 5 showed the relative humidity and temperature stratification in drying chamber by using unfinned solar air collector. Fig. 6 and Fig 7 showed the relative humidity and temperature stratification in drying chamber by using helical finned solar air collector.

Fig. 4. Relative humidity distribution in drying chamber by using unfinned collector

Fig. 5. Temperature distribution in drying chamber by using unfinned collector

It is clear that the product loses its moisture in a short time at the beginning of the process, and much time is needed for the remaining water content to be lost. Humidity stratification is more obvious with using unfinned collector. In five hours for 2 kg of apple slices drying, the final weight of the dried product is 1.237 kg using an unfinned solar collector, while 1.039 kg using helical finned solar collector.

Fig. 6. Relative humidity distribution in drying chamber by using helical finned collector

Fig. 7. Temperature distribution in drying chamber by using helical finned collector

## **4. Conclusions**

1. The daily efficiency for unfinned solar collector was 54.8%.
2. The helical fins increased the standers solar collector efficiency by about 6%.
3. In five hours for 2 kg of apple slices drying, the final weight of the dried product is 1.237 kg using an unfinned solar collector, while 1.039 kg using helical finned solar collector.
4. The costs of designing and manufacturing process of solar drying system are low compared with other drying methods.
5. The maintenaces costs are uncomplicated and cheap.
6. Clean process with low electricity consumption.

### **Abstract**

*One-phase model have been reported to describing the simultaneous heat and mass transfer in a horizontal drum partially filled by sugarcane bagasse with attention to the loss of water promoted by the increase of temperature. Mass and energy balances were written in MatLab language and solved by finite difference method. Predicted temporal and spatial profiles of moisture content and temperature are shown. Experimental tests were carried out in a horizontal drum and the temporal profiles were obtained. Great adjustments between experimental and predicted data were observed, indicating that the model is able to describe the transport phenomena in this system.*

**Keywords:** *horizontal drum; heat and mass balances; sugarcane bagasse; solid-state fermentation process.*

---

## **1. Introduction**

Rotary drums are widely employed in several industrial processes involving particulate systems. Specifically in solid-state fermentation processes, the use of rotary drum bioreactors have been investigated because these equipments offer more mechanisms to control of operational conditions during the fermentation process [1].

Solid-state fermentation (SSF) is a prodigious technology that it enables the obtention of high-value compounds from solid cultivate of microorganisms in wet agro-industrial residues [2], as such the fibers of sugarcane bagasse [3]. Promissors results have been reported by literature in laboratorial scale on the yield of compounds through FES [4]. However, the industrial scale yet is not available to use due to difficulties related to scale-up of bioreactors for FES, such as the undesirable increases of temperature during the process. Considering the use of rotation in intermittent regime as a mechanism of heat removal, the particles bed keeps static during long periods and then are periodically moved. This allows tha analysis of this process from a static bed in a horizontal drum.

The increase in the temperature observed during SSF process can promote other phenomena that deserve attention, such as the loss of water in heated regions of the bed. The recent literature has reported that the moisture content of the organic particles is directly related to bed properties as porosity and efficient thermal conductivity [5,6]. Fundamental studies have been reported about the no-reactional particulate systems in geometries similar to bioreactors and are important to understand some aspects about transport phenomena in these systems [7,8]. In this context, this work aims the proposition of heat and mass balances to describe the temperature and water profiles in a partially filled horizontal drum by a sugarcane bagasse bed, in attention to possible water remotion due to increases on the temperature.

## **2. Materials and Methods**

### **2.1. Physical situation**

The physical situation in this case study is presented in Fig. 1. The horizontal drum was built in stainless stell and has 10 cm of inner dimeater and 20 cm of length. The inner wall of the drum was kept at constant temperature (45 °C or 65 °C) and the bed was initially at 25 °C. The bed was continually heated by heat penetration through of the wall and the water removal occurrred simultaneously as a response to increases in the temperature. The fibers of sugarcane bagasse were employed at 3 kg-water/kg-dried solid, which is corresponding to the operational condition for a solid-state fermentation process [3,9].

Fig. 1. Physical situation to verify the water removal in a partially filled horizontal drum due to increase in the temperature.

## 2.2. Mathematical model

A one-dimensional and one-phase model was proposed to describing the temporal and spatial temperature and water profiles in a partially filled horizontal drum. The water balance is shown in Eq. (1). In this equation, the first term of left hand represent the temporal variation of water in the bed, the first term of the right hand represent the spatial variation of water in the radial direction and the last term represent the water removal due to increase in the temperature. In this term, it was assumed that the moisture of the particles was carried by the air amidst the porous bed. The air was continuously heated and it described radial flow through of the bed with velocity  $V_r$ .

$$\frac{\partial X}{\partial t} = D_{\text{eff}} \left[ \frac{1}{r} \frac{\partial X}{\partial r} + \frac{\partial^2 X}{\partial r^2} \right] + \frac{\rho_a}{\rho_s} V_r f \frac{dT}{dr} \quad (1)$$

The energy balance is shown in Eq. (2).

$$\rho_b C_p \frac{\partial T}{\partial t} = K \left[ \frac{1}{r} \frac{\partial T}{\partial r} + \frac{\partial^2 T}{\partial r^2} \right] + \left[ (C_{p_a} - \lambda f) \rho_a V_r \frac{\partial T}{\partial r} \right] \quad (2)$$

The initial and boundary conditions are shown in Eqs. (3) to (8).

$$t = 0, \quad \left\{ \begin{array}{l} T = T_0 \\ X = X_0 \end{array} \right. \quad (3)$$

$$X = X_0 \quad (4)$$

$$r = r_{i(0)}, \quad \left\{ \begin{array}{l} K \frac{\partial T}{\partial r} = -\alpha (T - T_\infty) \\ D_{\text{eff}} \frac{\partial X}{\partial r} = -\beta (X - X_{\text{eq}}) \end{array} \right. \quad (5)$$

$$D_{\text{eff}} \frac{\partial X}{\partial r} = -\beta (X - X_{\text{eq}}) \quad (6)$$

$$r = R, \quad \left. \begin{array}{l} T = T_w \\ D_{\text{eff}} \frac{\partial X}{\partial r} = 0 \end{array} \right| \quad \begin{array}{l} (7) \\ (8) \end{array}$$

in which  $r = r_{i(0)}$  is the superficial position and  $r = R$  represents the wall of the drum.

For the solution, the spatial variation were discretized by finite difference method. The resultant equations were written in MatLab® language and solved by *ode15s* for a geometry of a partially filled circumference, as described by [8].

### 2.2.1. Parameters of the model

The effective diffusivity of the water through the bed have been experimentally determined by [10] as a function of the temperature. The effective thermal conductivity of sugarcane bagasse bed as a function of moisture content of the fibers was extracted from [5].

The coefficients  $\alpha$  and  $\beta$  were teorically estimed using correlations available in the literature for the parallel flow of a fluid above the surface of a rugous flat plate. The velocity  $V_r$  was estimed using correlations for free convection through a packed-bed constituted by spherical particles.

### 2.2.2. Simulations and verification of the model

Simulations were carried considering the temperature of the wall ( $T_w$ ) at 45 or 65 °C and the temporal predicted profiles were compared with experimental profiles. The experimental tests were carried out in a jacketed horizontal drum (inner diameter: 10 cm, length: 20 cm). The inner wall of the drum was kept at 45 or 65 °C and the fibers of sugarcane bagasse were insered in the drum at 25 °C and about 3 kg-water/kg-dried solid in filling degree 0.5. Samples of the bed were collected to determination of moisture content in a drying oven at 105 °C until constant weight. The quality of adjustment was evaluated thorough statistical indicators such as the coefficient of determination ( $R^2$ ) and the root mean square error (RMSE).

## 3. Results and Discussion

The temporal mean temperature profiles for  $T_w$  at 45 and 65 °C are shown in Fig. 2.

Fig. 2. Temporal mean temperature profiles of a sugarcane bagasse bed in a horizontal drum with temperature of the wall drum at 45 and 65 °C.

The temperature increases subtly in the first hour as reported by [11] for a bed composed by dried fibers of sugarcane bagasse in this same horizontal drum. Discrete increase on the temperature were observed for the interval from 1 to 4 hours and the thermal equilibrium was obtained around  $t = 4$  h of process for all conditions. It indicates that the initial non-isothermal problem becomes an isothermal problem along the time and it could be approximated and solved just through a mass balance for the equilibrium temperature in the interval from  $t = 4$  h to  $t = 10$  h. The spatial moisture content profiles for  $T_w$  at 45 and 65 °C for  $t = 1$  hour (on left hand) and 10 hours (on right hand) are shown in Fig. 3.

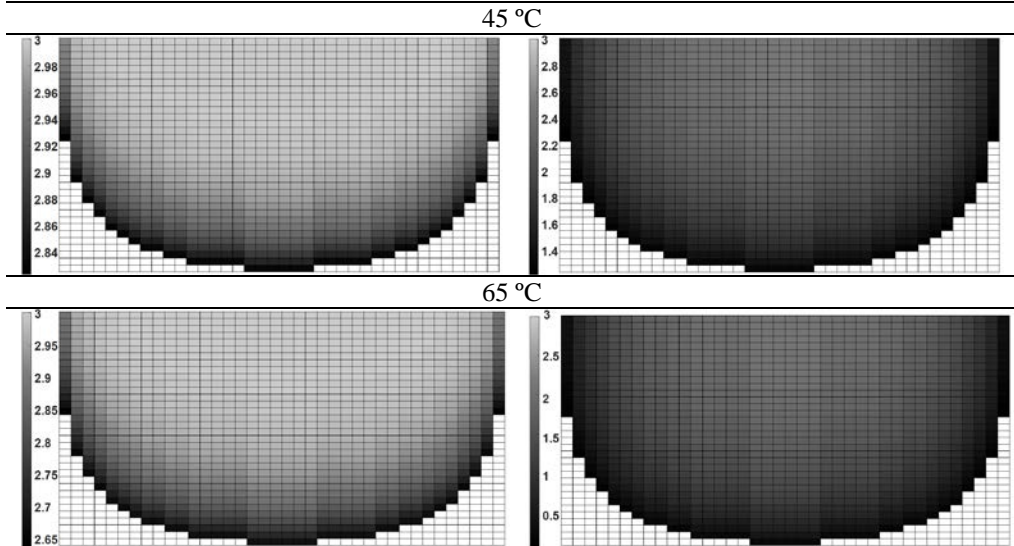

Fig. 3. Spatial moisture profiles (kg/kg-ds) of a sugarcane bagasse bed in a horizontal drum with temperature of the wall drum at 45 and 65 °C.

The mass flux was observed in the radial direction from the wall to the surface of the bed. The presence of the air in the headspace promoted discrete variation on the moisture content in the surface of the bed because the air was partially saturated on water vapor and its capacity to carry water was reduced. After 10 hours of process, the simulated profiles show that the system is near to the mass equilibrium.

The verification of the model is shown in Fig. 4 and 5 for the temperature and moisture profiles, respectively, for  $T_w$  at 45 and 65 °C. Good agreements were observed between experimental and predicted profiles and them were supported by statistical indicators ( $R^2 > 0,95$  and  $RMSE < 0,62$ ).

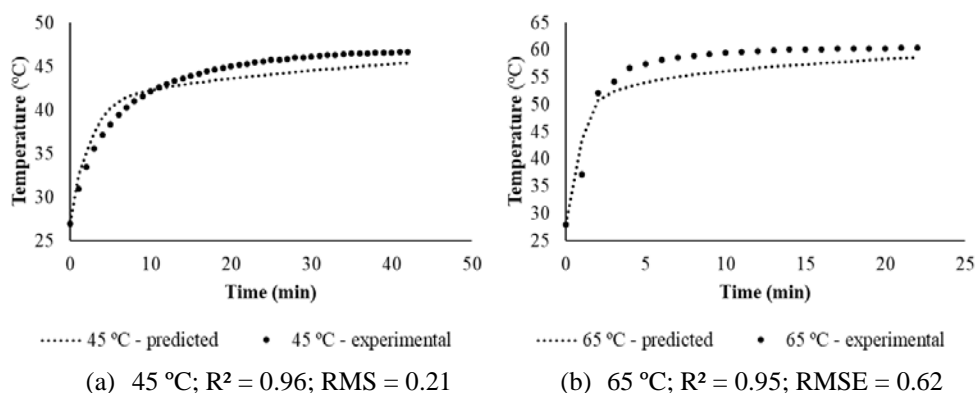

Fig. 4. Predicted and experimental temperature profiles in a horizontal drum partially filled by fibers of sugarcane bagasse ( $T_w = 45$  °C (a) or 65 °C (b);  $T_0 = 25$  °C).

Fig. 5. Predicted and experimental moisture profiles in a horizontal drum partially filled by fibers of sugarcane bagasse ( $T_w = 45$  °C (a) or 65 °C (b);  $T_0 = 25$  °C).

#### 4. Conclusions

The proposed model to describing the simultaneous heat and mass transfer in a sugarcane bagasse bed in a horizontal drum presented great adjustment with the experimental data ( $R^2 \geq 0.95$  and  $RMSE \leq 0.62$ ) for temperatures of the drum wall at 45 and 65 °C. The temporal temperature profiles shown that the thermal equilibrium is reached and the problem could be solved just through a isotherm mass balance. The loss of water in the regions near to the drum wall was visible in the spatial moisture profiles, indicating that the mass balance is sensible to increase in the temperature.

### **Abstract**

*The goal of reducing energy consumption (EC), losses and waste (FL) in the food processing is a challenge worldwide. The use of active solar greenhouse dryers (GHD) for EC and FL reductions has increased due to its capacity, and low operating costs. In this work the effective diffusivity ( $D_{eff}$ ) and the moisture content modeling were analyzed for basil (*Ocimum basilicum*) and blackberry pulp (*Rubus roseoideae*) dried in a conventional stove (CD) and an GHD coupled to an additional air solar heating system ( $SCH_a$ ). The loss of water and the drying rate in food materials dehydrated in the GHD is consistent with the increment or decrement of temperature during the solar day. The  $D_{eff}$  values for basil and blackberry pulp ranged between  $-1.1044 \times 10^{-7}$  and  $-3.9167 \times 10^{-9}$ . The solar energy obtained in the GHD supplied the heating requirements. In general, the Page's model was the best fit for the drying kinetics for basil and blackberry pulp.*

**Keywords:** Solar Collector for air heating, solar energy, variable conditions.

## 1. Introduction

In the world, 1.3 billion tons of food loss and waste are generated each year [1]. Therefore, it is necessary to implement food conservation methods. These technologies could also allow the reduction of energy consumption.

The energy consumption for food preservation in Mexico is not fully quantified. According to SENER of Mexico, (2016), 28.9% of the energy is used by the industrial sector in this country. The major energy consumption of the food industry is 43% and it is used for processing and distribution. Processing, drying, and curing are the most energy-intensive farm operations, due to the high costs of heating and the removal of moisture from the saturated air and the food matrix[2].

Drying is a unitary operation, that allows the water reduction from food, to extend its shelf life. Different solar drying systems have been used for food preservation, and they are classified as follows: direct, indirect, and mixed solar drying technologies[3]. Solar greenhouse dryers are classified as direct solar drying systems. They have been used for the drying of grains, fruits, and vegetables[3,4,5,6]. However, drying times are long and the product quality is poor[7,8].

Solar greenhouse dryers can also be connected to an air solar heating system (SCHA). The air heating concept or preheating system was recently introduced[9]. This system was used for drying of pepper, where different air mass flows rates and the drying kinetics were analyzed. The maximum temperature inside the greenhouse dryer was 45°C.

Moreover, there are drying predictive models, and, they derived from Fick's second law and Newton's law of cooling[7,8,9,10]. But, the study of effective diffusivity is necessary in this novel system. Therefore, the main objective of this work was to evaluate the moisture diffusivity of basil (*Ocimum basilicum*) and blackberry (*Rubus rosoideae*), which were dehydrated in a solar greenhouse dryer coupled with an additional air solar heating system.

## 2. Modeling

The mass transfer phenomenon in drying has been simplified when considering the liquid mass transportation according to Fick's second law, where the driving force is a concentration gradient.

$$\frac{dX_a}{dt} = -D_{Ax} \frac{d\rho X_a}{dx^2} \quad (1)$$

Considering that the water movement is unidirectional, in a case of a flat plate with a constant diffusivity, the equation (1) can be expressed according to Crank & Park[11] in the following form,

$$W = \frac{X(t) - X_e}{X_0 - X_e} = \frac{8}{\pi^2} \sum_{i=0}^{\infty} \frac{1}{(2n+1)^2} e^{-\frac{\pi^2}{4L^2}(2n+1)^2 D_{Ax} \cdot t} \quad (2)$$

Where W is the normalized moisture content. Simplifying the equation (2), the Fick's second law solution is expressed as:

$$W = \frac{X(t) - X_e}{X_0 - X_e} = \frac{8}{\pi^2} e^{-\frac{\pi^2}{4L_0^2} D_{Ax} \cdot t} \quad (3)$$

Where the diffusive coefficient ( $D_{Ax}$ ) can be evaluated considering an effective mass transference ( $D_{eff}$ ).

### 2.1. Empirical and semi-empirical modeling

Semi-empirical models are calculated for specific conditions of relative moisture, temperature, and air-drying speed. In solar drying, empirical and semi-empirical models have been used on thin plane plates to describe the behavior of W during the process (Table 1). The adjustable parameters must be calculated for each food type and drying condition. Some models are derived from the solution of Newton's law of cooling equation and others from Fick's second law (Equation 1).

Table 1. Predictive models for W

Semi-empirical models	Model	Equation	Reference
Models Resulting from Newton's Law of Cooling	Newton	$W = \exp(-kt)$	[12]
	Page	$W = \exp(-kt^n)$	[13]
	Modified Page	$W = \exp(-(kt)^n)$	[7]
Models Resulting from Fick's Second Law of Diffusion	Henderson and Pabis	$W = a \exp(-kt)$	[14]
	Logarithmic	$W = a \exp(-kt) + c$	[15]
	Two-term	$W = a \exp(-kt) + b \exp(-k_1t)$	[16]
	Two-term exponential	$W = a \exp(-kt) + (1 - a)\exp(-k_1t)$	[17]
	Midilli and Kucuk	$W = a \exp(-kt^n) + bt$	[18]
Empirical models	Wang and Singh	$W = 1 + at + bt^2$	[19]

Where W can be adjusted to the shown models in Table 1. In this work, adjustments were made to the Newton's, Page's, and Wang and Singh's equations.

### 2.2. Statistical analysis

The square root means deviation (RMSD) between the predicted and experimental data were evaluated with the following equation,

$$RMSD = \sqrt{\frac{\sum_{i=1}^{i=n} (W_{Exp,i} - W_{Th,i})^2}{n-1}} \quad (4)$$

The main deviation between the experimental data and the results produced by the model were evaluated with relative error:

$$Error(\%) = \frac{100}{n} * \sum_{i=1}^{i=n} \frac{(W_{Exp,i} - W_{Th,i})^2}{W_{Exp,i}} \quad (5)$$

The reduced chi-square value of ( $\chi^2$ ) was calculated as follows,

$$\chi^2 = \frac{\sum_{i=1}^{i=n} (W_{Exp,i} - W_{Th,i})^2}{n - N} \quad (6)$$

where  $W_{Exp,i}$  represents the experimental moisture ratio,  $W_{Th,i}$  is the humidity ratio predicted by the mathematical model,  $n$  is the number of observations and  $N$  is the number of constants.

### 3. Materials

Basil (*Ocimum basilicum*) was obtained from a local farmer in Tequesquitengo, Morelos, Mexico, and blackberry (*Rubus roseidae*) from Los Reyes, Michoacán, Mexico was used. In the basil drying case, only leaves were used. The samples were put over a perforated plastic mesh, covering a total surface of 16 m<sup>2</sup>. The blackberry was liquefied and the seeds separated. A thin layer of about  $5 \pm 1$  mm of strawberry pulp was spread over 40.4 x 26.5 cm trays. In this case, a drying surface of 8 m<sup>2</sup> was used for the drying process. The results were compared with samples dried in an electric oven at 60°C with forced convection at 1 m/s. The weight loss was measured during the drying process.

#### 3.2. Description of the drying equipment

A solar greenhouse dryer (Figs 1 and 2) was used (GHD), it was connected to an air solar heating system (SCH<sub>a</sub>). The air solar heating system was constituted by three air heating flat plate solar collectors that consist in a box with insulation, an absorber, and a glass cover. The collector dimensions are 2.10 m in length, 1.20 m in width and 0.093 m in thickness. The cover was made of texturized corrugated tempered glass with a thickness of 4 mm. The SCH<sub>a</sub> was oriented to the south and inclined at an angle of 22° to the horizontal plane to maximize the absorption of solar radiation during the test. For the air inlet to the GHD a radial fan (Air Technology, CFD-7-3, Mexico) was connected to the SCH<sub>a</sub>. Therefore, the system can be operating with natural or forced convection (Figure 1). Two air-diffusers with honeycomb structure for air distribution in the GHD was connected in the south wall. For air moisture and air flow removal from the GHD, two air fans (SilentVent, HAE 150) was connected in the north wall. The temperature was measured using Type T thermocouples (uncertainty of  $\pm 1^\circ\text{C}$ ). The solar irradiation (W/m<sup>2</sup>) outside and inside of the GHD was measured using two pyranometers (Kipp & Zonen, CMP6, Netherlands). The air humidity (HR%) was measured using sensors (AOSONG, DHT22, uncertainty of  $\pm 2\%$ ). The inlet and outlet air velocity was measured using an anemometer (Extech Instruments, SDL 350).

The tests were carry out in Temixco, Morelos, Mexico (18.85° latitude North and -99.2333° longitude East and an altitude of 1219 m above sea level). The experiments were done in the months of March, May, and June 2017. In the tests with forced convection, an air velocity of  $0.58 \text{ m/s} \pm 0.12 \text{ m/s}$  was used and a maximum irradiance of  $806 \text{ W/m}^2$  was recorded.

**Fig. 1** Solar greenhouse dryer (GHD). Outside view.

**Fig. 2** Solar greenhouse dryer (GHD), view without the plastic cover and with air heaters.

A software for data acquisition was used during the test. The data collecting was done every 30 s.

### 3. Results

The maximal average drying temperature into the greenhouse was  $44.02 \pm 1.90 \text{ }^\circ\text{C}$  with a maximal average solar irradiance of  $806.34 \pm 6.12 \text{ W/m}^2$  and inlet average air velocity of  $0.58 \pm 0.12 \text{ m/s}$  of the greenhouse. In figure 2, the drying kinetics of dehydrated basil and blackberry are observed. In the greenhouse (GHD) and electrical stove (CD), the drying kinetics are according to the typical behaviour of drying processes. The initial moisture content of basil was  $7.021 \pm 0.001 \text{ kg}_w/\text{kg}_{ds}$  and for the blackberry was  $9.470 \pm 0.422 \text{ kg}_w/\text{kg}_{ds}$ . For the basil (Figure 2a.), the drying time in the GHD was 330 minutes and in the CD was 123.8 minutes. Figure 2b shows the blackberry pulp drying kinetics, in the stove the drying time was 480 minutes. But in the GHD, the dehydration was prolonged until a second day (960 minutes).

The  $\ln(W)$  (figure 3) was used to get the linearization of equation 3[20], considering the decreasing drying rate interval. With CD, the slope is less than with GHD, due to the mean temperature of each system ( $60$  and  $43.52^\circ\text{C}$  for CD and GHD respectively).

The  $D_{\text{eff}}$  results with the slopes of the lines in fig. 3 shows a difference in the values obtained (Table 2). It can be observed that the  $D_{\text{eff}}$  values for blackberry pulp are greater than the basil; therefore, the mass transference is major in the blackberry pulp. Furthermore, the  $D_{\text{eff}}$  values

for CD indicate that a higher mass flux can be obtained. Nevertheless, the energy-saving with GHD is greater than with CD, and a good dried product was obtained in both technologies.

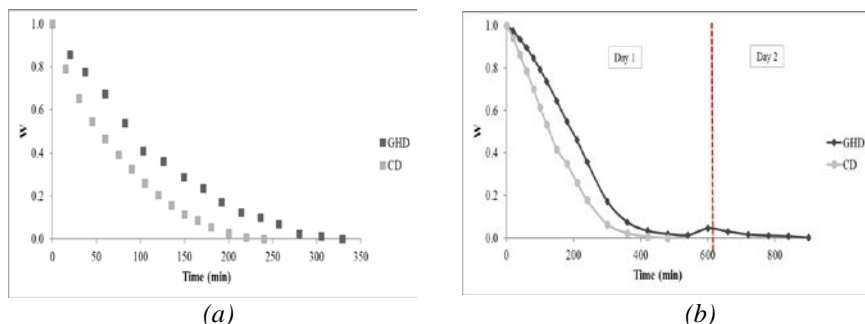

Fig. 2 Basil (a) and blackberry (b) drying kinetics, using greenhouse dehydrated (GHD) and electrical stove (CD).

Fig. 3  $\ln(W)$  vs drying times for (a) basil, and (b) blackberry pulp.

Table 2. Effective diffusivity values

	$R^2$	$D_{\text{eff}}$ ( $\text{m}^2/\text{s}$ )
CD, Blackberry	0.961	-1.3577E-07
GHD, Blackberry	0.989	-1.1044E-07
CD, Basil	0.981	-3.9167E-09
GHD, Basil	0.977	-2.5938E-09

Table 3 shows adjustable parameters and the values for Newton's, Page's, and Wang and Singh's models for the blackberry and basil experiments. In the basil-GHD, the best adjustment with Wang and Singh's equation was found, followed for Page's model. In the basil-CD, blackberry-GHD and blackberry-CD the best was with Page's, it was due to a minor value of %error,  $\chi^2$  and RMSD and major value of  $R^2$ .

#### 4. Conclusions

The loss of water and the drying rate in food materials dehydrated in the greenhouse dryer (GHD) is consistent with the increment or decrement of temperature during the solar day. The  $D_{\text{eff}}$  values for basil and blackberry pulp was ranged between  $1.1044 \times 10^{-7}$  and  $-3.9167 \times 10^{-9}$ . The  $D_{\text{eff}}$  values for CD was higher than for GHD, and in both technologies, a good dried product was obtained. In GHD the sun supplied the heating requirements for free. In general, the Page's model was the best fit for the drying kinetics for basil and blackberry pulp.

### Abstract

*This study was conducted to determine the drying characteristics of oyster mushroom (*Pleurotus ostreatus*) at 50, 60 and 70 °C. *Pleurotus ostreatus* were cleaned and dried in a laboratory cabinet dryer. The drying data were fitted to six model equations namely Newton, Pabis and Henderson, Logarithmic, Two-term diffusion, Wang and Singh, as well as Modified Henderson and Pabis equations. The goodness of fit of the models were evaluated by means of the coefficient of determination ( $R^2$ ), root mean square error (RMSE) and reduced chi-square ( $\chi^2$ ). The Logarithmic model best describes the drying data and could be used to predict its drying behaviour.*

## 1. Introduction

Drying is the removal of moisture from food material, to make it stable and thus promote its shelf life. Mushrooms are highly perishable and lose their qualities during storage. Due to the high moisture content, there is the problem of seasonal availability and wastage. The shelf life of mushrooms is only due to 2 to 5 days after harvest depending on the variety, hence there is a need for adequate preservation to ensure proper shelf stability and all year round availability without quality compromise [1]. Drying is seen as the removal of undesired moisture from a product. Many agricultural products are dried for various purposes like safe storage, easy handling, value addition, further processing and quality improvement [2]. Therefore, the drying process offers an alternative way for food material consumption and especially, the seasonal and perishable ones. The renewed interest in high quality fast-dried foods [3] and the upward swing in the demand for convenient foods including ready to eat and instant products, which are desired to contain the minimum quantities of additives and preservatives [4] is increasing the interest in drying operations. The drying process can be carried out using the sun (solar drying), though it is cheap however this method of drying is time consuming, it is climate dependent, time consuming and produces products of low quality especially in terms of colour and microbial infestation. Hence the conventional means of drying is a better alternative because they were able to overcome this short coming even though, they may be more expensive and out of all the different mechanical means of drying such as drum dryer, freeze dryer, fluidized bed dryer, the hot air oven drying (cabinet dryer) is the most commonly used because they are generally acceptable and they are cheaper. Drying kinetics is generally evaluated experimentally by measuring the weight of a drying sample as a function of time. Drying process can be described completely using an appropriate drying model, which is made up by differential equations of heat and mass transfer in the interior of the product and at its interphase with the drying agent. The drying behaviour of biological materials can be predicted using many thinlayer drying mathematical models which have been classified into three groups namely; theoretical (Fick's second law of diffusion), semi-theoretical (Lewis, Page, modified Page, Henderson-Pabis, logarithmic, Two-term, Two-term exponential, approximation of diffusion, Verma, etc.), and empirical (Wang-Singh). These models have been found to be drying time and constants, dependent while influence of all other factors is negligible [5]. The objectives of this study therefore were to: (i) to study the drying kinetics of oyster mushroom specie (*Pleurotus ostreatus*) in a cabinet dryer, (ii) to evaluate a suitable thin layer drying model, and (iii) the optimum temperature of drying at which best quality product is obtainable.

## 2. Materials and Methods

### 2.1. Material

Freshly harvested samples of oyster mushrooms (*Pleurotus ostreatus*) were cleaned and used for the drying study. Before the commencement of a drying test, the initial moisture content of the mushrooms was determined.

## 2.2. Experimental procedure

Drying experiments were performed in a laboratory cabinet dryer designed in the Department of Food Science and Technology, Federal University of Technology, Akure, Nigeria. The dryer consists of a centrifugal fan to supply the air flow, an electric heater, and an electronic proportional controller. The temperature and relative humidity in the drying chamber were measured by temperature sensor (accuracy  $\pm 1\%$ ) and relative humidity sensor (accuracy  $\pm 2\%$ ), respectively. The air velocity in the drying chamber was measured with a Tri-Sense hot wire probe anemometer (accuracy  $\pm 2\%$ ). Air flow was perpendicular to the drying surfaces of the samples and the hot air used in the drying process was circulated in the cabinet. The dryer was started about one hour before each drying run to achieve steady-state conditions. After the dryer had reached this condition, 100 g samples of the mushroom were uniformly spread in a single layer on a sample tray and were dried. The drying experiments were performed at 50, 60 and 70 °C air temperatures. The air velocity was kept constant at 0.6 m/s in all drying experiments. Relative humidity of the ambient air changed between 21% and 23%. During drying, the samples were removed at intervals and weighed. Removing, weighing, and replacing the mushrooms took about 1 min. The weight loss of the samples was recorded using an electronic balance (Midfield, MF-1000, Göttingen, Germany) in a range of 0–1100 ( $\pm 0.01$ g) at hourly intervals until no measurable weight loss was observed. At the end of each drying experiment, the final moisture content of the sample was determined. Moisture contents were reported on wet basis. The amount of dry matter was calculated by using the mean final moisture content and the weight of the dried mushrooms [6]. All the experiments were replicated three times at each air temperature and the average values were used. Calculations of the moisture ratio, correlation coefficient, mean bias error, random square error and fitting the values generated into six drying models were carried out [6].

### 2.2.1. Moisture ratio

The moisture ratio (MR) of oyster mushrooms during the single layer drying experiments was calculated using equation (1).

$$MR = \frac{M_t - M_e}{M_0 - M_e} \quad (1)$$

Some investigators [7]; [6]; [8] observed continuous fluctuations in the instantaneous moisture content during the drying processes, and therefore reduced equation (1) to:

$$MR = \frac{M_t}{M_0} \quad (2)$$

where MR indicates the moisture ratio (dimensionless quantity),  $M_0$  the initial moisture content (kg water/ kg dry matter,  $M_t$  the instantaneous moisture content at time  $t > 0$  (kg water/kg dry matter), and  $M_e$  the equilibrium moisture content (kg water/ kg dry matter).

### 2.2.2. Drying rate

The drying rates of the samples were calculated using equation (3)

$$\frac{dM}{dt} = \frac{M_{(t+\Delta t)} - M_t}{\Delta t} \quad (3)$$

where  $\frac{dM}{dt}$  denotes the drying rate and  $\Delta t$  is elemental time increment (hr).

## 2.3. Mathematical modelling of the drying curve

The drying curves obtained were evaluated to find the most suitable model for describing the drying process of the selected mushroom species. Drying curves data were fitted into six (6) thin-layer drying equations at three temperatures 50, 60 and 70 °C. The drying curves obtained were processed for drying rates to find the most convenient model among the six different expressions (Table 1). A nonlinear regression analysis was performed using the SigmaPlot and Microsoft Excel 2010 Statistical software to evaluate model parameters and determine the predicted moisture ratio for each model equation. The correlation coefficient ( $R^2$ ) is generally considered one of the primary criteria for evaluating the goodness of fit of a drying model. It was therefore used for comparing the predictive ability of the models in this study. Other criteria used for model evaluation and comparison are reduced chi-square ( $\chi^2$ ) and root mean square error (RMSE). The model with the highest  $R^2$  and lowest  $\chi^2$  and RMSE was considered to best fit the drying data [9], [10]. Both  $\chi^2$  and RMSE were calculated, respectively, from the following equations.

$$\chi^2 = \frac{1}{(N-n)} \sum_{i=1}^N (MR_{o,i} - MR_{p,i})^2 \quad (4)$$

$$RMSE = \sqrt{\frac{1}{N} \sum_{i=1}^N \left( \frac{MR_{o,i} - MR_{p,i}}{MR_{o,i}} \right)^2} \quad (5)$$

Where MR and  $\overline{MR}$  are the instantaneous and average moisture ratio values, while the subscripts o,i and p,i denote the  $i^{\text{th}}$  observed (i.e. experimental) and predicted moisture ratio, respectively. N is the number of observations, and  $n$  is the number of constants in the drying model.

### 3. Results and Discussion

The changes in the moisture content during drying of the three species of oyster mushrooms are presented in Fig. 1 at different temperatures of 50, 60 and 70 °C. The drying behaviour of the samples exhibited the characteristic moisture desorption behaviour. High rate of moisture removal was observed, followed by the slower moisture removal in the later stages. This characteristic behaviour can be attributed to the various forms in which water is present in the food products. In the progression of drying process, the moisture ratio was observed to decrease non-linearly with respect to drying time for all the samples. Various reporters such as Doymaz [11] and Kingsley *et al.* [12] also observed that it is a general trend adopted by other food products such as sweet potatoes and mulberry. The drying rate for the *Pleurotus ostreatus* decreased with time and decreasing moisture contents and drying occur in the falling rate period. There was no constant rate-drying period in the entire drying process from the curves shown in Figure 1, all the drying process occurred in falling drying period, rather there was an increasing drying rate as drying progressed, which shows that drying is govern by the intense internal water and vapour flow and the drying processes were mainly controlled by diffusion mechanisms. The time taken for drying of mushroom samples varied with drying temperature, the drying time decreases with increase in drying temperature, the drying time was higher at 50°C and lowest at 70 °C for all the samples. This trend agrees with the observation of several authors on the drying of various food materials [13], [14], [15].

#### 3.1 Mathematical Modelling of Drying Curves

Table 1 shows the result of the statistical analysis for the six models namely; Newton, Pabis and Henderson, Logarithmic, Two-term, Wang and Sighn and Modified Henderson and Pabis. Drying constants a, b, c, d, g and h for the thinlayer drying obtained from drying data (moisture ratio against drying time) for the *Pleurotus ostreatus* mushrooms at varied temperatures 50, 60 and 70 °C at fixed air velocity 1 m/s respectively. The regression results presented in Tables 2 shows that Logarithmic model gave the lowest RMSE and  $\chi^2$  when compared with the other five models. It also gave the highest  $R^2$ . Hence it is the model that best fits the drying of *Pleurotus ostreatus* mushrooms. This agrees with Doymaz [16] who reported that the Logarithmic model equation as the best fit model. However, this is at variance with Tulek [17] who reported that the model of Midilli *et al.* [8] is the best fit model to predict the drying characteristics of mushrooms.

### 3. Conclusions

The drying behaviour of oyster mushroom (*Pleurotus ostreatus*) exhibited the characteristic moisture desorption behaviour. High rate of moisture removal was observed at the beginning, followed by a slower rate moisture removal at the later stages. The drying rate for the *Pleurotus ostreatus* decreased with decreasing moisture contents and drying occur in the falling rate period, with internal diffusion in the mushroom. An increase in the drying temperature reduced the drying time and increased the drying rate. Drying air temperature of 60 °C was found to be better as it gave dried product with lower shrinkage, better colour and better crispness. Logarithmic model gave the best fit to the drying data, and thus considered to best predict drying characteristics of *Pleurotus ostreatus*.

### Abstract

*The purpose of this work was to study the drying process of Ca(II)-alginate beads with/without sucrose, monitored by infrared thermography (IRT), in order to describe the critical points and the transformations suffered by the systems. Beads were obtained by the drop method and the drying process was performed at 40 °C and 1.5 m/s. IRT was measured by a thermal imager Optris PI<sup>®</sup> 160. Mass,  $a_w$ ,  $x_w$  and volume were also obtained. It was demonstrated that IRT is a good monitoring tool, able to analyze heat transfer in colloidal systems. A thermodynamic model able to predict the mechanical phenomena of the beads throughout drying process has been developed.*

**Keywords:** encapsulation; thermodynamic; spectrophotometry; drying; beads.

## **1. Introduction**

Over the years, crosslinked hydrogels have been widely studied as suitable matrices for the stabilization and controlled release of biomolecules, both in the food, chemical and pharmaceutical industries <sup>[1]</sup>. Ca(II)-alginate is one of the anionic polyelectrolyte most used for the encapsulation of bioactive compounds due to its low-cost, its non-toxic character, eco-friendly and biocompatibility <sup>[2,3]</sup>. Nevertheless, Ca(II)-alginate shows some disadvantages such as high biomolecule leakage, low mechanical strength and large pore size <sup>[4]</sup>. Moreover, their high water activity also make them susceptible of microorganism deterioration <sup>[5]</sup>. Therefore, the coupled application of conservation treatments, such as hot air drying and the addition of protective disaccharides (as sucrose) can improve the stability of the hydrogels.

Drying operation is one of the most widely used unit operations to preserve products over time, and it involves a lot of mechanisms coupled together <sup>[6,7]</sup>. According to the traditional kinetic theory, it is divided into three main stages: induction period, constant drying velocity period and falling drying rate period <sup>[8]</sup>. An innovative technique used to control this process is the infrared thermography (IRT). IRT is an excellent method, used for studying heat transfer, which converts the radiation emitted by a body surface into temperature data without establishing contact with the object <sup>[9]</sup>. Taking into account that drying process involves a lot of mechanisms coupled together, where heat and mass transfers and mechanical effects take place simultaneously <sup>[10]</sup>, the combined used of irreversible thermodynamics and infrared thermography represents a good and promising tool.

The aim of this research is to determine the real critical points in the transformation of Ca(II)-alginate beads with/without sucrose during the drying process, by means of an irreversible thermodynamic model which considers gradients of activity, temperature and mechanical energies.

## **2. Materials and Methods**

### **2.1. Materials**

Sodium alginate (Algogel 5540) from Cargill S.A. (San Isidro, Buenos Aires, Argentina), molecular weight of  $1.97 \cdot 10^5$  g/mol and mannuronate/guluronate ratio of 0.6; D-sucrose (Scharlab S.L., Barcelona, Spain), molecular weight of 342.2 g/mol. 0.05 M sodium acetate buffer pH 3.8 was prepared from acetic acid and sodium acetate (Scharlab S.L., Barcelona, Spain) <sup>[11]</sup>.

### **2.2. Hydrogel beads preparation**

Two different formulations were used: alginate (A) and alginate-sucrose (AS). All the solutions were prepared in 0.05 M sodium acetate buffer pH 3.8. For A beads preparation, 25 mL of 1% (w/v) sodium alginate solution was dropped into 250 mL of 2.5% (w/v) CaCl<sub>2</sub> (Scharlab S.L., Barcelona, Spain) solution. For AS preparation, a 1% (w/v) alginate with 20%

(w/v) sucrose was dropped into the 2.5% (w/v) CaCl<sub>2</sub> solution supplemented with 20% (w/v) sucrose using the same procedure previously described. A peristaltic pump (Damova S.L., Barcelona, Spain, model CPM-045B) was used to Ca(II)-alginate bead production according to the drop method described by Traffano-Schiffo et al., (2017), with a pump speed at  $20 \pm 0$  rpm, regulated by an inverter Panasonic DV-700 (Osaka, Japan) <sup>[12]</sup>. The CaCl<sub>2</sub> solution (with or without sucrose) was maintained in a cold bath with constant stirring by using a vortex IKA® MS3 basic (IKA, Staufen, Germany). A needle with 0.25 mm diameter and 6 mm length (Novofine 32 G, Novo Nordisk A/S, Bagsvaerd, Denmark) was used for the dropping. The distance between the needle and the CaCl<sub>2</sub> solution was 6.0 cm. After beads generation, they were maintained for 15 min in CaCl<sub>2</sub> solution (with constant stirring), and then they were washed 5 times with bidistilled cold water ( $5 \pm 1$  °C) in order to remove free Ca<sup>2+</sup>. Then, they were maintained at 4 °C until the drying treatment and further characterization.

### **2.3. Drying process**

Ca(II)-alginate beads were placed into the interior of a conventional air dryer. Considering previous results, the temperature and the optimal air velocity values were determined at 40 °C and 1.5 m/s, during a total drying time previously optimized at 22 and 24 min for A and AS, respectively. The drying air flow was kept turbulent to prevent the boundary layer from preventing inhomogeneous drying of the samples. The mass of the beads was measured continuously by a balance Mettler Toledo AB304-S (Greifensee, Switzerland) with a precision of  $\pm 0.001$ . The infrared analysis was carried out following the method described by Traffano-Schiffo et al. (2014) <sup>[13]</sup>, using an infrared camera (Optris PI® 160 thermal imager, Optris GmbH, Berlin, Germany) installed in front of the sample, at an angle of 45° relative to the plane in which the samples were placed. The camera uses a two-dimensional Focal Plane array with 160x120 pixels, a spectral range of 7.5-13 μm, resolution of 0.05 °C and an accuracy of  $\pm 2\%$ . A reference material of known emissivity ( $\epsilon = 0.95$  - Optris GmbH) was placed next to the samples and recorded with the infrared camera with the aim to correct the emissivity of the sample. Also, the temperature of the drying air, beads, reference material and environment were measured with K-thermocouples connected to an Agilent multiplexer 34901A (Agilent Technologies, Malaysia) and registered by an Agilent Data Acquisition equipment 34972A (Agilent Technologies, Malaysia). Thermal images were analyzed by the software Optris PI Connect (Optris GmbH). After the drying treatment, the samples were kept in aqualab® disposable sample cups, sealed with parafilm® for further analysis. Mass, water activity, moisture, size and shape were measured in wet samples, immediately after drying (non-equilibrated samples) and also after 24 h at 4 °C in order to allow them to reach the equilibrium (equilibrated samples).

## 2.4. Hydrogel beads characterization

Water content ( $x_w$ ) was obtained gravimetrically by the weight difference of the beads. The drying conditions were previously described by Santagapita et al. (2008). Water activity ( $a_w$ ) of beads was determined by a dew point Hygrometer Decagon (Aqualab®, series 3 TE, Decagon Devices, Pullman, WA, USA), using a special sample holder. A calibration curve was performed with saturated salt solutions of known  $a_w$ . Measurements were made in duplicate. The size and shape were analyzed through digital images captured by a digital camera and analyzed by the free license software ImageJ (<http://rsbweb.nih.gov/ij/>), as was described by Aguirre Calvo & Santagapita (2016) [14]. At least 30 wet or dried beads of each system were analyzed.

## 3. Results and discussion

In order to obtain the surface (interfacial) temperature during beads drying, an infrared model has been developed. There are two phenomena involved in the transformation of the energy that reaches the pyrosensor of the infrared camera at the real surface temperature of the sample. Firstly, the fluid located between the pyrosensor and the emitter sample (in this case is air) could be not totally transmitter, inducing a default error to the energy received. Secondly, the energy of the environment produces an overestimation of the energy emitted by the surface of the sample, adding an error in excess for the measured temperature. Therefore, it is necessary to include these phenomena as was previously developed by Traffano-Schiffo et al. (2014) [13].

In order to calculate the real temperature that is emitted by the surface of the sample obtained by the infrared camera, it is necessary to know the emissivity of the sample. Thus, comparing the temperature of the reference surface obtained by the thermocouple and the infrared camera (corrected with its known emissivity  $\epsilon_{ref} = 0.95$ ), it is possible to calculate the energy being overestimated by reflection of the environment (Eq. 1). Once this energy is known, with the temperature data obtained with the thermocouple and the camera, it is possible to calculate the emissivity of the sample.

$$E_T^{ref} = \epsilon_{ref} \cdot \sigma \cdot T_{ref}^4 + E_{surr} \quad (1)$$

Where  $E_T^{ref}$  is the energy flux of the reference material ( $W/m^2$ ) and  $T_{ref}$  is the temperature registered by the K-thermocouple (K) and  $E_{surr}$ , the energy flux emitted by the surroundings ( $W/m^2$ ).

Figure 1 shows the surface temperature of the sample and the emissivity calculated for A samples. It is possible to observe that until 15 min the drying temperature is not reached (remaining at wet temperature), indicating that the mobility of the water inside the Ca(II)-alginate matrix is so high because the water transport is controlled by the superficial evaporation, from this minute, the internal mechanisms regulate the dehydration process.

Fig. 1. Surface temperature variation (♦) and emissivity evolution (▲) of alginate beads.

In order to model the transport, it has been necessary to characterize the mean water activity of the beads with regard to their moisture. Figure 2 shows the sorption isotherms obtained by the dynamic technique [8], for each sample.

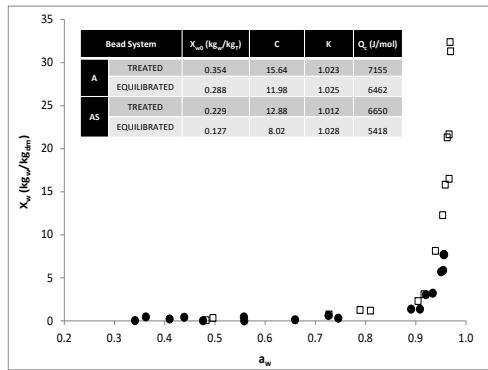

Fig. 2. Desorption isotherm (equilibrated samples), where (□) corresponds to alginate and (●) alginate-sucrose beads. The table shows the GAB parameters obtained.

With the aim to describe the different behaviors involved in the drying process, a thermodynamic approach has been developed. Gibbs free energy variation can be explained by the following equation [15]:

$$dG = -SdT + VdP + Fdl + \psi de + \sum_i \mu_i dn_i \quad (2)$$

Where  $SdT$  corresponds to the thermic term and it is directly related to heat fluxes,  $VdP$  and  $Fdl$  are the mechanical energies related to the structural changes; corresponding to the pressure variation and to the elongation force, respectively; and  $\psi de$  represents the effect of the electric field induced by solved ions. The term  $\sum_i \mu_i dn_i$  corresponds to the activity term and is the addition of the chemical potentials of the “ $i$ ” component, being constant the rest of state variables.

If the variation of free energy per mole of water is considered, it is possible to define the extended water chemical potential ( $\Delta\mu_w$ ) (J/mol) as the quotient between the variation of the Gibbs free energy (J) and the variation of moles of water (mol). From the extended water chemical potential and Eq. 2 it is possible to obtain Eq. 3. It should be note that the terms  $Fdl$  and  $\psi de$  can be neglected because Ca(II)-alginate beads are an elastic system and there is no ions effect in the medium, respectively.

$$\Delta\mu_w = -s_w (T^{air} - T^{samp}) + v_w (p^{air} - p^{samp}) + RT^{samp} \ln \frac{a_w^{samp}}{\phi^{air}} \quad (3)$$

Where  $s_w$  corresponds to the partial molar entropy of water (J/K mol);  $v_w$ , the partial molar volume of water ( $m^3/mol$ );  $P$ , the pressure (Pa);  $R$ , the ideal gases constant (8.314472 J/K mol) and  $\phi$ , the relative moisture. The superscripts *samp* and *air* refer to the sample and the air surrounding it, respectively.

Once the entropic and the activities terms are obtained, it is possible to calculate the water chemical potential without considering the mechanical terms  $\Delta\mu_w^*$  (Fig. 3). In the Figure, it is possible to observe how, for AS beads, the gradient decreases much earlier than A beads. This is due to the effect of higher water activity values in alginate samples, which allows them to maintain a higher value of water activity for longer.

Fig. 3. Water chemical potential evolution without considering the mechanical terms, where (□) corresponds to alginate and (●) alginate-sucrose beads.

Applying the first relation of Onsager<sup>[13]</sup>, the water molar flux ( $J_w$ ) ( $mol/s\ m^2$ ) is related to the water chemical potential, as a driving force of the water transport, by the phenomenological coefficient ( $L_w$ ) ( $mol^2/J\ s\ m^2$ ) (Equation 4).

$$J_w = L_w \cdot \Delta\mu_w \quad (4)$$

Applying Eq. 4 with data of chemical potential without considering the mechanical terms and the water fluxes, it is possible to obtain the phenomenological coefficient without considering the mechanical term ( $L_w^*$ ). Figure 4 shows the evolution of the phenomenological coefficient, calculated without mechanical terms during drying. It is possible to observe how the coefficient increases from minute 15 to compensate the imbalance between the water flux and the chemical potential obtained from the terms of activity and entropy, when it would be expected to follow a proportionality between both extensive variables as the relation of Onsager shows.

There is a linear relationship between the phenomenological coefficient without considering the mechanical terms and the water flux during the entire drying process in both systems. Therefore, following this linear prediction of the phenomenological coefficient and extending

it for the entire drying treatment, the mechanical terms could be estimated from the following equation:

$$v_w \Delta P = \Delta\mu_w - \Delta\mu_w^* \quad (5)$$

Fig. 4. Phenomenological coefficient evolution during drying, where (□) corresponds to alginate and (●) alginate-sucrose beads.

Figure 5 shows the evolution of the pressure term during drying process for both systems. As can be observed in this figure, the alginate samples suffer strong over atmospheric pressures from the minute 15 of the process caused by a great contraction of the system, which greatly accelerates the dehydration process. However, alginate-sucrose samples suffer the contraction process from minute 10, generating minor overpressures. This indicates that the addition of sucrose to the Ca(II)-alginate structure weakens the mechanical resistance to the shrinkage of the matrix, reducing its capacity to store liquid phase.

Fig. 5. Evolution of the pressure term during drying process, where (□) corresponds to alginate and (●) alginate-sucrose beads.

#### 4. Conclusions

It has been demonstrated that IRT is a good tool to control the drying process of Ca(II)-alginate beads, providing valuable information about the heat transfer in colloidal systems, being possible to obtain the evolution of the beads emissivity during drying.

It has been developed a thermodynamic model based in Gibbs free energy. The desorption isotherm was also obtained.

### **Abstract**

*Puffing is an attractive alternative for the production of healthy crisp snacks without frying. Although image analysis has been used in some prior studies to evaluate puffing, such an evaluation was made only in one or two dimensions, which is inadequate when a sample deforms in three dimensions. In this study, use of combined hot-air and microwave drying to dry and puff banana slices was first evaluated. Algorithms were then developed to characterize the changes in the appearance of puffed banana slices. Various image-based parameters, both in two and three dimensions were assessed and used to monitor the puffing.*

**Keywords:** *Deformation; Puffing; Image analysis; Physical properties; Surface texture*

## **1. Introduction**

Snacks, especially those made from fruits and vegetables, have recently received increasing attention and are widely consumed by health-conscious consumers. Such an increased consumption is due to the fact that modern consumers are paying more attention to their health and trying to switch from traditional to non-sugary and low-fat or even fat-free snacks. Low-fat or fat-free snacks, which are produced by hot air drying, however, suffer important drawbacks; these snacks generally exhibit inferior texture to those obtained via the process of frying. An alternative drying technology is clearly needed to alleviate the drawbacks. Combined hot-air and microwave drying has indeed been suggested and applied to produce dried fruit snacks with more desirable texture.[1] The superior texture is due to puffing, which occurs due to rapid expansion of the fruit microstructure as a result of rapid internal evaporation of water into vapor that cannot escape from such a microstructure at an adequate rate.

Puffing is generally evaluated and reported in terms of volumetric deformation, which is calculated as the ratio of the volume of a sample after drying to that before drying.[2] However, volumetric deformation cannot be used to describe non-uniform or irregular puffing, which normally takes place and can significantly affect the appearance and hence the consumer's acceptance of a final product.[3] It has in fact been reported that two pieces of a material may exhibit similar volumetric shrinkage (or deformation) despite the fact that they had gone through different methods of drying and clearly possess different forms (shape and size) of deformation.[4]

Although image analysis has been used in some earlier studies to evaluate deformation during drying, attempts were usually made only to evaluate deformation in one or two dimensions, which is not adequate when a sample deforms non-uniformly[3] or exhibits irregularly rugged surface in three dimensions such as in the case of puffing. This is simply because one and two dimensional imagings are much easier than three-dimensional imaging, eventhough they cannot accurately well represent deformation.[3] In addition, despite some recent attempts to describe deformation using indicators derived from image-based information, most studies only focused on uniform deformation of simple shapes, e.g., spherical, cylindrical and cubical shape.[3] The ability to precisely identify the shape and its changes of an irregularly shaped materials remains a challenge.

In this study, the use of combined hot-air and microwave drying to dry and puff banana slices was first evaluated. Algorithms and software were developed to characterize the changes in the appearance of puffed banana slices. Various image-based parameters, both in two dimensions (i.e., projected area, major and minor axes, equivalent diameter, perimeter, fractal dimension, extents, form factor and aspect ratio) and three dimensions

(i.e., image-based volume, surface area, sphericities, Wadell's roundness, radius ratio and Hoffmann shape entropy), were assessed and used to monitor the puffing.

## 2. Materials and Methods

### 2.1. Banana slices preparation

Banana of the Namwa variety (*Musa sapientum* L. (ABB group)) was used in this study. Banana was purchased from a local supermarket and kept at room temperature ( $28^{\circ} \pm 3^{\circ}$  C) until its total soluble solids (TSS) reached  $28.5^{\circ} \pm 0.5^{\circ}$  Brix. Banana was peeled and sliced to the dimensions of  $5 \pm 0.5$  mm in thickness and  $30.0 \pm 2.0$  mm in diameter; the dimensions were measured by a Vernier caliper (Winston, Japan).

### 2.2. Drying and puffing experiments

Drying experiments were conducted in a convective hot-air dryer (Memmert, UF30, Germany) at  $70^{\circ} \pm 5^{\circ}$  C until the banana moisture content reached either 10, 20, 30 or 40% dry basis (d.b.). Puffing was then conducted in a domestic microwave oven (Samsung, MS23K3513AW, Malaysia) at an input powder of 800 W for either 0, 20, 40 or 60 s.

### 2.3. Image acquisition

Two-dimensional images of banana slices were first taken via the use of a scanner (Epson, V30, Indonesia) at 300 dpi with black background to reduce the shadow. Three-dimensional images were produced from the two-dimensional images as per the procedures developed by Jinorose et al.[3] Two-dimensional images were preprocessed by MeshLab (ISTO-CNR, Visual computing Laboratory) to reduce unwanted objects and then reconstructed using Autodesk Recap 360 software (Autodesk Inc., San Rafael, CA) into three-dimensional images.

### 2.4. Image analysis

Each 2D image was preprocessed and analyzed using MATLAB<sup>®</sup> (version R2015b, MathWorks Inc., MA). Image segmentation was conducted by converting RGB image into binary image using Otsu's thresholding method. Edge detection and holes filling were performed to segment the area of interest (AOI). All the basic image parameters including projected area, major axis length, minor axis length, equivalent diameter, perimeter and extent were calculated using the functions of MATLAB<sup>®</sup> image processing tools box. Other parameters were also calculated as per the following equations.[5]

$$\text{Extent 2} = \frac{A}{D_{f\max}D_{f\min}} \quad (1)$$

$$\text{Form factor} = \frac{4\pi A}{P^2} \quad (2)$$

$$\text{Aspect ratio} = \frac{D_{\text{fmax}}}{D_{\text{fmin}}} \quad (3)$$

In the case of 3D analysis, after a 3D image was reconstructed, the image was converted into an STL file and imported into COMSOL Multiphysics® version 3.5 (COMSOL, Inc., Sweden) to calculate the image-based volume, surface area, sphericity, Wadell's sphericity, Wadell's roundness, radius ratio and Hoffmann shape entropy.[5,6] 'fine mesh' setting was adopted when assigning meshes to the object prior to the calculation.

$$\text{Sphericity} = \frac{(36\pi)^{\frac{1}{6}} V^{\frac{1}{3}}}{SA^{\frac{1}{2}}} \quad (4)$$

$$\text{Wadell's sphericity} = \frac{SA_v}{SA} \quad (5)$$

$$\text{Wadell's roundness} = \frac{4A}{\pi D_{\text{fmax}}^2} \quad (6)$$

$$\text{Radius Ratio} = \frac{R_{\text{min}}}{R_{\text{max}}} \quad (7)$$

$$\text{Hoffmann shape entropy} = \frac{1}{\ln(\frac{1}{3})} \sum_{i=1}^3 p_i \ln p_i \quad (8)$$

## 2.5. Moisture content determination

The moisture content of a sample was determined as per AOAC method 984.25 (2000).

## 2.6. Volume determination

The volume of a sample was determined as per the methods of Yan et al.[7] The sample was suspended in 125 mL of 95% *n*-heptane, which was filled in a 250-mL beaker placed on a 3-digit balance (Want, WT3203N, China).

All experiments were performed in triplicate and the results, where appropriate, are reported as mean values and standard deviations.

## 3. Results and discussion

### 3.1. Drying of banana slices

Preliminary experiments revealed that banana slices suffered phase transition and stuck to the tray when drying was conducted at 90° C. Drying was therefore conducted at 50 and 70° C; the degrees of puffing (or deformation) and visual appearance were noted to be almost the same at the same moisture content either when drying was conducted at 50 or

70° C. As a result, drying at 70° C was finally selected in the interest of time and energy conservation.

### 3.2. Puffing of banana slices

After drying to the predetermined moisture content, puffing was conducted. Selected images of the samples at different puffing time are shown in Fig. 1. Deformation occurred rather uniformly until about 40 s, after which the sample started to deformed non-uniformly. This visually observed critical point corresponded to the moisture ratio of around 0.4-0.5 (Fig. 2a).

*Fig. 1 2D images of banana slices during puffing.*

The evolution of the degree of puffing (volumetric deformation) as a function of the moisture ratio with moisture content prior to puffing as a parameter is shown in Fig. 2b. Degree of puffing increased linearly even when the moisture ratio reached around 0.2 (or the puffing time of around 60 s as seen in Fig. 2a). It is important to note that the degree of puffing, which was obtained from liquid displacement measurement, could not identify the start of the non-uniform deformation period, which took place at around 40 s as mentioned earlier.

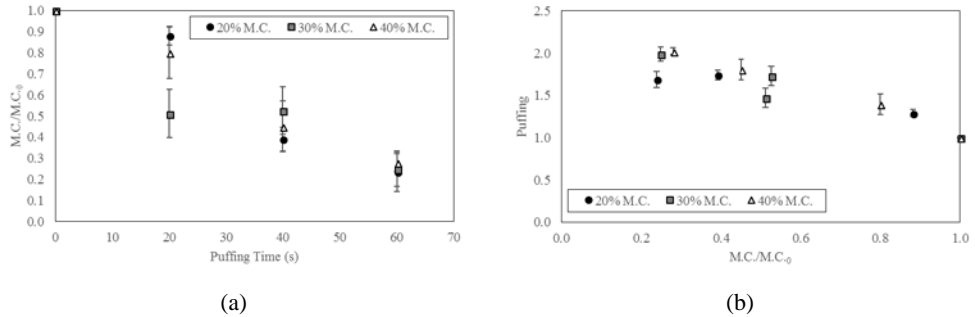

Fig. 2 (a) Moisture ratio as a function of puffing time of banana slices.  
(b) Degree of puffing of banana slices as a function of moisture ratio.

### 3.3. Image-based information

Fig. 3a shows the evolutions of the 2D image-based parameters as a function of the moisture ratio of banana slices undergoing puffing. When considering which parameters could be used to describe the non-uniform deformation (or, in other words, change of shape), only the aspect ratio and extent 2 could be used. It is seen that while other parameters stayed unchanged, these two parameters started to vary significantly when the moisture ratio was around 0.5, beyond which their values started to increase. This corresponded to the critical point where non-uniform deformation was observed to start (see Fig. 1). Nevertheless, these two parameters could only identify the onset of the non-uniform deformation but not the deformation itself. These 2D parameters could also not be used to monitor the volume change of the samples, as expected. Since puffing naturally involves the change of volume, inability to monitor such a change is clearly inadequate.

Fig. 3 (a) Evolutions of image-based parameters as a function of moisture ratio of banana slices undergoing puffing.  $P$  = parameter of interest;  $0$  = initial value.

Interestingly, form factor and fractal dimension, which are widely used to indicate circularity and shape changes, remained unchanged over the whole puffing period. This incorrectly implies that banana slices retained their shape throughout the process, which contradicted to the visual observation results. This is most probably because 2D top-view images are not adequate for the evaluation of a sample with rugged surface (as in our case of puffed banana slices). For this reason, choosing appropriate parameters is very important if non-uniform deformation is to be monitored; widely used parameters cannot always be used for such a purpose.

Fig. 3b shows the evolutions of the 3D image-based parameters as a function of the moisture ratio of banana slices undergoing puffing. The volume and surface area values were those of the reconstructed 3D images; the values increased with decreasing moisture ratio. Only the Wadell's sphericity exhibited a similar trend to the aspect ratio and extent 2 (started to decrease after the moisture ratio was lower than 0.5) and might be able to be used to monitor the non-uniform deformation.

Based on the aforementioned observations, volume and surface area along with the Wadell's sphericity should be used to monitor the puffing of banana slices. Fig. 4 indeed illustrates that the volume as obtained from image analysis agreed well with the values obtained from the liquid displacement experiments.

*Fig. 4 Evolutions of 3D image-based parameters as a function of volume ratio of banana slices undergoing puffing. P = Parameter of interest; 0 = initial value.*

#### 4. Conclusions

Image analysis algorithms were developed to characterize puffing, which is a non-uniform deformation phenomenon, of banana slices in three dimensions. Various image-based parameters, both in 2D and 3D, were calculated and tested for their suitability to monitor such a deformation. As for the 2D-based parameters, aspect ratio and extent 2 could be used to indicate the start of the non-uniform deformation period; Wadell's sphericity represented the 3D-based parameters that could be used to perform the similar task. These parameters, however, could not be used to monitor the volume change of the samples. 3D-based volume

and surface area along with the Wadell's sphericity should instead be used to monitor the puffing of banana slices.

## 1. Introduction

The thermal performances of constructions are getting more and more challenging and designers need to model physical phenomena with great accuracy [1-3]. Among them, the strong influence of coupled heat and mass transfer on energy consumption is well established. This is especially true for renewable materials, which generally have a high moisture buffering effect. Consequently, Building Energy Simulations (BES) models must account for coupled heat and mass transfer, which gave rise to a strong demand for mass transfer characterization: mass diffusivity and sorption isotherms. In addition, due to side effects such as molecular relaxation and dual-scale effects, these materials must be characterized in transient state as these materials are always in transient-state in buildings.

However, the characterisation of hygroscopic materials is not simple as, due to the latent heat of vaporization, no mass transfer can occur without heat transfer. Consequently, the temperature field is not uniform in the sample, which induces gradients of saturated water vapour, well known to affect mass diffusion. The present work is focused on a particular family of building materials: LDF or other hygroscopic insulation materials. Due to their particular morphology, these materials present a very high mass diffusivity in the connected gaseous phase and a very low thermal conductivity. Together with the hygroscopicity, this combination of properties exacerbates the coupling between heat and mass transfer in transient state. This fact is carefully analysed in the present work, using a unique combination of experiments and simulations.

## 2. Materials and Methods

### 2.1. Experimental set-up

*Fig. 1 - Schematic cross-sectional view of the double plate (left) and photograph of the sample placed inside the climatic chamber (right).*

The material used in the present work is LDF ( $160 \text{ kg}\cdot\text{m}^{-3}$  low-density fiberboard produced by Steico, Therm). The experiment consists in submitting a sample face to a sudden variation of RH and to record the evolution of RH on the other face [4]. To rigorously assess the coupling between heat and mass transfer in this case of insulation material, a specific design was imagined to avoid any thermal perturbation and obtain 1-D transfer without any

heat and mass flux at the back face of the sample (Fig. 1). For that purpose, a temperature/RH sensor (Sensirion SHT25, HDI Electronics, Perois, France) was placed between two 20-mm thick plates of LDF. Side effects were avoided by choosing large dimensions (30 cm x 30 cm), which is more than 7 times the diffusion thickness. Finally, to avoid lateral water vapor leakages, the two superimposed LDF plates were coated with an aluminium foil glued to the lateral faces by epoxy resin. This double sample is placed inside a climatic chamber (HPP110, Memmert, Schwabach, Germany) to control external conditions. Three RH/T sensors are placed inside the chamber to record the actual conditions applied to the sample.

## 2.2. Results

Fig. 2 presents a typical example of experimental data. This test was performed for a double layer of LDF panel ( $\rho = 160 \text{ kg.m}^{-3}$ , thickness =  $2 \times 20 \text{ mm}$ ) for a stepwise change of RH from 20% to 40% at 35°C. Low RH values were intentionally chosen to reduce the effect of molecular relaxation on the dynamic of sorption equilibrium<sup>[5]</sup>. The RH collected at the back-face of the sample needs about 10 hours to reach the new external RH. This information is the basic information used to identify the dimensionless mass diffusivity of the panel in the method proposed in<sup>[4]</sup>.

What is new in figure 2 is the temperature collected at the back-face of the sample. This value is relevant thanks to the symmetrical configuration: as the back-face of the sample is the value in the centre of two large plates, the assumption of 1-D transfer is valid and not artefact of heat transfer is likely to perturb the temperature value. As a result, we can observe an impressive temperature peak due to condensation: this peak is large in magnitude (more than 4°C above the ambience) and in duration (more than 10 hours, the same duration as for mass transfer). Simulation performed using a comprehensive formulation of coupled heat and mass transfer will be used to analyse this impressive coupling and its effect on material characterisation.

## 3. The physical formulation

A comprehensive physical formulation was used in the present work. More detailed information regarding this set of equations can be found in published works<sup>[6]</sup>. For the sake of simplification, all liquid water contributions have been discarded, as the sample stays inside the hygroscopic domain. The simplified transport equations read as follows:

### Water conservation

$$\rho_s \frac{\partial X}{\partial t} + \nabla \cdot (\rho_v \bar{v}_g) = \nabla \cdot (\rho_g \mathbf{f} \mathbf{D}_v \cdot \nabla \omega_v + \rho_b \mathbf{D}_b \nabla X) \quad (1)$$

On the importance of heat and mass transfer coupling for the characterization of hygroscopic insulation materials.

**Energy conservation**

$$\begin{aligned} & \frac{\partial}{\partial t} (\varepsilon_g (\rho_v h_v + \rho_a h_a) + \bar{\rho}_b \bar{h}_b + \varepsilon_s \rho_s h_s) + \nabla \cdot ((\rho_v h_v + \rho_a h_a) \bar{\mathbf{v}}_g) \\ &= \nabla \cdot (\lambda_{eff} \nabla T + \rho_g \mathbf{f} \mathbf{D}_v (h_v \nabla \omega_v + h_a \nabla \omega_a) + h_b \rho_b \mathbf{D}_b \nabla X) \end{aligned} \quad (2)$$

**Air conservation**

$$\frac{\partial (\varepsilon_g \rho_a)}{\partial t} + \nabla \cdot (\rho_a \bar{\mathbf{v}}_g) = \nabla \cdot (\rho_g \mathbf{f} \mathbf{D}_v \nabla \omega_a) \quad (3)$$

Fig.2 - Experimental results for a double plate (2 x 20 mm) of LDF (160 kg.m<sup>-3</sup>): time evolution of RH (top) and temperature (bottom) at the back-face of the sample.

### Boundary conditions

At the external faces of the sample, the boundary conditions were assumed to be of the following form:

$$\begin{aligned} \mathbf{J}_v|_{x=0} \cdot \mathbf{n} &= h_m c M_v \ln \left( \frac{1 - x_{v,\infty}}{1 - x_v|_{x=0}} \right) \\ \mathbf{J}_q|_{x=0} \cdot \mathbf{n} &= h(T|_{x=0} - T_\infty) \\ P_g|_{x=0^+} &= P_{atm} \end{aligned} \quad (4)$$

where  $\mathbf{J}_v$  and  $\mathbf{J}_q$  represent the fluxes of water vapour and the heat at the boundary, respectively, while  $x$  denotes the distance from the boundary along the external unit normal.

In the previous equations, the barycentric gaseous velocity comes from the generalized Darcy's law:

$$\bar{\mathbf{v}}_g = - \frac{\mathbf{K} k_g}{\mu_g} \nabla p_g \quad (5)$$

In the hygroscopic domain, the total flux of mass should be expressed as the sum of two parallel fluxes (bound water and water vapour). However, as this work is solely devoted to Low Density Fibreboards, the contribution of bound water diffusion to the macroscopic flux can be neglected. In equations (1-3),  $\mathbf{D}_v$  is the water vapour diffusivity,  $f$  the dimensionless diffusivity,  $\rho_g$  the bulk density of gas,  $\rho_s$  the bulk density of the lingo-cellulosic part,  $X$  the moisture content (dry basis) and  $\omega_v$  the mass fraction of water vapour. The reduced diffusivity  $f$  characterizes the porous medium:  $f$  ranges from 0 (sample impervious to any moisture transfer) to 1 (open sample having the same behaviour of an air layer at rest). This set of equations was solved by the very fast 1-D version of *TransPore* with actual boundary conditions used as input data. A full simulation requires about one second of CPU time on a personal computer, even when using thousands of experimental times  $t_i$  to unroll the boundary conditions. The time step of *TransPore* was adjusted throughout the simulation, not only to secure convergence, but also to obtain the simulated results at the exact experimental times.

## 4. Results and discussion

Fig. 3 depicts simulation results for our reference test ( $f = 0.5$  and  $\lambda = 0.05 \text{ W.m}^{-1}\text{.K}^{-1}$ ). The  $f$  value allows the experimental RH value at the back-face to match the experimental data. The value of thermal conductivity is determined by a classical mixture law using the gaseous and solid volume fractions and their conductivities. After the sudden increase in RH, water vapour condensates on the front face of the sample. By releasing the latent heat of vaporization, this moisture flux heats up the surface. Because of this temperature

increase, the vapour pressure at the surface increases as well, as it is the product of water activity by the saturated vapour pressure, which increases rapidly with temperature. The primary effect of this change in surface vapour pressure is to reduce the external driving force, which slows down the process [7]. This temperature increase eventually affects the whole sample, by a tricky coupling of heat and mass transfer: the temperature increase at one point increases the mass fraction of vapour, which gives rise to a vapour flux that condensates in neighbouring parts. In turn, condensation increases the temperature further inside the medium, which allows the process to continue inwards. This produces a "heat wave" propagating towards the back-face, clearly visible on the temperature profiles. Once this wave reaches the back-face of the sample, a temperature gradient establishes towards the external face, to drive outwards the heat supplied in the medium via the latent heat of vaporization. In figure 3, the effect of this temperature gradient on the mass fraction of vapour is obvious, namely for the profiles at 10 and 30 minutes: although the internal value of moisture content (MC) is still close to the initial value, the mass fraction of vapour already increased significantly due to the temperature rise.

**Fig. 3 – Profiles computed at selected times for the reference test ( $f = 0.5$  and  $\lambda = 0.05 \text{ W.m}^{-1}.\text{K}^{-1}$ ).**

The model is also able to compute the time evolution of the two variables measured during the experiment: temperature and RH at the back face of the sample. The reference test is in perfect agreement with the experiment, which confirms the relevance of the chosen thermal conductivity value. In addition several virtual configurations were computed:

**Modified thermal conductivity ( $\times 2$  and  $\times 0.5$ ):** these simulations exhibit the crucial effect of thermal conductivity, not only on the temperature overshoot (peak at respectively  $38.6^\circ\text{C}$  and  $41.2^\circ\text{C}$  instead of  $39.8^\circ\text{C}$ ) but also on the dynamic of RH evolution,

**No heat and mass coupling:** the coupling is easily cancelled by setting the latent heat of vaporization,  $L_v$ , to zero. Consistently, the temperature remains at the external temperature. As a consequence of the absence of coupling, the dynamic of RH evolution is much faster (2.5 hours instead of 4.3 hours for the reference test to attain 35% of RH). This confirms the importance of the heat and mass coupling on the global behaviour.

**No internal heat transfer:** setting the conductivity  $\lambda$  to zero cancels the heat flux inside the sample. Consequently, the latent heat of vaporization released by condensation cannot be driven towards the exchange face. A balance between water intake and temperature rise takes place: the amount of water condensed in the solid phase raises the temperature until the mass fraction of vapour equals the external value. The steady-state is obtained with an MC increase of 0.5% (against ca. 2% for the reference test) and an temperature of 43.4°C. In this extreme, virtual, configuration, the coupling completely stops mass transfer !

Fig. 4 - Simulation results for LDF ( $160 \text{ kg.m}^{-3}$ ): RH (top) and temperature (bottom) at the back-face versus time. The various virtual configurations tested are defined in the legend.

## 5. Conclusions and prospects

Based on experimental data obtained using an original set-up and relevant simulations performed using a comprehensive physical formulation, a throughout vision of the heat mass transfer in Low Density Fiberboards is proposed in the present study. In particular, we emphasize on:

- The impressive change in core temperature in terms of magnitude and duration,
- The great impact of the internal temperature gradient, which slows down mass diffusion,
- The dramatic error on mass diffusivity value if the coupling is ignored.

Further works are in progress in our team to go even further in the analysis of coupled transfers in hygroscopic materials used for building insulation. Besides the heat and mass transfer coupling, sorption hysteresis, dual-scale effects and molecular relaxation have also to be taken into account. However, the strong coupling between these phenomena forces us to be very careful when determining the unknown parameters by inverse analysis. To gain in robustness, several physical parameters will have to be measured during experiments in transient state. By this way, additional parameter values, such as thermal conductivity, could be determined by inverse method.

### Abstract

*Fractional order derivatives provide useful alternatives to their integer order counterparts due to their ability to model memory and other properties of the porous medium, such as nonlocal behaviour. These phenomena are driven by the constrained interactions within the complex and non-homogeneous microstructures evident at the pore scale.*

*In this work, we investigate the suitability of time and space fractional operators for modelling drying processes and provide a physical interpretation of these operators. At first, the concept and the general formulation in the case of a 1-D finite domain is summarised. Then a selection of simulations allowed us to analyse the physical effects of these operators on the solution. In particular, we elucidate: (i) the ability of these operators to break the fundamental relationship between mean square displacement and time in the simple example of diffusion in an open space, (ii) the caution to be taken with the formulation of boundary conditions and source terms to obtain consistent balance equations, (iii) the effect of fractional in space diffusion as a way to alter the MC profiles compared to standard diffusion, therefore potentially avoiding the dependence of the diffusivity on the variable*

## 1. Introduction

Modelling the transport of moisture through heterogeneous porous media finds application across a number of important environmental problems, such as drying [1] and groundwater flow in freshwater coastal aquifers [2-4]. Experimental work performed by Perré et al. [5] highlighted that the traditional diffusion equation did not adequately describe the absorption of water in the cell wall of beech wood. An unrealistically small diffusion coefficient was required to best fit the experimental data, which was clearly impractical. The observed experimental phenomenon exhibited a large deviation from the stochastic process of Brownian motion, which is a typical case of anomalous, or non-Fickian, diffusion. The bound water migration through the cell walls was thought to be anomalous because the water molecules that are bound to the macromolecules via their hydrogen bonds move by successive jumps within the complex structure of these macromolecules. This finding motivated us to explore alternate modelling approaches for this process.

Based on this assumption, Turner et al. [1] derived a coupled anomalous transport model, which introduced a moisture potential linked to the moisture content field via a non-local fractional-in-space operator involving the Laplacian raised to a negative fractional index. The simulation results highlighted that this model accurately described the absorption of water in the cell wall and provided a good overall mass balance error. Most importantly however, good agreement with experimental data for a suitable range of diffusivity values was achieved only for a fractional index of  $\alpha = 0.76$  ( $\alpha = 2$  is standard Fickian diffusion).

Both Turner et al. [1] and Fomin et al. [6,7] proposed a fractional-in-space model of the form:

$$\frac{\partial X}{\partial t} = -D_{\alpha} D_b (-\Delta)^{\frac{\alpha}{2}} X \quad (1)$$

for the so-called *super-diffusion* of moisture in the porous matrix. In Fomin et al. [6,7] the Caputo definition is adopted for the fractional-in-space operator, whereas in Turner et al. [1] the fractional Laplacian is defined in terms of its spectral decomposition together with homogeneous boundary conditions (BCs). One notes, however, that it can be shown using Laplace transforms that the two definitions are equivalent on semi-infinite domains.

The solution of (1) with standard (Dirichlet, Neumann or Robin) inhomogeneous BCs has been explored previously by the authors [8-10]. In deriving equation (1) the following expression for the moisture flux was used:

$$\mathbf{j} = -\rho_0 D_b \nabla \mathcal{X} \quad (2)$$

where  $\mathcal{X}$  was defined as the moisture potential.

Using this expression for the moisture flux leads to the BCs at the exposed surface  $\partial\Omega$  of the domain  $\Omega$  being defined for a given function  $f$  as

$$j \cdot n = f(X) \text{ on } \partial\Omega \tag{3}$$

Clearly BC (3) is nonlinear and very challenging even for the standard problem  $\alpha = 2$ . One of the aims of this research is to provide an analysis of such problems. Another important contribution of this work is the extension of the model (1-3) to include both fractional in time and space operators in the mass conservation balance law, as well as a nonlinear source term  $g(u)$ . The derivation of analytical and numerical solutions is quite complex and will therefore not be presented here. We focus primarily on the following:

- The best fractional modelling framework to ensure mass conservation is achieved.
- Whether fractional in space diffusion can be used as a way to avoid the dependence of the diffusivity on the variable.
- The effect of the material thickness on the global behaviour for fractional in space or fractional in time formulations.

We also pay careful attention to the caution that must be taken with the formulation of boundary conditions and source terms to obtain consistent balance equations.

## 2. Fractional Transport Model

Before commencing the model derivation, we provide some preliminary background information on the various definitions of the fractional in time and space operators used throughout the paper.

### Definition 1. Caputo fractional derivatives on a finite interval [11]

Let  $[a, b]$  be a finite interval of the real axis,  $\alpha > 0, n-1 < \alpha < n$ ,  $n \in \mathbb{N}$ , then the left sided Caputo fractional derivatives with order  $\alpha$  is given by

$${}^c D_{a-}^\alpha f(t) = \frac{1}{\Gamma(n-\alpha)} \int_a^t \frac{f^{(n)}(\xi) d\xi}{(t-\xi)^{\alpha-n+1}} \tag{4}$$

where the gamma function is defined as  $\Gamma(z) = \int_0^\infty t^{z-1} e^{-t} dt$ ,  $\Re(z) > 0$  with  $t^{z-1} = e^{(z-1)\log t}$  and  $\log t \in \mathbb{R}$ .

### Definition 2. Riemann-Liouville fractional derivatives [11]

Let  $[a, b]$  ( $-\infty < a < b < \infty$ ) be a finite interval of the real axis,  $f(t) \in AC^{n-1}([a, b])$  and  $n-1 < \alpha < n$ ,  $n \in \mathbb{N}$ , then the left-sided Riemann-Liouville fractional derivative of order  $\alpha$  is given as

$${}^{RL}D_{a+}^{\alpha} f(t) = \frac{1}{\Gamma(n-\alpha)} \frac{d^n}{dt^n} \int_a^t \frac{f(\xi) d\xi}{(t-\xi)^{\alpha-n+1}} \quad (5)$$

**Definition 3. (Fractional Laplacian) [8, 9, 10]**

Let  $\{\varphi_n\}$  be a complete set of orthonormal eigenfunctions corresponding to eigenvalues  $\lambda_n^2$  of the operator  $(-\frac{d^2}{dx^2})$  on a bounded domain  $-L < x < L$ , with homogeneous boundary conditions  $\mathcal{B}(\varphi) = 0$  defined at  $x = -L$  and  $x = L$ . Let

$\mathcal{F}_{\gamma} = \{f \in C(\Omega) | \sum_{n=1}^{\infty} |\lambda_n^{\gamma}| \|c_n\|^2 < \infty, c_n = \langle f, \varphi_n \rangle, \gamma = \max(2\alpha, 0)\}$ . Then, for any  $f \in \mathcal{F}_{\gamma}$  we define  $(-\frac{\partial^2}{\partial x^2})^{\alpha/2} f = \sum_{n=1}^{\infty} \lambda_n^{\alpha} c_n \varphi_n$ .

**2.1. Fractional Modelling Framework**

Assuming the solid matrix is rigidly fixed, we can express the mass  $m = \rho_0 X$  where  $X$  is the moisture content. The flux of mass is taken as either standard (Fickian) diffusion ( $\alpha = 2$ ) with  $\bar{j} = -\rho_0 D_b \nabla X$ , or anomalous (non-Fickian) diffusion ( $0 < \alpha < 2$ ) with  $\bar{j} = -\rho_0 D_b \nabla \mathcal{X}$  and the moisture potential defined as  $\mathcal{X} = D_{\alpha} (-\Delta)^{\alpha-1} X$ . The constant  $D_b$  has the usual dimensions of diffusivity ( $m^2 s^{-1}$ ), whereas the constant  $D_{\alpha}$  is introduced, if for no other reason, to recover the correct units for the flux, i.e.  $D_{\alpha} = 1 m^{\alpha-2}$ .

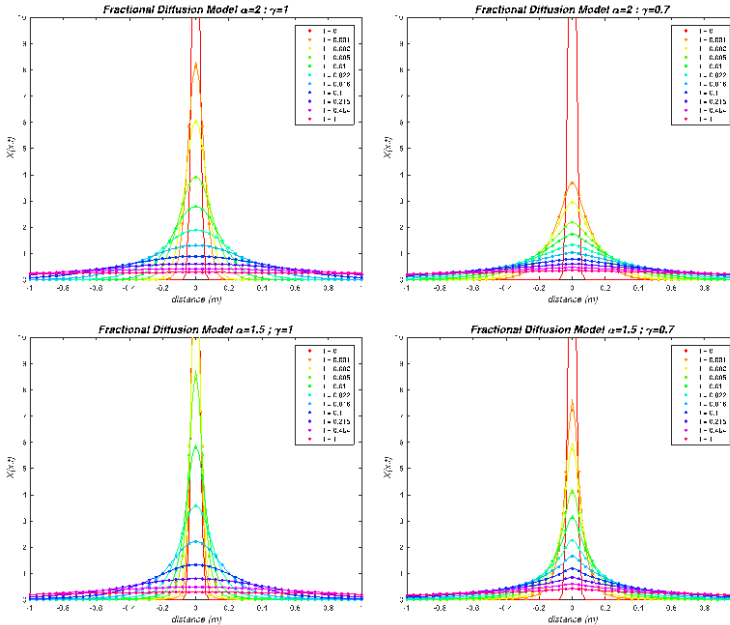

To complete the formulation, one needs an initial condition and boundary conditions, which are usually given in terms of a mass flux that is typically a nonlinear function of  $X$ . A one-dimensional framework for these fractional models provides the perfect mechanism by which to test these important hypotheses and to study the evolution of the solution behaviour. In order to achieve these objectives, we discuss the following generalised one-dimensional model that must be solved for  $X$ :

**2.2. General formulation - Fractional in Time and Space:**

$$\begin{aligned} \frac{\partial X}{\partial t} &= {}^{RL}D_{0+}^{1-\gamma} \left( D_b \frac{\partial^2 \mathcal{X}}{\partial x^2} \right) + g(X), \quad -L < x < L, t > 0, \quad 0 < \alpha \leq 2 \\ {}^{RL}D_{0-}^{1-\gamma} \left( -D_b \frac{\partial \mathcal{X}}{\partial x}(-L, t) + \sigma_L \mathcal{X} \right) &= f_1(X), \quad x = -L, t > 0 \\ {}^{RL}D_{0+}^{1-\gamma} \left( D_b \frac{\partial \mathcal{X}}{\partial x}(L, t) + \sigma_R \mathcal{X} \right) &= f_2(X), \quad x = L, t > 0 \\ X(x, 0) &= X_0(x), \quad \text{with } 0 < \gamma < 1, \quad 0 < \alpha \leq 2 \end{aligned}$$

In this formulation,  $\sigma_L, \sigma_R$  are regularisation parameters with the choice  $\sigma = 0$  giving Neumann boundary conditions (suitable when only time fractional operators are employed);  $\sigma \rightarrow \infty$  gives Dirichlet conditions and otherwise mixed or Robyn type conditions prevail. We explore finite values of  $\sigma$  ( $\sigma \ll 1$ ) to ensure non-singularity of the fractional potential operator  $(-\Delta)^{\alpha/2-1}$  at the smallest eigenvalue. The functions  $f_1(X)$ ,  $f_2(X)$ ,  $g(X)$  and  $X_0(x)$  are assumed smooth and defined in the context of the problem. We also use the relationship between the Caputo and Riemann-Liouville fractional derivatives given in [11]. A key point in our investigations will be the way in which the fractional operators are applied to the boundary fluxes and source terms to ensure consistent physical behaviour is observed and that an overall mass conservation is achieved.

**Fig. 1** Plots of moisture content profiles for test problem 1 at various times for (a) standard diffusion ( $\alpha = 2, \gamma = 1$ ); (b) fractional in time ( $\alpha = 2, \gamma = 0.7$ ); (c) fractional in space ( $\alpha = 1.5, \gamma = 1$ ); (d) Fractional in time and space ( $\alpha = 1.5, \gamma = 0.7$ ).

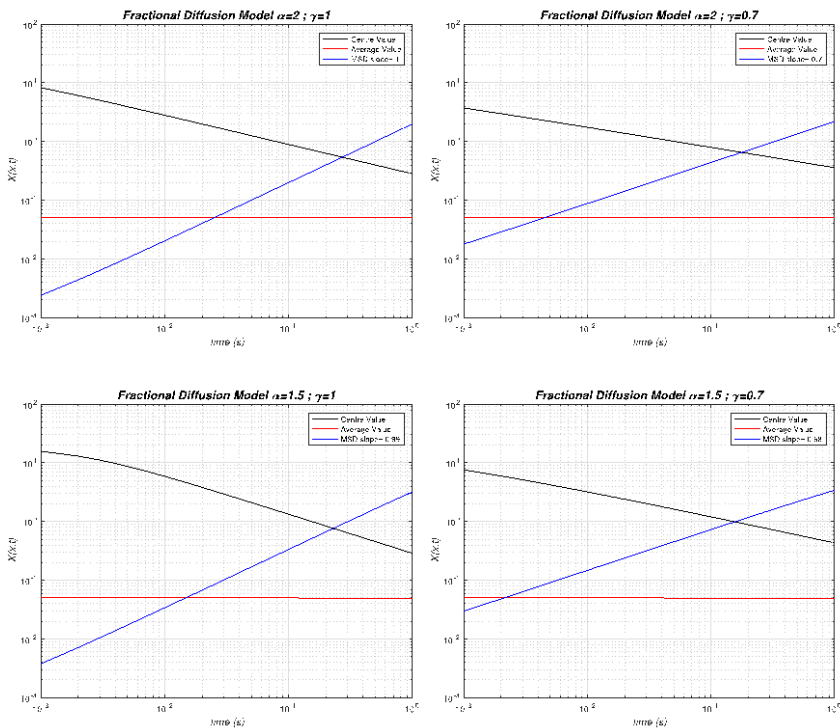

### 3. Results and discussion

The first problem presented here concerns the time-evolution of an initial field in an infinite domain. Therefore, neither BCs, nor source terms are involved in the model formulation. To come back to the basic definition of diffusion, the initial profile is chosen as a narrow Gaussian curve, likely to be close to the diffusion of a Dirac function (Fig. 1). Consistently,

the mean square displacement (MSD) is proportional to time for normal diffusion (Fig. 2a). This slope equals the fractional value  $\gamma$  for the fractional in time diffusion (Fig. 2b).

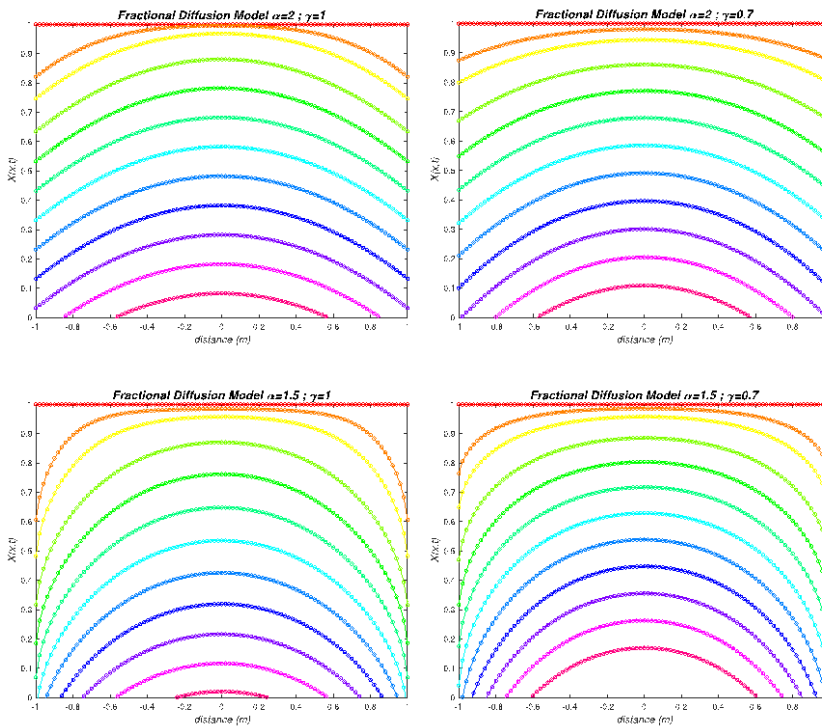

In this case, the total mass is conserved, however the allocation of this mass over time is very different from standard diffusion: the center value decreases rapidly at short times but is much slower at longer times compared to normal diffusion. The fractional in space diffusion produces a MSD quasi-proportional to time, which is similar to normal diffusion. However, this MSD is obtained with different spatial fields: the center peak is higher than for normal diffusion at similar times, but this is compensated by a slight moisture increase over long distances, even at short times. The fractional in time and space diffusion accumulates these trends (Fig. 1d).

**Fig. 2** Plots of means square displacement (MSD), average and centre value for test problem 1 (a) standard diffusion; (b) fractional in time ( $\alpha = 2, \gamma = 0.7$ ); (c) fractional in space ( $\alpha = 1.5, \gamma = 1$ ); (d) Fractional in time and space ( $\alpha = 1.5, \gamma = 0.7$ ).

The solution of the general problem when BCs and/or source terms are involved is more challenging. In particular, great care should be taken in the way the fractional operator has to be applied to the source term and boundary fluxes for the mass balance to be respected. Due to space restrictions, these developments cannot be presented here.

As a final example, we show in Fig. 3 simulation results for different assumptions in the absence of a source term and with Newman boundary conditions (obtained in the general formulation with  $\sigma = 0.001$ ). The standard diffusion exhibits a classical behavior as a result of the flux imposed at the boundaries. The profiles first establish and maintain the same shape which is just regularly shifted towards lower values along time to respect the mass balance. In Fig. 3a, the distance between two successive profiles is exactly the same, as the profiles are plotted with constant time intervals. At first sight, the fractional in time solution (Fig. 3b) is similar to standard diffusion. Note however that the profiles evolve in shape, becoming steeper and steeper as time advances. This effect is more spectacular for the fractional in space solution (Fig. 3c). In this case, the profiles are very steep near the exchange faces. In this case, the spatial rather than the temporal effects modify the local ability of the flux to establish as a function of the moisture gradient.

**Fig. 3** Plots of moisture content profiles for Newman BC at various times for (a) standard diffusion; (b) fractional in time ( $\alpha = 2, \gamma = 0.7$ ); (c) fractional in space ( $\alpha = 1.5, \gamma = 1$ ); (d) Fractional in time and space ( $\alpha = 1.5, \gamma = 0.7$ ).

The fractional in time and in space solution (Fig. 3d) combines these two effects: again, the fractional in time operator acts more particularly at longer times, for which the profiles are steep both at the boundaries due the fractional in space operator and inside the slab due to

the fractional in time operator. One can easily imagine that when combined, these two behaviors may address different kinds of experimental observation.

#### **4. Conclusion**

In this work, we investigated the suitability of fractional operators for simulating drying processes and we also provided a physical interpretation of these operators. At first, a general formulation in the case of a 1-D finite domain was summarised. Then a selection of simulations allowed us to identify the physical effects of these operators on the solution behaviour. In particular, we highlighted:

- The ability of these operators to break the fundamental relationship between mean square displacement and time in the simple example of diffusion in an open space,
- The caution to be taken with the formulation of boundary conditions and source terms to obtain consistent balance equations (not detailed here because of the space restrictions),
- The effect of space fractional diffusion to change the MC profiles compared to standard diffusion, therefore potentially avoiding the dependence of the diffusivity on the variable.

#### **Acknowledgements**

This work was supported financially by a visiting Professorial Fellowship that enabled Turner to work at CentraleSupélec, Université Paris-Saclay, France for a period of three months. Both authors acknowledge the financial support for this research received through the Australian research Council (ARC) grant DP150103675.

### **Abstract**

*Intermittent microwave convective drying (IMCD) is an advanced drying system where a unique volumetric heating mode is facilitated. However, the physical phenomena of IMCD system and its effect on nutritional quality are not well understood yet. The aim of this research is to develop a coupled IMCD and quality prediction model and experimentally validate it. A coupled 3D mathematical model considering Maxwell's equation for electromagnetic heating, and reaction kinetics for predicting quality was developed and validated. COMSOL Multiphysics, engineering software was used to solve the developed model. It is found that IMCD significantly affect the nutritional quality during drying of apple tissue.*

---

## 1. Introduction

Drying, like any other food processing methods, is a very energy intensive operation that accounts for up to 15% all industrial energy usage [1]. Understanding the coupled heat and mass transfer during drying are the dominant factor for optimising the energy and quality [2-3]. The physics-based mathematical models can provide realistic understanding of drying process.

A conventional drying or hot air drying is the easiest way of drying [4-5]. However, longer time consumption, formation of crust at the surface due to an elevated temperature, lower energy efficiency and poor quality attributes are associated with convective drying [6]. To overcome these problems, microwave drying is introduced. Microwave drying is getting popularity because it heats the sample quickly, is energy efficient, and easy to control [7]. However, the drying process using microwaves is known to yield low-quality product if not appropriately applied [8]. Hence, microwave drying has usually been combined with other drying techniques including convective hot air, vacuum and freeze-drying to achieve more uniform, fast and effective drying without significant quality loss [9]. Microwave-aided convective hot-air drying has been successfully used for some agricultural products such as grapes [10], carrot [11], apple and mushroom [12], potato [13]. However, continuous supply of microwave and convective heat may cause uneven heating or overheat or create hot spots in the product. Heat and mass transfer should be carefully balanced to avoid such overheating and to use applied energy more efficiently [14]. Also, the quality degradation has been frequently reported during drying of foods with the continuous application of microwave energy due to uneven temperature and moisture distribution [15]. This problem can be eliminated by the application of microwave energy in a pulsed or intermittent manner that is defended as intermittent microwave convective drying (IMCD).

Intermittent microwave convective drying has proved itself an alternative method to avoid uneven heating, and to improve product quality and energy enhancement by allowing redistribution of temperature and moisture profiles within the product during off times, due to thermal diffusion [16]. Considering the benefits of IMCD drying, many researchers investigated the drying kinetics for different food samples [8, 16, 17] experimentally or empirically. However, only experimental work cannot provide the physics for the heat and mass transfer involved in the process. Physics based mathematical modelling can provide a physical understanding of heat and mass transfer during IMWC. Malafrente, et al. [18] used multiphysics approach to model microwave-assisted convective drying. They considered heat and mass transfer and variable dielectric properties in their model. A comprehensive model for heating in microwave oven of mashed potato was developed by Chen, et al. [19]. However, these models did not consider intermittency of microwave power; thus, the temperature redistribution by means of intermittency of microwave heat source was not investigated. On the other hand, there are some single-phase models which consider the intermittency of microwave heat source [20] but these are only for microwave heating without considering mass transfer. Kumar, et al. [21] developed IMCD model using Lambert's law and observed that the predicted temperature is higher than the experimental value at the end of drying. Moreover, they pointed out that according to Lambert's law the sample surface always absorbed maximum power irrespective of moisture content, which is obviously not correct. Therefore, in this case,

Maxwell model is the more accurate options to predict the microwave field distribution during IMCD.

In addition to this, the quality degradation is the main problem for conventional drying system. In this case, IMCD could be the best solution as it heated the sample intermittently in a periodic cycle [21]. However, the theoretical studies that deals about the effect of intermittency on quality degradation during IMCD are very rare. Therefore, the main aim of the present work is to develop a coupled 3D IMCD and quality prediction model considering the Maxwell equation for the volumetric heat generation, and reaction kinetics for predicting the quality degradation during IMCD.

## 2. Model Development

### 2.1 Governing Equations

#### 2.1.1 Energy equation

The energy balance is considered using Fourier's Law of heat transfer, as given below.

$$\rho c_p \frac{\partial T}{\partial t} = \nabla \cdot (k_{eff} \nabla T) + Q_m \quad (1)$$

Where  $T$  is the temperature ( $^{\circ}\text{C}$ ) at time  $t$ ,  $\rho$  is the density of the sample ( $\text{kg}/\text{m}^3$ ),  $c_p$  is the specific heat of the material ( $\text{J}/\text{kg}/\text{K}$ ),  $k_{eff}$  is the thermal conductivity of the material ( $\text{W}/\text{m}/\text{K}$ ),  $Q_m$  is the volumetric heat source.

#### 2.1.2 Mass transfer equation

Mass balance equation is developed based on Fick's law of diffusion that is given by,

$$\frac{\partial c}{\partial t} + \nabla \cdot (-D_{eff} \nabla c) = 0 \quad (2)$$

where  $c$  is the instantaneous moisture concentration ( $\text{mol}/\text{m}^3$ ),  $t$  is time (s) and  $D_{eff}$  is the effective moisture diffusivity ( $\text{m}^2/\text{s}$ ).

#### 2.1.3 Maxwell's equation for electromagnetics and heat generation

Maxwell's equations provide the electromagnetic field at any point in the computational domain. In frequency domain time harmonic Maxwell's equations can be written as [22].

$$\nabla \times \left( \frac{1}{\mu} \nabla \times E \right) - \frac{\omega^2}{c} (\epsilon' - i\epsilon'') E = 0 \quad (3)$$

Where,  $E$  is the electric field strength,  $\omega$  is the angular frequency of the microwave oven,  $c$  is the speed of light,  $\epsilon'$ ,  $\epsilon''$ ,  $\mu$  are the dielectric constant, dielectric loss factor, and electromagnetic permeability of the material, respectively.

The total electromagnetics heat sources represent electromagnetic losses,  $Q_m$ , given by, [23]

$$Q_m = Q_{rh} + Q_{ml} \quad (4)$$

Where,  $Q_{rh}$  is the resistive loss and  $Q_{ml}$  is the magnetic loss. For food products, the magnetic losses are negligible, i.e.  $Q_{ml} = 0$ .

The resistive loss can be calculated as

$$Q_{th} = 0.5 \cdot \vec{J} \cdot \vec{E}^* \quad (5)$$

Where,  $\vec{E}^*$  is the conjugate of  $E$  and the electric current density  $\vec{J}$  is given by

$$\vec{J} = \sigma \cdot E = 2\pi f \epsilon_0 \epsilon'' \cdot E \quad (6)$$

Where  $f$  is the frequency of microwave,  $\sigma$  is the electrical conductivity,  $\epsilon''$  is the dielectric loss factor and  $\epsilon_0$  is permittivity in free space.

### 2.1.4 Quality prediction model

The equation for a degradation reaction:

$$-dC/dt = k \cdot C \quad (7)$$

Integration lead to

$$C = C_0 \exp[-k_0 \cdot \exp(-(\Delta E_a)/(Q_e \times Pr + T))] \quad (8)$$

where  $C_0$  is the initial concentration of nutrient,  $Pr$  is the power ratio, and  $k_0$  is the pre-exponential factor.

## 3. Material and Method

### 3.1 Drying Experiment

A new IMCD drying system has been developed to conduct the experiment, as shown in Figure 1. The IMCD system consisted of three main parts: an axial flow fan, a 3-phase 6kW heater, and a modified NN-SD691S Panasonic inverter microwave oven (2450 MHz, maximum 1100W power capacity). Moisture loss was recorded automatically by the load cell connected to a computer. The internal temperature evolution of the sample was monitored by 4 fibre optic thermal sensors which were connected to Fiber Optical 4-Channel Thermometer (OPTO con AG, Germany). The power ratio was programmed to trigger the microwave heating at the controlled condition. IMCD operations were performed at microwave power 100W, power ratio (on/off) of 1/4, and convective temperature of 60 °C, respectively. On the completion of drying, the samples were cooled for 30 min in desiccators, wrapped with aluminium foil and store in a laboratory freezer at -18°C for further analysis.

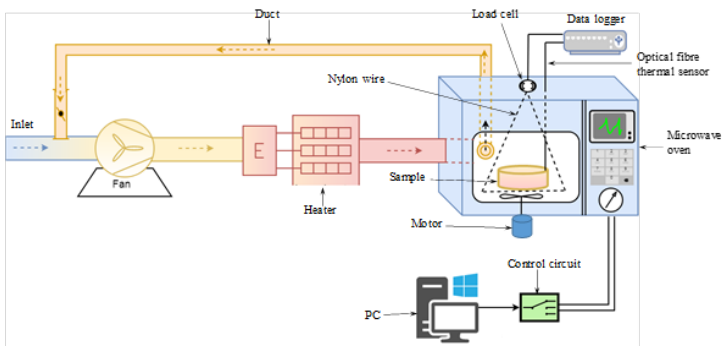

Fig. 1: Schematic diagram of the IMCD experimental setu

## 3.2 Analytical Determinations

### 3.2.1 Total phenolic extraction and content measurement

The amount of total polyphenol in the samples were determined by the Folin-Ciocalteu method [24] with some modification. The sample was extracted in extraction solvent (methanol / distilled water (50:50 v/v)) in amber vial at laboratory condition before homogenized in 20 mL of extraction solvent at maximum speed in Waring mini container blender in 1 minute. Extracts were centrifuged at 15,000 g for 15 minutes at 20 °C. The supernatant was filtered through a Whatman no. 3 analytical filter paper. Then 0.5ml of the diluted extract solution was mixed with 2.5 ml Folin– Ciocalteu reagent (10%) and allowed 5 minutes to react, then added 0.5ml of 7.5% Na<sub>2</sub>CO<sub>3</sub> solution. After 30 minutes of incubation in a water bath at 37°C, the absorbance was measured against water at 765 nm by Cary 50 UV Spectrophotometer.

### 3.2.2 HPLC analysis of ascorbic acid (Vitamin C)

The sample was extracted in extraction solvent (3 % metaphosphoric acid, 1 mM Na<sub>2</sub>EDTA). Extracts were centrifuged at 15,000 g for 15 minutes. The supernatant was filtered through a Whatman no. 3 filter paper. Extraction processes were repeated three times. Vitamin C contents were determined based on Asami et al's [25] HPLC method with some modifications. The analysis was carried out using an Dionex UHPLC RS3000 system. The reverse-phase separation was obtained using a Waters Symmetry C18 column (4.6 x 250 mm, 5 µm). The isocratic mobile phase was HPLC graded water with 1mM EDTA and 25mM sodium acetate buffer acidified to pH 4.25 with o-phosphoric acid.

## 3. Results and Discussion

### 4.1 Drying Kinetics

Average moisture content of the sample throughout the whole drying time was calculated and validated with the extensive experimental results, as shown in Figure 4. It is found that the simulated moisture content is consistent with the experimental data. To find the accuracy of the predicted data, the goodness of Fit ( $R^2$ ) was calculated and found that the value of  $R^2$  is 0.975. This precise  $R^2$  value indicates the developed model is quite accurate and able to predict the moisture distribution of plant-based food material during IMCD. For better interpretation about the moisture level throughout the IMCD process, 2D moisture concentration profile were drawn, as shown in Figure 5. It can be seen that the initial moisture concentration for a fresh apple tissue is uniformly distributed in the whole sample (Figure 5a). The moisture concentration decreases while drying is in progress (Figure 5 b-e). Interestingly, it can be observed that the moisture concentration is higher at the left side of the sample as compared to the right side. This is mainly due to the non-uniform microwave energy although the temperature distribution remain almost uniform, as shown in Figure 6.

Figure 6 shows the average temperature distribution during IMCD drying. It can be seen the experimental results are closely matched with the simulated results. The dispersion pattern (fluctuation) of this figure indicates the tempering and heating period during IMCD drying. The different peak points indicate the heating time (microwave on time) and the various nadir points mean tempering time. During the IMCD, microwave heats the sample rapidly for few seconds (20s) and then it was stopped automatically for a period (e.g 60s) for completing on cycle (80s).

Fig. 4 The average moisture content during IMCD drying

Fig. 5: The concentration distribution at different stages of IMCD (a) at 0 min (b) at 20 min (c) at 40 min (d) at 80 min, and (e) at 100 min

The frequent microwave stop allows a time to redistribute the heat energy within the sample properly, prevents the material from overheating and therefore the better quality of the product (discussed in section 4.2) can be maintained. The trend of the temperature distribution remains almost similar throughout the whole drying processes although a little attenuation can be observed at the final stages of drying. This temperature distribution mainly depends on the moisture concentration at different stages of drying (Figure 5) because microwave mainly heat firstly where it gets more moisture. At the final stages of drying, most of the water has been transported by continuous evaporation due the IMCD process progress simultaneously. As a result, most of the sample become dry, and hence the microwave cannot generate more heat. Due to this reason, the temperature decreases at the final stages of drying.

Fig. 6: The average temperature distribution during IMCD drying

#### 4.2 Reaction Kinetics

Understanding of IMCD process on important quality parameters such as ascorbic acid (AA) and total polyphenol content (TPC) is an important issue due to their thermos labile sensitivities and should be taken into account in the drying process. Initial values of AA and TPC were found to be 4.842 (mg/100g fresh weight) and 70.74 (mg/100g fresh weight), respectively in a fresh granny smith apple. Figures 7 and 8 represent the degradation kinetics of AA and TPC in the Granny Smith apple slice. It can be seen that the retention remaining AA, and TPC values were reduced with drying time, and the degradation rate accelerated with increasing temperature and microwave

power density, meaning that the loss of bioactive compounds increased. This study found that, at the beginning of the process, the effect of moisture content on the reaction rate of AA degradation seems to be predominant, while the temperature effect becomes major as the process proceeds. The degradation rate of AA was low at the beginning of the IMCD process (Figure 7) with the reduction of moisture content from 86% to 60% (Figure 4). When moisture content reached 55–60%, the rate of this reaction reached a maximum value and at moisture contents below 55%, the rate decreased significantly (Figure 7) with moisture reduction. This rapid degradation phenomenon can be attributed to the destruction of cell structure under microwave heating as it can lead to ascorbic acid release and contribute to the rapid oxidation of ascorbic acid.

Considering the evolution of ascorbic acid retention during the drying process in the present paper (Figure 7), experimental data were fitted to a first-order kinetic model. The natural logarithmic ratio of nutrient retention ( $\ln C/C_0$ ) versus drying time representation revealed linear correlations with the degradation rate constant ( $k$ ) and coefficients of determination ( $R$ ) higher than 0.98 (Figure 8), suggesting that the model was suitable in describing the degradation of ascorbic acid during IMCD drying of granny smith apples.

**Fig. 7** Kinetics of ascorbic acid and total polyphenol alteration of Granny Smith apple during IMCD

**Fig 8:** Predicted first-order kinetics of retention of nutrient during IMCD drying Granny Smith apple

In addition, apple is a good source of total polyphenol, which can be affected by temperature, oxygen, pH, metal, the release of polyphenol oxidase (PPO) and other parameters. It can be seen from Figure 7, the TPC degrades highly at the first 40 minutes of IMCD, and extends even beyond the first drying period corresponded to the activation of PPO enzyme and rapid linear decrease of free moisture during IMCD drying. Then TPC gradually decreases over the vast majority of the time to reach the final stage where degradation is found to be marginal. Finally, between the two key nutrients in apple tissue, the degradation rate of ascorbic acid is higher than total polyphenol. This is may be due to higher thermal sensitivity of ascorbic acid as compared to TPC.

#### 4. Conclusion

In this research, an IMCD model for food drying has been developed to predict the moisture and temperature distribution and its effect on quality of apple tissue. A 3D model has been developed considering Maxwell equations to generate volumetric heating and reaction kinetics to predic the quality degradation during IMCD drying. The developed model was then validated with the experimental results. It has been found that the predicted moisture and temperature distribution results is fully consistent with the experimental results. The precise goodness of fit ( $R^2$ ) value

indicates the developed model is quite accurate and able to predict the moisture distribution of plant-based food material during IMCD. It is also found that the IMCD significantly alter two different key nutrient qualities: ascorbic acid and total polyphenol content of apple tissue. Between these two nutrients, ascorbic acid has the highest tendency to alter its character during IMCD as compared to total polyphenol content.

### **Abstract**

*Turmeric (Curcuma longa), belongs to Zingiberaceae family. The rhizomes contain bioactive compounds of the curcuminoids group (natural phenols). They are used in food and pharmaceutical industry. The aim of this research was to acquire dried turmeric with high total curcumin content. In this study, optimum turmeric drying conditions and new extraction techniques were explored. Fresh turmeric samples were subjected to constant vs changing drying air temperatures and pre-treatment (blanching). Changing drying air temperature and use of non-blanching turmeric slices resulted in the highest concentration of curcumin. Ultrasonic extraction instead of Soxhlet extraction improved the extraction efficiency and decreased extraction time.*

**Keywords:** Turmeric, Curcumin; Drying; Blanching; Extraction

---

## 1. Introduction

Turmeric, known as *Curcuma longa*, belongs to the Zingiberaceae family like ginger and cardamom. It is an erect perennial herb which has a short stem with large oblong leaves and produces ovate, pyriform or oblong rhizomes. The rhizomes may have many branches and are of brownish-yellow colour. The aroma of turmeric is musky, pepper-like and the flavour is slightly aromatic, bitter. The colour of dried turmeric varies from orange brown to pale yellow or reddish yellow. The main compounds responsible for these properties are curcuminoids that include curcumin, demethoxycurcumin and bis-demethoxycurcumin. They are mainly extracted from dried turmeric. Curcuminoids are natural phenols and produce a pronounced yellow colour. They are popular as pigments in food industry that uses turmeric oleoresin as the starting material. The rhizome of turmeric is an important raw material to extract curcumin that contains 3.1%~10%. The dried rhizome contains 45%~50% starch, 40%~50% cellulose<sup>[1]</sup>. They are also well known for their pharmaceutical and nutritional properties, particularly as anti-oxidants. The pharmaceutical properties include anticancer, antibacterial, anti-infective and insecticidal effect.

In turmeric powder manufacturing, dehydration is an important process step since the water activity can be reduced by drying so that the growth and reproduction of food spoilage microbial can be inhibited by passivating the food enzymes which would cause adverse chemical reactions<sup>[2]</sup>. Thereby it helps extend the shelf life of food and reach the preservation goals. However, different drying conditions may affect the amount of curcumin content in turmeric powder. Thus, the curcumin should be extracted after drying and the concentration of curcumin can be detected by using HPLC measuring method at 425 nm wavelength. There are several extraction methods for curcumin including soxhlet.

The aim of this research was to acquire dried turmeric with high total curcumin content. In this study, optimum turmeric drying conditions and new extraction techniques have been explored before quantitating the curcumin in dried rhizomes by HPLC.

## 2. Materials and Methods

### 2.1. Turmeric Samples

#### 2.1.1. Sample Procurement

Matured, healthy and fresh turmeric rhizomes were supplied by Earthcare Enterprises located in Maleny on Queensland's Sunshine Coast Hinterland. They were refrigerated and transported in a thermally insulated container to the University of NSW laboratory in Sydney. Once in the laboratory, they were placed in zip bags made from polyethylene film and kept in a freezer at -20 °C until needed for experiments.

### 2.1.2. Sample preparation

The frozen turmeric samples were removed from the freezer and left overnight in a refrigerator at + 4 °C. after procurement.

For each drying run, around 70 g of rhizomes were weighed and peeled to obtain around 50 g of peeled rhizomes that were either quartered or sliced (slices 5 mm thick).

### 2.1.3. Blanching

Some of the quartered samples were blanched in 70 °C water bath for different times (5, 15 and 30 minutes). After blanching, the samples were dipped into ice cold water directly for 1 minute and then left for 10 minutes to allow the water to drip off

### 2.1.4. Moisture content determination

The moisture content in the fresh and also in the dried slices was determined following the AOAC Official Method 934.06<sup>[3]</sup>. Triplicate samples of of turmeric (5 g) were dried in a convection oven at 110 °C for 6 hours.

## 2.2. Drying experiments

### 2.2.1. Dryer

The drying experiments were carried out in a cabinet dryer designed in the workshop of the School of Chemical Engineering of the University of New South Wales. The cabinet dryer (see Fig. 1) has an electric heater (15 kW) fitted with a PID controller and a fan (0.75 kW). The airflow is parallel to the tray on which the drying samples are placed in a thin layer. The temperature and relative humidity were monitored and recorded with a datalogger. The weight loss was recorded with an electronic balance placed under the samples holding tray.

Fig. 1 Cabinet dryer.

### 2.2.2. Drying conditions

The drying conditions were defined either by a constant temperature or a changing temperature (see Table 1). The reason for choosing the drying temperatures in the range 40-60 °C was that this corresponds to temperatures used by the industry including solar drying. Including changing conditions within this temperature range in addition to constant conditions was aiming at exploring the possibility of increasing the curcumin recovery.

*Table 1. Drying conditions for experiments*

Run	Temperature (°C)	RH (%)	Shape	Blanching (min)
1	40	20	quartered	0
2	40	20	sliced	0
3	50	10	quartered	0
4	50	10	sliced	0
5	50	20	quartered	0
6	55	12	quartered	0
7	55	12	sliced	0
8	60	10	quartered	0
9	60	10	sliced	0
10	60	20	quartered	0
11	60	20	sliced	0
12	60	10	quartered	5
13	60	10	quartered	15
14	60	10	quartered	30
15	60 – 50	20	sliced	0
16	50 – 60	20	sliced	0
17	60 – 40	20	sliced	0
18	40 – 60	20	sliced	0
19	50 – 40	20	sliced	0
20	40 – 50	20	sliced	0

## 2.3. Curcumin determination

### 2.3.1. Extraction

A sample of dried turmeric (5 g) was ground for 1 min in the Single-phase Resis Tanlestart Grinder (Shanghai Rihui Electrical Machinery Co). Each ground sample was passed through a sieve (250 µm size).

The powder sample (1.00 g) from each drying treatment was placed in a centrifuge tube (medical grade polypropylene) tube. An aliquot of 15 mL 100% ethanol (HPLC grade) was added into each tube and mixed. Then the tubes were closed with a cap and sonicated for 1

hour at 55 °C. After sonication, the tubes should be covered with an aluminium foil and vortexed for 1 h at room temperature. Then, all samples should be diluted by mixing 750 µL of extraction solution with 750 µL of 100% ethanol (HPLC grade) and then filtered.

### 2.3.2. Quantitation by HPLC

The solvents used in the quantitation work were as follows: 100% ethanol (HPLC grade) manufactured by Merck Pty Ltd; acetic acid (HPLC grade) manufactured by VWR; acetonitrile (HPLC grade) manufactured by VWR; Milli-Q Water (HPLC grade).

The curcumin analytical standard was obtained from Fluka.

HPLC detection was performed by applying a Shimadzu-LC system (Shimadzu, Japan) including an LC-20AD liquid chromatograph, a SIL-20A HT auto sampler (auto-injector), a CBM-20A communications bus module (UV-VIS detector), LC Solution software and the Xterra C18 Column (MS 3.5 µm; length: 150 mm; diameter: 2.1 mm, Waters, Ireland).

The HPLC assay was implemented in a reverse-phase by using an isocratic elution with a total flow rate of 0.1500 mL/min, a column oven temperature of 30 °C; a mobile phase of 2% acetic acid and 100% acetonitrile (60:40); a detection wavelength of 425 nm for curcumin. The injection volume was 20 µL. All solutions were filtered by using the glass vacuum filtration apparatus and accessories with filter membrane (hydrophilic PTFE with 0.45 µm pore size) under the fume cupboard prior to HPLC injection. The total time for testing was 10 min for each sample.

Standard solutions of curcumin in pure ethanol were prepared separately from the stock solution with the concentration of 1000 µg/mL that was diluted with 100% ethanol to obtain concentrations of 20 µg/mL, 30 µg/mL, 40 µg/mL, 50 µg/mL, 60 µg/mL, 70 µg/mL of standard solutions. A calibration curve was produced on the basis of the values obtained.

## 3. Results and discussion

### 3.1. Moisture content

The samples were dried until a constant weight of the sample was obtained, i. e. had to remain unchanged during at least three consecutive readings. This corresponded to the equilibrium moisture content for a given set of drying conditions (temperature and RH).

The drying runs 1-4 and 6-11 were set up to compare different effects of the sample shape (sliced vs. quartered) on the equilibrium moisture content of dried samples. It appears that at drying air temperatures of 40, 50 and 55 °C at any of the three RH values (10, 12 or 20%), the quartered samples had a higher moisture content. However, at 60 °C there was no difference in the final moisture content between the different shapes of cut turmeric

rhizomes. As for runs 12-14 it appears that there was no effect of blanching time on the final moisture content. Finally, the runs 15-20 are showing the effects of drying conditions on the final moisture content. It appears that in all six runs the procedure of starting with the higher drying temperature and then changing it to lower one (60 °C to 40 °C vs 40 °C to 60 °C) resulted in a higher final moisture content.

*Table 2. Average equilibrium moisture content for each run*

Run Number	Run conditions	Equilibrium Moisture Content (% db)	Drying time (min)
1	40 °C 20%RH (quartered)	7.50	220
2	40 °C 20%RH (sliced)	7.29	196
3	50 °C 10%RH (quartered)	4.40	243
4	50 °C 10%RH (sliced)	4.32	147
5	50 °C 20%RH (quartered)	5.65	204
6	55 °C 12%RH (quartered)	3.69	188
7	55 °C 12%RH (sliced)	3.44	145
8	60 °C 10%RH (quartered)	2.49	247
9	60 °C 10%RH (sliced)	2.51	157
10	60 °C 20%RH (quartered)	4.59	202
11	60 °C 20%RH (sliced)	4.58	187
12	60 °C 10%RH (quartered, blanched 5 min)	2.48	272
13	60 °C 10%RH (quartered, blanched 15 min)	2.52	272
14	60 °C 10%RH (quartered, blanched 30 min)	2.51	280
15	60 °C 20%RH to 50 °C 20%RH (sliced)	5.54	176
16	50 °C 20%RH to 60 °C 20%RH (sliced)	4.81	192
17	60 °C 20%RH to 40 °C 20%RH (sliced)	6.76	186
18	40 °C 20%RH to 60 °C 20%RH (sliced)	5.28	177
19	50 °C 20%RH to 40 °C 20%RH (sliced)	7.21	299
20	40 °C 20%RH to 50 °C 20%RH (sliced)	5.95	264

### 3.2. Curcumin content

With regard to the effect of RH during drying of sliced non-blanched rhizomes at 60 °C it was found that sample from run 11 exposed to 20% RH had a 23% higher curcumin concentration (3.53 mg/g dry matter) than sample from run 9 (2.86 mg/g dry matter).

As for the effect of the drying temperature at the same RH (20%), during drying of sliced non-blanched rhizomes, it is found that sample from run 2 had a 13% higher concentration of curcumin (3.99 mg/g dry matter) than sample 11 (3.53 mg/g dry matter). The drying

temperature of samples 2 and 11 was 40 °C and 60 °C, respectively. The same phenomenon was observed when comparing the effects of drying air temperature on the curcumin content in quartered rhizome samples, see samples 1 (3.86 mg/g dry matter) vs. sample 10 (2.86 mg/g dry matter) and sample 5 (2.81 mg/g dry matter) dried at 40 °C, 60 °C and 50 °C, respectively. Hence, it can be considered that a lower drying temperature leads to a higher curcumin content.

*Table 3. Curcumin content in dried samples*

<b>Run number</b>	<b>Weight of curcumin extracted from dried samples (µg)<sup>a)</sup></b>	<b>Curcumin concentration on dry matter basis (mg/g dry matter)</b>
1	1.24	3.86
2	1.97	3.99
3	1.08	2.70
4	1.67	3.33
5	1.39	2.81
6	1.57	3.82
7	n.a. <sup>b)</sup>	n.a.
8	1.27	2.49
9	1.69	2.86
10	1.25	2.88
11	1.88	3.53
12	1.30	2.37
13	1.42	3.27
14	1.68	3.72
15	1.26	3.04
16	1.39	3.32
17	1.09	6.95
18	1.22	3.70
19	1.80	4.01
20	1.52	4.96

<sup>a)</sup> Total weight of curcumin extracted from entire dried sample; <sup>b)</sup> n.a. = data not available

With regard to the difference between quartered and sliced samples, the comparison of results from runs 1 vs 2, 3 v 4 and 10 vs 11 shows clearly that the dried quartered samples had a lower curcumin content.

Finally, with regard to the effects of changing conditions on the curcumin content, they resulted generally in a higher concentration than constant conditions.

In this experiment, ultrasonic extraction was used in extraction instead of traditional soxhlet extraction. The time of ultrasonic extraction was 1 h. It was determined after comparing the

sonication at 55 °C for 15 min, 30 min and 1 hour. It is found that there was no peak at 425 nm wavelength times of less than 1 hour. This extraction method is reported to strength extraction efficiency and decrease extraction time [4]. The use of sonication had a significant advantage over the conventional soxhlet extraction taking several hours.

#### 4. Conclusions

This study compares the concentration of curcumin in samples of dried turmeric rhizomes subjected to different drying treatments. It has been found that the changing conditons and use of of non-blanched sliced turmeric rhizome dried at 40 °C and 20%RH yielded 3.99 mg curcumin/g dry matter which was higher than in any other sample dried under constant conditions. In comparison, the changing conditions resulted in higher curcumin content. Moreover, blanching would generally lead to a higher concentration of curcumin in the dried samples. Finally, 20% RH led to a higher concentration of curcumin than 10% RH.

### **Abstract**

*Electrohydrodynamic (EHD) drying is a novel non-thermal dewatering technology using electric discharge in air to enhance dehydration of heat-sensitive biomaterials. Low energy consumption and high product quality make it attractive for industry. In this study, the mushrooms slices have been dried under sole EHD with 12, 14, and 16 kV DC, and EHD in combination with air cross-flow at 1 m s<sup>-1</sup> and different relative humidity (RH) from 30 to 70 %. It was found that drying kinetics was exponential over initial moisture contents from 3.3 to 14.1 g·g<sup>-1</sup> (db). The equilibrium moisture content ranged from 0.15 to 0.1 g g<sup>-1</sup> depending on RH. Decrease of RH or air cross-flow significantly improved efficiency of EHD drying.*

**Keywords:** mushrooms; electrohydrodynamic; ionic wind; air humidity; equilibrium moisture content.

---

## 1. Introduction

Electrohydrodynamic (EHD) drying is regarded as a non-thermal dewatering technology, suitable for drying of heat-sensitive materials because of high product quality and low energy consumption.<sup>[1]</sup> Hence, it is excellent alternative as compared to hot-air convective drying of mushrooms with extremely short shelf life, which should be consumed or processed within hours after harvest.<sup>[2]</sup>

Commonly accepted hypothesis is that EHD drying occurs due to ionic wind. The effect of ionic wind on shiitake mushrooms drying was first investigated by Xue et al.<sup>[3]</sup> under 6, 8, 10, 12 kV AC (electric field strength from 3 to 6 kV cm<sup>-1</sup>), concurrent airflow at 45°C and 40% RH. The results showed that electro-convective drying for 10-14 hours was faster by 1.1 to 1.6 times compared to control. The effect of ionic wind increased with increasing voltage and decreased with increasing airflow rate. However, slight browning of the dried shiitake gills under the effect of ionic wind was noticed. Dutta et al.<sup>[4]</sup> showed that pre-treatment of mushroom slices with AC electric field 4.3 kV cm<sup>-1</sup> accelerated subsequent convective or freeze drying. They also reported that the EHD pre-treatment improved quality of dry mushrooms, in particular lesser shrinkage, higher rehydration ratio and enhanced color as compared to control. Dinani et al.<sup>[5, 6]</sup> investigated the effect of EHD in combination with hot air drying at 60°C and 10% RH for voltages 17, 19 and 21 kV DC, and gaps between electrodes 5, 6 and 7 cm. Electric field accelerated drying rate by 1.38, 1.41, and 1.43 times for voltages, and by 1.52, 1.36, and 1.33 times for gaps, so one can conclude that increasing of electric field strength significantly increased water diffusion in mushrooms. These experiments were done under conditions of natural convection. Similar experiments with EHD in combination with hot-air drying at 45°C under conditions of forced convection<sup>[7-9]</sup> showed significant effect of air velocity. The enhancement of the drying rate due to EHD was as high as 1.40, 1.56, and 1.78 times at 0.4 m s<sup>-1</sup>, while at 2.2 m s<sup>-1</sup> these were 1.08, 1.03, and 0.97 times (no significant effect of EHD). These results confirmed previous conclusions of Xue et al.<sup>[3]</sup> that EHD is efficient only under low air velocities, while increase of air velocity above certain threshold results in purely convective drying. Unfortunately, all these experiments with mushrooms were conducted for combination of EHD with hot air drying with temperature as the dominant drying factor. These settings hindered the role of EHD in drying, making difficult interpretation of sole EHD effect on drying kinetics and product quality.

Promising experiments on EHD mushroom drying confirmed the importance of industrial scaling of the EHD technology. This research was initiated on the request of industry partner Jantex Ltd (Poland) to improve efficiency and quality of white champignons drying because of high sensitivity of product color to drying temperature. The main objective of this paper is to present preliminary results of EHD drying of sliced white champignons, including the effects of relative humidity, air cross-flow, initial moisture content, electric

field strength and configuration of discharge electrode, which are instrumental for industrial scaling of EHD technology.

## 2. Materials and methods

White champignons (Highline, Leamington, Canada) purchased from a local grocery were cut perpendicularly to the head into 5-mm slices and then spread uniformly in a single layer on the collecting electrode. Initial mass of sliced champignons varied from 30 to 34 g. Initial moisture content was in the range 3.3 to 14.1 kg kg<sup>-1</sup> (db).

Experimental apparatus is shown in Figure 1. The drying chamber (1) was made of Plexiglas (40×20×20 cm) with two openings 10 cm in diameter. Discharge electrode (2) was built from 143 needles arranged into 11×13 rows giving 1×1 cm needles packing density or 42 needles arranged into 6×7 rows giving 2×2 cm needles packing density. Discharge electrode was connected to the positive pole of a DC high voltage source, while aluminum plate (3) with the size (20×10 cm) was used as a grounded electrode. Both electrodes were placed in the drying chamber. The room air humidity was maintained at 20% by the air conditioning system. Airflow velocity was maintained at 1.0 m s<sup>-1</sup> by a 1.5 W fan (5) and measured with the hot wire anemometer HD300 (Extech Instruments, USA). High voltage (6) was supplied by DC power supply BAL-32-5 (Voltronics, USA). Voltage and current were recorded continuously using the LabView2012 (National Instruments, USA) data acquisition system with USB-6120 interface and desktop computer (7). The weight of mushrooms was determined with a digital scale (4) (model HCB 1002, Adam Equipment, Oxford, CT, USA).

*Fig. 1 EHD experimental setup.*

Experiments for determination of equilibrium moisture content were carried out for sole EHD at 12, 14, and 16 kV with a gap 3.0 cm between electrodes, or EHD combined with air cross flow of 1.0 m s<sup>-1</sup>. The effect of initial moisture content on EHD drying rate was measured for fresh slices and for slices after storage in the cooler from one to three days. The effects of EHD (1) and EHD + air cross-flow (2) were compared with sole air cross-

flow (control 1) or natural convection (control 2) for the same batch of slices. Drying rate for each treatment was calculated for 30 min using four-steps drying protocol. For these experiments the RH was kept constant at  $20\pm 2\%$  and room temperature of  $20\pm 0.5^\circ\text{C}$ .

### 3. Results and discussions

The effect of discharge electrode geometry and air humidity on drying kinetics is shown in Figure 2. The effect of  $1\times 1$  and  $2\times 2$  cm needle packing density was studied at 15 kV, 3.5 cm gap, RH 70-80% and air cross-flow  $0.4\text{ m s}^{-1}$  (Fig. 2A). Drying kinetics showed the difference between effects of two electrodes. In particular,  $1\times 1$  electrode initiated linear drying kinetics (constant drying rate), which indicates convection-limited conditions. In contrast,  $2\times 2$  electrode initiated exponential drying kinetics (falling drying rate), which indicates diffusion-limited drying. Both cases have been reported in literature,<sup>[5,10]</sup> however the reason for the difference in drying behaviour has not been discussed.

Better results of EHD drying, obtained with  $2\times 2$  electrode, determined preferable use of such electrode in further experiments. The effect of 30, 50, and 70% relative humidity on the drying kinetics was studied with  $2\times 2$  electrode at 22 kV, 3.5 cm gap (electric field  $6.3\text{ kV cm}^{-1}$ ) and superficial velocity of air cross-flow  $1.0\text{ m s}^{-1}$  (Fig. 2B).

**Fig. 2** Moisture kinetics for different discharge electrodes (A) and relative humidity (B).

Drying time was in the range from 7 to 20 hours, depending on relative humidity. The equilibrium moisture content at the end of drying was in the range from 0.1 to  $0.15\text{ g g}^{-1}$ . This moisture content for white champignons corresponds to the range of water activities  $a_w$  from 0.3 to 0.35<sup>[11]</sup>, which is considered as safe for shelf-life stability.<sup>[12]</sup> These data demonstrate how important is to maintain low air relative humidity in the EHD drying.

Effect of sole EHD and EHD combined with convective air cross-flow on drying kinetics is presented in Figure 3. It follows that drying rate increases with voltage, which corresponds to results reported earlier.<sup>[8, 9]</sup> Drying time to reach  $0.2\text{ g g}^{-1}$  of moisture content (dashed line) significantly decreased from 25 h at  $4.0\text{ kV cm}^{-1}$  to 12 h at  $5.3\text{ kV cm}^{-1}$ . Effect of combined air cross-flow and ionic wind was significant at 12 and 14 kV, however at 16 kV

the drying effect of sole ionic wind was higher. This result is difficult to explain within existing theories of EHD drying. Therefore, the phenomenon of interaction between ionic wind and air cross-flow requires additional research.

Fig. 3 Effect of EHD drying and combined EHD with convective cross-flow drying ( $1.0 \text{ m s}^{-1}$ ) under different voltages on drying time (3 cm gap, 20% RH).

The effective moisture diffusivity ( $D_{eff}$ ) can be calculated from the following equation:

$$D_{eff} = \ln\left(\frac{\pi^2}{8} MR\right) \cdot \left(\frac{4L^2}{\pi^2 t}\right) = (-0.0851 - 0.4053 \ln MR) \cdot \frac{L^2}{t} \quad (1)$$

Based on equation (1) it is possible to estimate instantaneous diffusion coefficient from experimentally determined parameter  $k$ :

$$D_{eff} = (-0.0851 \cdot \frac{1}{t} + 0.4053k) \cdot L^2 \quad (2)$$

Results of experimental evaluation of  $k$  for different modes of EHD drying are presented in Figure 4. Parameter  $k$  was stable over drying period from 0 to 14 hours in the wide range of voltages with/without forced convection, which indicates a suitability of the exponential model for approximation of drying kinetics in EHD drying. Based on the average value of parameter  $k$ , the effective moisture diffusivity coefficient has been calculated (Table 1):

Table 1. Effective moisture diffusivity coefficient,  $D_{eff} \cdot 10^{-10} \text{ m}^2 \text{ s}^{-1}$

Drying	12 kV	14 kV	16 kV
EHD	$3.29 \pm 0.31$	$4.84 \pm 0.11$	$6.42 \pm 0.30$
EHD + $1.0 \text{ m s}^{-1}$	$3.78 \pm 0.23$	$5.09 \pm 0.14$	$5.39 \pm 0.20$

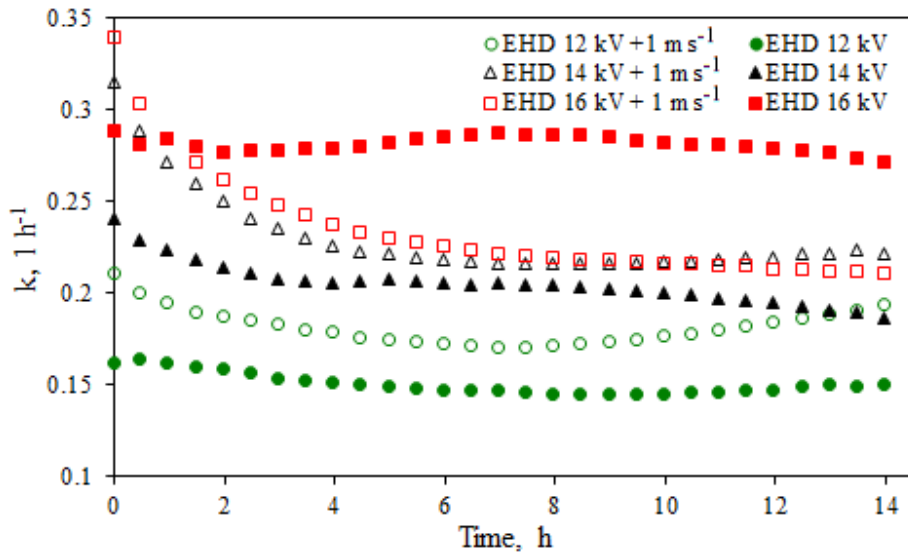

Fig. 4 Velocity of EHD drying and EHD + convective cross-flow drying ( $1.0 \text{ m s}^{-1}$ ) under different voltages on drying time.

Fig. 5 Dependence of drying rate (DR) on initial moisture content ( $X_0$ ) at EHD 14 kV and RH 20% (fitted linear regression  $DR = 3.056 + 0.4087 X_0$  with  $R^2 = 0.962$ )

From these results it is clear that drying rate is proportional to moisture content, which validates initial assumption, underlying simplified diffusion model. To study interactions between forced air cross-flow and electro-convection, the four-step experimental protocol

was designed, exploring three cases in various combinations: (1) Sole EHD, (2) air cross-flow, and (3) EHD with simultaneous air cross-flow (Fig. 6).

Fig. 6 An interactions between forced air cross-flow ( $1 \text{ m s}^{-1}$ ) and electro-convection ( $18 \text{ kV}$ ) at  $3.5 \text{ cm}$  gap,  $20 \pm 2\% \text{ RH}$ .

The case # 3 was found to be the most efficient. The enhancement ratio was: EHD/Free convection =  $6.66/1.4 = 4.757$ , EHD/Cross-flow =  $6.66/3.36 = 1.982$ , EHD+Cross-flow/Free convection =  $10.04/1.4 = 7.171$ , EHD+Cross-flow/Cross-flow =  $10.04/3.36 = 2.988$ . It follows that EHD effect was always positive, resulting in enhancement of drying rate in the range from 1.98 to 7.17 times.

#### 4. Conclusions

1. EHD drying kinetics typically followed the exponential curve, hence it is diffusion-limited and could be described by Fick's equation.
2. Drying rate of white champignons is proportional to initial moisture content, increases with electric field strength and with decrease of relative humidity.
3. The effect of needle packing density on drying rate of white champignons was significant.
4. The effect of  $1.0 \text{ m s}^{-1}$  cross-flow air on EHD drying was found significant at 12 and 14 kV, while at 16 kV the drying rate was higher than EHD without air cross-flow.
5. Effect of electric field on effective moisture diffusion was much more pronounced in the case of sole EHD: from  $3.38 \cdot 10^{-10} \text{ m}^2 \text{ s}^{-1}$  (12 kV) to  $7.22 \cdot 10^{-10} \text{ m}^2 \text{ s}^{-1}$  (16 kV).

### **Abstract**

*Agglomeration is a particle formulation process in which at least two primary particles are combined to form a new one. The growth of agglomerates depends on interactions of particles covered with wet spots that generated by depositions of binder droplets. This work experimentally compares the influence of external feed rate and sprayed binder content on product properties and process stability with internal separation at different drying conditions. Due to the identification of parameters a populations balance model (PBM) is developed. The PBM includes the agglomeration kernel function, which characterizes the kinetics, i.e. the rate at which primary particles build agglomerates.*

**Keywords:** *spray fluidized bed agglomeration; drying; continuous process; internal separation; population balances*

---

## 1. Introduction

Agglomeration is a particle formulation process in which at least two primary particles are combined to form a new one. The principle of fluidized bed spray agglomeration is especially used in chemical, food and pharmaceutical industry<sup>[1]</sup>. The advantages are good mixing and uniform high heat and mass transfer rates between particle, liquid and gas phase. Compared to previous batch processes the additional benefits of continuous processing are a constant product quality and higher throughputs. In case of fluidized bed spray agglomeration, a solid-contained liquid, called binder, is sprayed on the particles. The binder can be a solution, suspension or melt. The present work experimentally compares the influence of external feed rate and sprayed binder content on product properties and process stability with internal separation at different drying conditions. Product properties like particle size distribution or structure of agglomerates depend on these conditions and due to this, there are changes in product qualities, e.g. solubility, flowability or creation of dust free atmospheres. The growth of agglomerates depends on interactions of particles covered with wet spots that generated by depositions of binder droplets. Due to evaporation of water from the binder, wet connections between primary particles are transformed to solid bridges<sup>[2]</sup>. Therefore, the drying rate associated with gas temperature and moisture content finally determines the rate and quality of agglomeration.

## 2. Materials and Method

The starting materials for the fluidized bed and continuous feeding during the process are glass beads with distributed shapes, shown in Fig. 1. The Sauter diameter is 200  $\mu\text{m}$ , measured optical by Camsizer, Retsch Technologies GmbH, Germany.

*Fig. 1: different shapes of glass beads as primary particles*

The operating binder is a solution of water and hydroxylpropylmethylcellulose (HPMC). HPMC is a biological binder also known as Pharmacoat and is used in food and pharmaceutical industries. In the present work it is used as a solution with water and a mass concentration of 4 %. To carry out the experiments a cylindrical fluidized bed is used, illustrated in Fig. 2. The fluidized bed is in a pilot plant scale.

Fig. 2: Scheme of the fluidized bed

The particles are fluidized by heated ambient air, which enters the fluidized bed chamber from the bottom through a distributor plate. The Chamber of the fluidized bed has a diameter of 300 mm. The spray nozzle, which atomized and sprayed the solution in top-spray configuration, is installed at a distance of 420 mm above the distributor plate of the fluidized bed. An external pump supply the feeding of the solution. Particles having the target size are continuously discharged by internal classification through a tube, which is centrally installed at the bottom of the fluidized bed. The important parameters (inlet temperature –  $T_{inlet}$ , air mass flow –  $\dot{M}_{inlet}$ , feed rate –  $\dot{M}_{Feed}$ , HPMC content –  $w$  and binder spray rate –  $\dot{M}_{Spray}$ ) are shown in Table 1, all experiments started with a bed mass of 8 kg.

Table 1: Experimental parameter

Experiment	$T_{inlet}$ , [°C]	$\dot{M}_{inlet}$ , [kg/h]	$\dot{M}_{Feed}$ , [g/min]	$w$ , [% HPMC]	$\dot{M}_{Spray}$ , [g/min]
T1F150	80	275	150	4	55.5
T1F250	80	275	250	4	55.5
T1F350	80	275	350	4	55.5
T2F150	100	275	150	4	55.5
T2F250	100	275	250	4	55.5
T2F350	100	275	350	4	55.5

### 3. Results and Discussion

The Comparisons of the results of the 4 Experiments, shown in Fig. 3 and Fig. 4, are indicate that the product size of the experiments at 100 °C are smaller and the product size increase with decreasing feed rate. A break takes place during the experiment at 80 °C, for a feed rate of 150 g/min (at 35 min).

**Fig. 3:** Sauter diameter of bed (•) and product (x) samples for 150 g/ min at 80 °C (left) and 100 °C (right)

**Fig. 4:** Sauter diameter of bed (•) and product (x) samples for 350 g/ min at 80 °C (left) and 100 °C (right)

The reason is the lower evaporation rate of the water content from the solid bridges between the glass beads at lower temperature. Due to this, the residence time of with binder wetted surface get longer. It is more time to collide and connect with other wetted surfaces. The influence of the feed rate is also clear visible, especially for the experiments at 100 °C. Here at low feed rate the product particles reached a size of 0.9 mm. With increasing the feed rate the size is getting smaller. The structure analysis of the agglomerates with the Scatter electron microscope (SEM) prove the study, that at lower temperatures more binder is on the particles. The structure analysis of the agglomerates are shown in Fig. 5 and Fig. 6. For both temperatures the lowest feed rate indicates a partial coating. This means a part up to the whole particle surface is covered with the binder. With increasing the feed rate, more particles enter the spray zone and the binder solution is more distributed over the bed particles. The particles in figure 6 are indicates optically a more compact structure as in figure 5, which is proved by Camsizer measurements, shown in Table 2. This indicates that the dense of the agglomerates increase by the inlet temperature, which is confirmed by Dadkhah<sup>[3]</sup>.

**Table 2: Density of agglomerates at experimental parameters**

Temperature [°C]	F150	F250	F350
80	>1.2	1.44	1.6
100	1.47	1.7	1.7

Fig. 5: SEM pictures of product particles at 80 °C with 150 g/min (left), 250 g/min (middle) and 350 g/min (right)

Fig. 6: SEM pictures of product particles at 100 °C with 150 g/min (left), 250 g/min (middle) and 350 g/min (right)

In order to describe the dynamic behaviour of continuous fluidized bed spray agglomeration, the following population balance model can be used:

$$\frac{\partial n(t,v)}{\partial t} = \dot{n}_{feed}(t,v) - \dot{n}_{prod}(t,v) + \dot{n}_{agg}(t,v), \quad (1)$$

where  $n$  symbolizes the number density distribution,  $v$  denotes the particle volume,  $\dot{n}_{feed}(t,v)$ ,  $\dot{n}_{prod}(t,v)$  and  $\dot{n}_{agg}(t,v)$  represent particle fluxes due to the external particles feed, the reflux of the product particles and agglomeration process respectively. The formation and growth of agglomerates including initial condition can be described by:

$$\dot{n}_{agg}(t,v) = \frac{1}{2} \int_0^v \beta(t,u,v-u) n(t,u)n(t,v-u) du - \int_0^\infty \beta(t,u,v) n(t,v)n(t,u) du, \quad (2)$$

$$n(t=0,v) = n_0(v), \quad (3)$$

where  $\beta(t,u,v)$  is an agglomeration function (kernel) characterizing the kinetics of the agglomeration process. This kernel can be represented as a product of a coalescence kernel

$\beta(u, v)$ , which depends only on the volume of the agglomerating particles and an agglomeration efficiency  $\beta_0(t)$ , which is a positive possibly time-dependent function:

$$\beta(t, u, v) = \beta_0(t)\beta(u, v). \quad (4)$$

**Fig. 7: Scheme of parameter identification**

The Estimation of kinetics for an agglomeration is particularly challenging due to its highly nonlinear process dynamics. The coalescence kernel  $\beta(u, v)$ , being a nonnegative symmetric function of two variables, describes an impact of particle sizes on the probability of its effective collision. In order to understand the formation of agglomerates in a first step the mechanical kernel based on Brownian motion<sup>[7]</sup> can be applied for simulation model:

$$\beta(u, v) = \beta_0 \left( v^{\frac{1}{3}} + u^{\frac{1}{3}} \right) \left( v^{-\frac{1}{3}} + u^{-\frac{1}{3}} \right). \quad (5)$$

Assuming that time dependency of the agglomeration efficiency  $\beta_0$  can be neglected, this scalar parameter can be estimated from the experimental particle size distributions using a parallel model approach Fig. 7<sup>[4]</sup>. Substituting this mechanical kernel into the population balance model a linear regression problem can be formulated:

$$\min_{\beta_0} \int_0^T \|q_{3,meas}(t) - q_{3,est}(t, \beta_0)\|_2^2 dt. \quad (6)$$

In order to compute the given population balance model the method of lines can be applied, where the spatial coordinate is discretized using the cell-average method<sup>[8]</sup> on a logarithmic grid. The experimental and simulation results with Brownian motion kernel are depicted in Fig. 8. In Fig. 9 is shown a comparison of the initial and steady state distribution. It can be seen that using this theoretical kernel for continuous fluidized bed spray agglomeration

process yields a qualitatively good approximation of the process particularly for steady-state region.

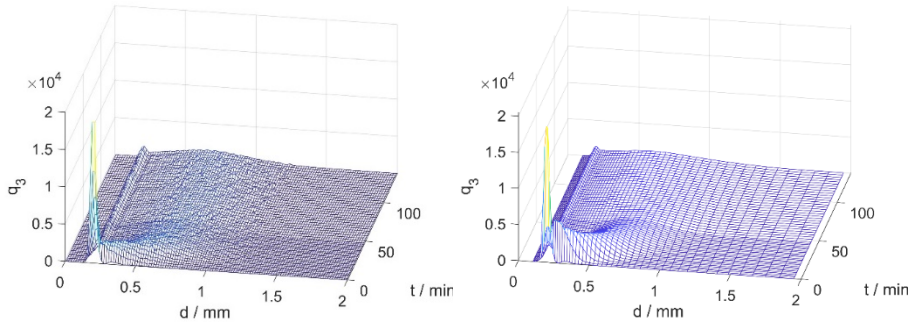

Fig. 8: Experimental (left) and simulated (right) particle size distribution  $q_3$

Fig. 9: Experimental (grey) and simulated (black) particle size distribution  $q_3$  for the initial (left) and steady state (right) distribution

#### 4. Conclusions

The Influence of the temperature and feed rate on the particle were investigated. The results of the experiments show that a lower temperature lead to bigger agglomerates. The increasing of the feed rate indicates smaller particles. A high temperature and high feed rate should be result in smaller product particles. The results of the structure investigations does not indicate a preferd shape, like sphericals or sticks, at different temperatures or feed rates.

The developed PBM model was qualitatively good approximation of the process particularly for steady-state region. In order to get more precise process approximation another kernel functions of more degrees of freedom, e.g. Laurent polynomials of two variables<sup>[6]</sup>, bilinear basis functions<sup>[5]</sup>, or time dependency of the agglomeration efficiency  $\beta_0(t)$  can be taken into account.

### Abstract

*An oil from Pacific krill (*Euphausia pacifica*) has a high content of PUFAs and phospholipids. The sediment was formed with homogenization of krill oil and maltodextrin (MD; dextrose equivalent (DE) = 19) solution using sodium caseinate, gum arabic, hydrolyzed whey protein or modified starch as a surfactant. Quillaja saponin could form the emulsion without the sediment. MD (28.5 wt%) was solubilized with distiller water (50 wt%) and mixed with krill oil (20wt%) and Quillaja saponin (1.5 wt%). The homogenized solution was spray-dried using Okawara-L8 spray dryer with a centrifugal atomizer. Spray-dried powder was evaluated in the oil-droplet size and surface-oil content.*

**Keywords:** krill oil, emulsion, Quillaja saponin, spray drying, PUFAs

## **1. Introduction**

Krill oil (KO) is a rich source of long chain n-3 polyunsaturated fatty acids (PUFAs) such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) [1], which have phospholipids, and has been suggested to have the higher bioavailability compared with fish oil. KO contains astaxanthin as antioxidant. Encapsulated KO has been used as a dietary supplement. PUFAs are inherently unstable and prone to oxidation. Gomez-Estaca et al. [2] investigated the encapsulation of an astaxanthin-containing lipid extract from shrimp waste by complex coacervation using a novel gelatin-cashew gum complex. Haidor et al. [3] investigated the encapsulation of KO using chitosan nanoparticle with emulsification and the electrostatic interaction to triphosphate. Sanguansri et al. [4] investigated the encapsulation of KO using the mixture of protein and carbohydrates by spray drying and showed the protein enhanced the oxidative stability of KO during storage. Yamada et al. [5] showed 8-hydroxyeicosapentaenoic acid (8-HEPE) acts as a peroxisome proliferator-activated receptor ligand and had higher activity than EPA. KO from the Pacific Ocean near Sanriku contained 8-HEPE.

The encapsulation efficiency of fish oil by spray drying is affected by several parameters such as oil-droplet diameter, solid and oil contents, and processing conditions. The surface-oil ratio is the most important parameter that estimates the shelf life of fish oil in spray-dried powders. Ghani et al. [7] investigated effects of oil-droplet diameter and DE of MD on the surface-oil ratio of microencapsulated fish oil and showed the surface-oil ratio was remarkably increased when the ratio of the average reconstituted oil-droplet diameter to the average particle diameter was higher than 0.01. Ghani et al. [8] investigated also the effect of DE of MD on oxidation stability in encapsulated fish oil with MD by spray drying. They indicated that the fish oil in spray-dried powder encapsulated fish oil prepared using MD of DE = 25 and 19 had lower peroxidative values (PVs) than those prepared with MD of DE = 11. The difference in PV can be ascribed to the difference in the surface-oil ratio of the spray-dried microcapsules.

In this study, the formation of emulsified KO was investigated with various emulsifier and the stability of encapsulated KO using MD (DE=19) and saponin emulsifier was examined at 50°C.

## **2. Materials and Methods**

### **2.1. Materials**

KO was purchased from Koyo Chemical Co., Ltd. (Osaka, Japan). In the formation of KO emulsion, sodium caseinate, hydrolyzed whey protein, gum arabic, modified starch or saponin emulsifier were used. Sodium caseinate and rosemary extract oil (RO) was gifted

from Mitsubishi-Chemical Foods Corporation (Tokyo, Japan). Hydrolyzed whey protein, Emulup® was purchased from Morinaga Milk Industry Co. Ltd. (Tokyo, Japan) and gum arabic was from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). Saponin emulsifier was Quillayanin S-100 from Maruzen Pharmaceuticals Co., Ltd. (Hiroshima, Japan) MD (DE=19) was gifted from Matsutani Chemical Industry Co., Ltd. (Itami, Japan). Other chemical reagents used were analytical grade chemicals from Wako Pure Chemical Industries, Ltd.

## 2.2. Method

### 2.2.1. Formation of KO emulsion

MD solution was prepared by dissolving MD in distilled water at 80 °C and cooling to room temperature. KO was blended with the solution to give 50 wt% solid content. The composition of the solution was 20 wt% KO, 1.5 wt% emulsifier, 28.5 wt% MD, and 50 wt% distilled water. The solution was mixed using a rotor-stator type homogenizer (Polytron, PT-6100; Kinematica, Littau, Switzerland) at 7,500 rpm for 3 min with a 30 s interval after 1 min and 2 min. This solution was further homogenized using a high-pressure homogenizer (Star Burst Mini; Sugino Machine Limited, Uozu, Japan) at 100 MPa for two passes.

### 2.2.2. Spray drying

The feed emulsions were spray dried using a pilot scale spray dryer (Ohkawara-L8; Ohkawara Kakouki Co., Ltd., Yokohama, Japan) equipped with a centrifugal atomizer. The feed rate was 25 mL/min, the atomizer speed was 10,000 rpm, and the air flow rate was set at 110 kg/h. In the drying process, the temperatures of inlet and outlet air were 140 °C and 70 to 95 °C, respectively

. After being cooled to room temperature, the collected powders were stored in closed glass containers at -80 °C until use.

### 2.2.3. Analysis of oil-droplet and powder-particle diameters

The size distributions of the oil droplets in the feed and reconstituted emulsion and the spray-dried powder particles were measured with a laser diffraction particle size analyzer (SALD-7100; Shimadzu Corporation, Kyoto, Japan) equipped with a batch sample cell. The reconstituted emulsion were obtained by dissolving the spray-dried powders in distilled water. The feed and reconstituted emulsion were pipetted directly into the cell containing distilled water for respective measurements. Meanwhile, the particle size distributions of the spray-dried powders were analyzed by dispersing the powders in 2-methyl-1-propanol. The volume-based diameter ( $D_{43}$ ) was considered to be the mean diameter for all measurements.

#### 2.2.4. Scanning electronic microscopy (SEM)

Surface and cross-cut images of encapsulated fish oil powders were observed by a JSM 6060 SEM (JEOL, Tokyo, Japan). The samples were placed onto the SEM sample holder using double-sided tape and coated with Pt-Pd using an MSP-IS Magnetron Sputter (Vacuum Device, Inc., Tokyo, Japan). The cross-cut structures were prepared using procedure as described by Soottitawat et al. [8].

#### 2.2.5. Measurement of DHA and EPA contents in KO

Approximately 0.2 g of oil or 0.5 g of powders was weighed in the test tube. Two ml of *N,N*-dimethylformamide (DMF) was added to solubilize KO in the tube. Then, 2 mL of hexane was added to extract KO from DMF and was stirred with a vortex mixer (Vortex-GENIE 2 Mixer, G-560 type, M&S Instrument Inc., Osaka, Japan). Hexane was sampled and 0.5 mL of KO was used to be methyl esterified with Fatty Acid Methylation Kit and Fatty Acid Methyl Ester Purification Kit (Nacalai Tesque, Inc., Kyoto, Japan). One  $\mu$ L of methyl esterified oil was injected to gas chromatography-mass spectrometry (GC-MS, Shimadzu Corp., Kyoto, Japan) with a fused silica capillary column (30 m x 0.25mm x 0.25  $\mu$ m; DB-1, Agilent Technologies Japan Ltd., Tokyo, Japan).

### 3. Results and Discussions

#### 3.1. Formation of KO emulsion

KO emulsion was formed with quillayanin, sodium casienate, hydrolyzed whey protein, or arabia gum as 3 wt% emulsifier in the solid powder by the mechanical homogenization (8,000 rpm for 3 min). The KO emulsions using sodium casienate, hydrolyzed whey protein, and arabia gum separated into two phase solution. No phase-separation occurred for the KO emulsion using quillayanin as emulsifier. Oil-droplet diameters for KO emulsions were measured with a laser diffraction particle size analyzer at 3 h after the emulsification. Except KO emulsion using quillayanin, the lower phase solution was used to measure oil-droplet diameter. Figure 1 shows the distributions of oil-droplet diameter for four KO emulsions. KO emulsions using sodium casienate and arabia gum formed aggregates and had larger oil-droplet diameter above 10  $\mu$ m. KO contains about 18wt% phospholipids. Genelally phospholipid make aggragation with proteins. These results show that protein emulsifier could not be used to emulsify KO. Saponin emulsifier, quillayanin was suitable emulsifier to form stable emulsion.

*Fig. 1. Distribution of oil-droplet diameter for KO emulsion using emulsifier, quillayanin, sodium casinate, hydrolyzed whey protein or arabia gum.*

### 3.2 Formation of spray-dried KO powder

By using quillayanin as an emulsifier, spray-dried KO powders were produced by two homogenization conditions, the mechanical homogenization and high-pressure homogenization. The spray-dried powder was also formed for the case where rosmarinic acid extract as an antioxidant was added to KO at mechanical homogenization. Table 1 shows physical properties of three spray-dried powders. Average oil-droplet diameters for three spray-dried powders were about 1.1-1.4 µm. Moisture contents were about 2 wt% for the mechanical homogenization and 3.6wt% for high-pressure homogenization. Reconstituted oil-droplet and powder diameters were about 1.4 µm and 58 µm for the mechanical homogenization and 1.1 µm and 70 µm, respectively. Figure 2 shows SEM images of surface structures and cross-cut structures of spray-dried powders. SEM images of cross-section structures for KO encapsulated spray-dried KO powders show clear oil-droplet distribution in spray-dried powder.

**Table 1. Physical properties of spray-dried powders.**

	KO emulsion		Spray-dried powder		
	Oil-droplet diameter ( $\mu\text{m}$ )	Viscosity ( $\text{mPa}\cdot\text{s}$ )	Moisture content (%)	Reconstituted oil-droplet diameter ( $\mu\text{m}$ )	Powder diameter ( $\mu\text{m}$ )
Mechanical homogenization (7500rpm)	$1.31 \pm 0.04$	$6.89 \pm 0.44$	$2.00 \pm 0.20$	$1.41 \pm 0.03$	$58.3 \pm 6.10$
High-pressure homogenization (100MPa)	$0.81 \pm 0.005$	$7.54 \pm 0.12$	$3.58 \pm 0.36$	$1.13 \pm 0.004$	$70.2 \pm 1.11$
Mechanical Homogenization + rosemary extract	$1.31 \pm 0.02$	$18.17 \pm 0.46$	$2.33 \pm 0.15$	$1.40 \pm 0.003$	$57.1 \pm 2.33$

**Fig. 2. SEM images of spray-dried KO powder by the mechanical homogenization (a, b and a', b') and high-pressure homogenization. KO in spray-dried powder for b and b' contained rosemary extract oil.**

### 3.2. Stability of EPA and DHA in spray-dried KO powder

Stabilities of EPA and DHA were investigated in spray-dried KO powders at 50°C for one- and two-week storages. Figure 3 indicates the retentions of EPA and DHA to the initial content of EPA and DHA in KO, KO plus 5wt% RO in KO, spray-dried KO powder by the

high-pressure homogenization (HP), KO encapsulated spray-dried powder by the mechanical homogenization (MH), and KO, which contained with 5wt% RO, encapsulated spray-dried powder with MH. The retentions of EPA about 0.4 in KO and KO contained 5wt% RO were higher than these of DHA about 0.1. The addition of RO to KO did not affect the retentions of EPA and DHA. The retentions of EPA and DHA for spray-dried KO powder by MH were higher than those of KO unencapsulated spray-dried powder with HP. These results suggest the force during homogenization affected the stability of EPA and DHA in KO. In spray-dried powder, RO addition improved the retention of DHA significantly in spray-dried powder. After two-weeks storage at 50°C, the retentions of EPA and DHA were obtained about 0.8 in spray-dried KO (+5wt% RO) powder. The encapsulation of KO could improve the stability of EPA and DHA. However, suitable homogenization condition and antioxidant concentration should be investigated to obtain the more stable KO encapsulated spray-dried KO powder.

Fig. 3. Stability of EPA and DHA at 50°C for on- and two-week storage

## 4. Conclusions

Spray-dried KO powder was formed by emulsification and spray drying. KO contained 5wt% RO could be encapsulated with MD (DE=19) using quillaja saponin as an emulsifier. After two-weeks storage at 50°C, the retentions of EPA and DHA were about 0.8 in encapsulated

### **Abstract**

*To assess the impact of a rest interval and bean turning on the thin-layer drying behavior of fermented cocoa beans, beans of mixed Trinitario varieties were dried in a cabinet oven at three temperatures (40, 50, 60°C) using three drying regimes, namely; continuous drying, intermittent drying (drying for 8h with a rest period of 16h), and intermittent drying with turning of beans. Moisture content, water activity, pH and colour attributes were measured and sensory evaluation of the cocoa liquor carried out on selected samples. Drying curves were constructed and drying rate constants ( $k$ ) and effective diffusivity ( $D_{eff}$ ) values determined.*

**Keywords:** *Oven-drying; Fick's Law; Rate constant; Diffusion coefficient*

## 1. Introduction

Drying of fermented beans is an important step in the primary processing of cocoa (*Theobroma cacao* L.) beans, which are dried to reduce the moisture content from about 60% to 6-7% for safe storage and transportation. During drying, oxidative chemical reactions that occur during fermentation to reduce the astringency and bitterness of the bean continue<sup>[1]</sup>. The rate of drying and the final moisture content of dried beans have a direct impact on bean quality and value-added products such as cocoa liquors and chocolates. Too rapid drying can result in the formation of a physical barrier to moisture and volatile acid movement, resulting in brittle beans with high acidity. Too slow drying can favour mould growth during storage and handling.

Sun-drying of cocoa beans is the most widely practiced method of drying due to the simplicity and use of natural energy. Sun-drying is, however, weather dependent, requires large areas of floor space and is labour intensive as the beans must be frequently mixed during drying. Artificial drying systems are used to shorten drying time and increase the rate of moisture removal from the beans<sup>[2,3,4,5,6,7]</sup>. The negative effects of rapid drying are thought to be alleviated during traditional sun-drying due to the low drying temperatures experienced, the regular turning of beans to ensure uniform drying, and through a 'resting' period which takes place during the evening and night-time. The tempering or rest period is reported to assist with moisture redistribution in the beans before the next drying phase commences<sup>[10]</sup>. For artificially dried beans, the risk of high bean acidity is exacerbated due to the typically high drying temperatures used<sup>[8,9,10]</sup>.

The objective of this study was to investigate the oven-drying of Trinitario (fine or flavor cocoa) beans at three temperatures (40, 50 and 60°C), with the specific objective of comparing the drying behaviour and selected quality attributes of beans dried continuously with that of beans handled in a manner which simulates the traditional sun-drying practice, namely, a rest period with and without the turning of beans.

## 2. Materials and Methods

Fermented cocoa beans of mixed Trinitario varieties were obtained from the Cocoa Research Centre (CRC) cocoa processing facility and dried in a Unitemp Drying Cabinet (LTE Scientific Ltd., Greenfield, Oldham). Beans were dried at 40, 50 and 60°C. The relative humidity of the drying air at each of the three oven temperatures averaged 60, 40 and 25%, respectively and the air velocity was less than 0.5 m/s. Beans were weighed ( $0.01 \pm 0.005$ g) using an Ohaus Explorer Pro Balance, Model EP2102C (Ohaus Corporation, NJ, USA) and drying was continued until there was virtually no change in weight. For Continuous drying (CD), beans were placed into the oven and dried until constant weight

was achieved. For Intermittent drying (ID), beans were allowed to dry at the respective temperatures for 8 hours, packaged and stored in a cool room (24°C) for 16 hours and re-loaded onto the trays the next morning. Beans were handled similarly for the last method; Intermittent with turning of beans (ID+Turn), with the additional turning (mixing) of beans at each weighing time. Bean moisture content, water activity ( $a_w$ ), pH and colour was assessed as previously described<sup>[11]</sup> and *Hue angle* (°) and *Chroma* were calculated as given in Equations 1 and 2<sup>[12]</sup>.

$$\text{Hue} = \text{Arc tan} \left( \frac{b^*}{a^*} \right) \quad (1)$$

$$\text{Chroma} = \sqrt{(a^{*2} + b^{*2})} \quad (2)$$

Drying rates and Moisture Ratio (*MR*) values were calculated as described by Mujaffar et al.<sup>[11]</sup> and liquor samples produced from selected dried beans were assessed based on thirteen flavour attributes<sup>[13]</sup>.

### 3. Results and Discussion

The initial moisture content and water activity values of fermented bean samples ranged from 0.78 to 1.02 g H<sub>2</sub>O/g DM (44 - 51% wb) and 0.954 to 0.966, respectively. Drying curves showing the change in moisture content with total drying time for each drying method for the range of temperatures are given in Figs. 1 (a) through (c).

Figure 1. Drying curves for cocoa beans dried as a function of total drying time.  
CD-Continuous ID-Intermittent ID+Turn (Intermittent with Turning)

Moisture content during drying was significantly affected by total drying time, drying temperature, drying treatment and time-temperature, time-treatment and temperature

treatment interactions ( $p \leq 0.05$ ). As also expected, the intermittent drying of beans (Figs. 1b and c) resulted in a step-wise decrease in moisture values due to the rest period during which there was no drying. For continuously dried beans (Fig. 1a), the effect of increasing temperature on the decline in moisture was most evident during the first 24h of drying, with higher temperatures effecting a greater decline in moisture. Bean moisture content, water activity values and the time taken to reach equilibrium moisture content are given in Table 1. Given that the moisture content of 6-8% (wb) is the industry standard as the maximum safe storage limit for cocoa beans, the time taken for beans to attain a 7% moisture value is also given in Table 1.

**Table 1. Moisture content, water activity values, time taken to reach equilibrium and 7% (wb) moisture content in dried cocoa beans.**

CD-Continuous ID-Intermittent ID+Turn (Intermittent with Turning)

Means in a column without a common superscript letter differ ( $p < 0.05$ )

Total drying time (time to attain equilibrium moisture content) for beans dried continuously at 60°C was half that of beans dried at 40°C. As expected, the drying of beans using intermittent drying (with and without turning) increased the total drying time approximately 1.5-fold at 40°C, 2.0-fold at 50°C and 2.5-fold at 60°C. Drying is enhanced at the higher temperatures, which favours increased moisture movement and increased drying potential of the air. The initial rapid decline in moisture content has been attributed to the higher moisture content of bean testa, due residual wet mucilage coating. As the testa dries and hardens, diffusion of moisture from the cotyledon to the outer surface of the bean is gradually restricted<sup>[14]</sup>. Compared with beans dried continuously, equilibrium moisture values were generally higher in intermittently dried beans (Table 1). For beans dried at 40°C, there was a slightly greater decline in moisture content in the beans dried

intermittently (ID) and with turning (ID+Turn), demonstrating that the rest period impacted positively on the decline in moisture at this temperature. No discernible drying treatment effect was observed for beans dried at 50 and 60°C. Hii et al.<sup>[7]</sup> also noted that the tempering period has little effect on the moisture reduction in beans dried at higher temperatures. The drying potential of the air at 40°C would be expected to be lower than at the higher temperatures, therefore, moisture redistribution to the surface of the bean during the rest period may have assisted the drying process. It is therefore likely that the rest interval improves moisture movement during traditional sun-drying due to the low temperatures (below 50°C) experienced during sun-drying, as well as a deeper depth of beans, typically 0.05m, compared with the single layer of beans used in this study.

The drying rate constants ( $k$ ) were determined from the initial straight line portions of plots of  $\ln$  free moisture ( $\ln MR$ ) as a function of actual drying time ( $t$ ). As given in Table 2,  $k$ -values increased as drying temperature increased ( $p \leq 0.05$ ) and there was a temperature-treatment interaction effect ( $p \leq 0.05$ ). Generally, as temperature increased the  $k$ -value increased. Drying treatment (CD, ID, ID+Turn) did not appear to have a discernible impact on the  $k$ -value, which was expected as the  $k$ -values apply to the initial stages of the drying process. The temperature dependence of the  $D_{eff}$  values and the activation energy for beans dried continuously was estimated from a plot of  $\ln D_{eff}$  versus  $1/T$  with the  $E_a$  value of 24.28 KJ/mol ( $R^2 = 0.9984$ ) obtained for continuously dried beans (CD), 36.0 KJ/mol ( $R^2 = 0.9316$ ), and 18.8 KJ/mol for intermittently dried beans with mixing (ID+Turn) ( $R^2 = 0.9369$ ).

**Table 2. Drying rate constants ( $k$ ) and diffusion coefficients ( $D_{eff}$ ) for dried cocoa beans.**

CD-Continuous ID-Intermittent ID+Turn (Intermittent with Turning)

Means in a column without a common superscript letter differ ( $p < 0.05$ )

\* $D_{eff} = k (4L^2/\pi^2)$  where  $L$  = half thickness 0.005m

At the end of drying of beans to equilibrium moisture content, there were no major visible differences in colour or appearance, although beans dried at 40°C generally appeared to be lighter in colour compared with beans dried at 50°C, and beans dried at 60°C looked slightly shrivelled. For all the drying treatments, pH values (of both testa and cotyledon) were generally higher in beans dried continuously at 50°C and lowest at 60°C (Fig.2). High acidity of beans dried continuously at 60°C was reduced through intermittent drying (with or without turning), as evidenced by a significant ( $p \leq 0.05$ ) increase in pH values. It has been recommended that drying of beans be performed at bean temperatures not exceeding 60°C to avoid retention of excessive acids<sup>[15]</sup>.

Fig. 2. pH values of bean testa and cotyledon  
CD-Continuous ID-Intermittent ID+Turn (Intermittent with Turning)

While trends in  $L^*$ ,  $a^*$ , Hue and Chroma values were not apparent, it was noted that colour attribute values were lower in all beans dried at 40°C. For beans dried at 50°C, no significant differences were seen amongst key flavour attributes such as Cocoa flavour, Bitterness, Total Fruity and Total Floral notes. Astringency scores ranged from 7.4 in beans dried continuously to 7.0 and 6.9 in beans dried intermittently, without and with turning. Total acidity scores were low, ranging from 2.4 to 3.6.

## Conclusions

Drying temperature had a significant impact on the drying rate and pH of beans dried continuously. Drying rates were optimized at 50°C, with these beans being least acidic. Increasing the drying temperature to 60°C resulted in shrivelled beans which were most acidic. With the exception of beans dried at 40°C, the introduction of a rest interval and turning of beans did not improve moisture loss. It is possible that improved moisture movement due to a rest interval during traditional sun-drying may be due to the low

temperatures (below 50°C) experienced during sun-drying, as well as the depth of bean layer during drying.

## Nomenclature

$A$	- drying constant
$a_w$	- water activity
$D_{eff}$	- diffusion coefficient (m <sup>2</sup> /s)
$DM$	- dry matter (g)
$E_a$	- activation energy (J/mol)
$FW$	- fresh weight (g)
$k$	- drying rate constant (1/min)
$L$	- half-thickness of sample (m)
$L^*, a^*, b^*$	- colour attributes
$M$	- moisture content (g H <sub>2</sub> O/g DM)
$MR$	- moisture Ratio ( $(M-M_e)/(M_o-M_e)$ )
$R^2$	- coefficient of determination
$e$	- equilibrium
$o$	- initial

### Abstract

*The objective of this research was to microencapsulating the pumpkin seed oil (PSO) by the spray dryer and also investigating the effects of some process conditions on physicochemical properties of PSO microparticles. Inlet drying air temperature (140-180°C), aspirator rate (55-75%), and peristaltic pump rate (5-15%) effects were studied. Moisture content (%W.b.), Microencapsulation Efficiency (MEE, %) and Peroxide value (POV, meq/kg sample) considered as model responses. Consequently, the ideal drying state for microencapsulation of PSO as a result of optimizing by Response Surface Methodology (RSM) determined with the aim of minimizing the Moisture content and POV and maximizing the MEE.*

**Keywords:** *Microencapsulation; spray dryer; pumpkin seed oil; optimization; RSM.*

---

## **1. Introduction**

pumpkin (*Cucurbita pepo.*) seed oil is a functional food and comprises various bioactive components such as vitamins[1], poly and monounsaturated fatty acids, proteins and minerals[2,3]. The major part of fatty acids of pumpkin seed oil (PSO) is linoleic acids (Omega-6 fatty acids) which is one of the most beneficial substances for human health[2]. Moreover, it has positive effects such as having anti-inflammatory and diuretic properties[4], decreasing total and LDL cholesterol levels, improving treatment of benign prostate hyperplasia[4], relieving diabetes by improving hypoglycemic activity[5], etc. In addition, utilization of PSO from pumpkin seeds as agro-industrial wastes, reduce the growth of environmental problems[6]. Microencapsulation is considered as an approach, which protects bioactive compounds, improves their stability and even can mask the unpleasant feelings during eating[7]. This process incorporates food ingredients in small capsules that may range from micrometer to millimeter in size and may have different shapes[8]. Among the numerous developed microencapsulation techniques, spray drying is the oldest and most widely used procedure in food industrial sector due to providing high-quality products[9]. Therefore the aim of this study was to investigate the process conditions as independent variables on dependent variables and suggest the optimal point for producing the PSO microencapsulated powder.

## **2. Materials and Methods**

### **2.1. Materials**

Pure PSO (*Cucurbita pepo* species, *Styrica* variety) was purchased after cold pressed process from Zardband Co.(Tehran, Iran). The used wall materials were gum Arabic (GA), maltodextrin DE-6 (MD), and whey protein concentrate (WPC) with 80% protein supplied by Merck Co.(Darmstadt, Germany), Roquette Co.(Lestrem, France), and Hilmar Ingredients Co.(California, USA), respectively.

### **2.2. Emulsion preparation**

The ratio of 10% core material, 20% wall material, and 70% water was used to prepare the emulsion[10]. Utilizing the formulation of 17% GA, 17% WPC, and 66% MD, wall materials were dissolved in distilled water one day before emulsification to access complete hydration. PSO was gradually added to the barricade material solution and homogenized at 1000 rpm for 5 min using a rotor-stator homogenizer (Ultraturrax Ika T25, Deutschland, Germany) at ambient temperature[11].

### **2.3. Drying apparatus and Microencapsulation of PSO**

laboratory scale dryer (BÜCHI Mini spray dryer B-191, Flawil, Switzerland) equipped with a two-fluid internal mixing nozzle atomizer with 0.7 mm diameter used. Before each

experiment, the dryer run with distilled water about 15 minutes to achieve the steady-state condition. The spray drying conditions examined in this study were inlet drying air temperature (140-180°C), aspirator rate (55-75%), and peristaltic pump rate (5-15%).

## 2.4. Analysis of microparticles

### 2.4.2. Moisture content

Moisture content was determined by drying 2 grams of powders at 70°C to constant weight (24 hours) in the oven according to AOAC method (1984) and reported as %W.b[12].

### 2.4.3. Microencapsulation efficiency

Microencapsulation efficiency (MEE) was measured based on the method described by Bae and Lee[13]. Surface oil was measured by extraction with hexane. According to preliminary tests, PSO is not volatile oil. Thus, total oil weight was assumed to be equal to the initial oil. Consequently, MEE was calculated using the following equation:

$$\text{MEE} = \frac{\text{Total oil} - \text{Surface oil}}{\text{Total oil}} \times 100 \quad (1)$$

### 2.4.4. Peroxide value

The POV was denoted after 3 months according to ISO 3976/IDF standard 74:2006 method[14], which is based on the co-oxidation of Fe (II) to Fe (III) and formation of the reddish Fe (III)-thiocyanate complex. The absorbance of the samples was read at 500 nm by a spectrophotometer against the blank solution [15]. Finally, the following equations were used to calculate the POV[14]:

$$\text{POV} = \frac{0.5mc}{55.84m} \quad (2)$$

$$mc = \frac{E}{b} \quad (3)$$

where m is the fat weight expressed as g, 55.84 is the atomic weight of Fe<sup>3+</sup>, E is the absorbance of the sample determined using a spectrophotometer, and b is the slope of the Fe (III) calibration curve obtained as 0.0276 from its standard plot.

### 2.4.5. Experimental design

The response surface methodology (RSM) was utilized to investigate the effects of process conditions on dependent variables, and also optimization. For this purpose, the Design-Expert software (State Ease Inc., Minneapolis, USA), version 11 was used and 17 random

runs in 5 central points were designed by Box-Behnken experimental design (BBD) in a full factorial plan. All data in this study were reported as averages of triplicate experiments.

### 3. Results and Discussion

The results of ANOVA and regression coefficients for the model by eradicating the non-significant terms of responses are listed in Table 1.

**Table 1. ANOVA results and regression coefficients for responses surface quadratic model.**

\*: significant effect at level  $p < 0.05$

The significance of all terms was expressed at a probability (P) level of 0.05. The results showed that the suggested model was quadratic for the whole responses. The following mathematical equation was fitted to data:

$$y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \beta_{11} X_1^2 + \beta_{22} X_2^2 + \beta_{33} X_3^2 + \beta_{12} X_1 X_2 + \beta_{13} X_1 X_3 + \beta_{23} X_2 X_3 + \varepsilon$$

where  $\beta_n$  are constant regression coefficients,  $y$  is the predicted response (Moisture content, MEE and POV), and  $X_1$ ,  $X_2$ , and  $X_3$  are the coded independent variables.

#### 3.1. Moisture content

Moisture content varied between 1.19% and 3.35% wet basis. Peristaltic pump rate had the most significant effect ( $P < 0.05$ ) on the MEE (Fig. 1a). As the inlet air temperature increased, the drying chamber temperature increased, which caused a decrease in the

moisture content. By raising aspirator rate, the supplied energy in the drying chamber increased and the moisture of droplets in the chamber evaporated more easily. At high peristaltic pump rates and subsequently high atomized emulsion in the drying chamber, the contact time of droplets with the hot drying air reduced; hence, their interior evaporation retarded. This procedure resulted in the generation of microcapsules with high moisture content at high feed flow rates. Similar results were reported by Goula et al.[16], Aghbashlo et al.[10], and Muzaffar and Kumar[17] about the effect of inlet air temperature, aspirator rate and peristaltic pump rate on spray drying, respectively. Fig. 1b shows the levels of inlet air temperature and peristaltic pump rate on moisture content.

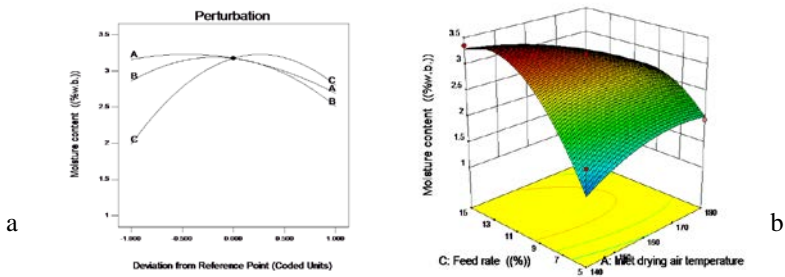

Fig.1. Effect of variables on moisture content(a), 3D response surface plot for moisture content (b).

### 3.2. Microencapsulation efficiency

The MEE varied from a minimum value of 75.36% to a maximum value of 90.95%. As demonstrated in Fig. 2a, increasing both aspirator rate and peristaltic pump rate directly affected and increased MEE. Fig. 2b shows the 3D surface response for MEE.

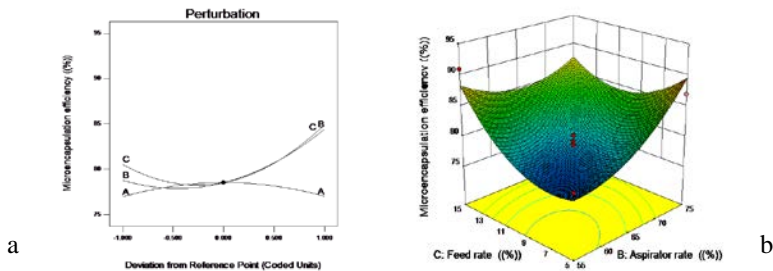

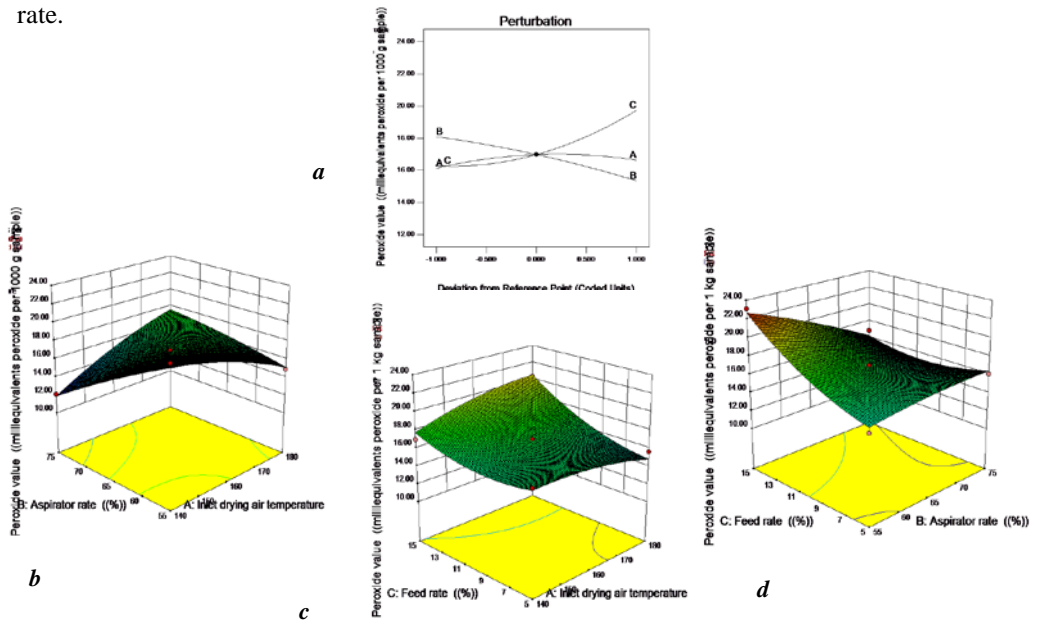

Fig. 2. Effect of independent variables on MEE (a), 3D response surface plot for MEE (b).

The fast formation of crust at early stages as a result of enhancing aspirator rate plays a vital role in generating particles with high MEE[18]. This acceleration in crust formation diminished diffusion of oil to the surface of microcapsules and consequently increased MEE. This was similar to the explanation of Aghbashlo et al in 2012[10]. The higher velocity of feed flow rate resulted in producing smaller particles during the drying process.

Break of the particles as the result of their collision with each other in the drying chamber was the main reason for this phenomenon[19], which hastened the crust layer formation. Moreover, it reduced the amount of surface oil and correspondingly enhanced MEE.

### 3.3. Peroxide value

After 3 months, the POV of the produced PSO microcapsules was found to be between 12.11 and 23.08 meq/kg. Inlet air temperature was an ineffective parameter in altering the POV ( $p > 0.05$ ; Fig. 3a). The 3D response surfaces for powder POV are illustrated in Fig. 3b, 3c, and 3d. As discussed earlier, increased aspirator rate increased the MEE (Fig. 2a) and led to high oil protection against oxidation and resulted in the reduction of POV (Fig. 3a). The presence of produced particles with high POV at high ranges of feed flow rate probably might be attributed to the chemical and physical changes taking place in the formation of the capsule walls. The higher the accumulated droplets in the drying chamber as a result of increasing the feed flow rate, the lower was the time spent for drying, which led to the appearance of the crust with insufficient solidity on the outer layer of particles. Aghbashlo et al.[10] reported similar results for POV, which was influenced by feed flow rate.

**Fig. 3. Effect of independent variables on POV(a), 3D response surface plots for POV (b,c, and d).**

The maximum and the minimum determined POV after 3 months was 23.08 meq/kg and 12.11 meq/kg, respectively. The microencapsulated powder was produced again under process conditions which the mentioned POV was determined, and the POV measured immediately were 9.03 and 6.93 meq/kg, respectively. Comparing these amounts of POV before and after the passage of the time represented that microencapsulation by a spray

dryer, could protect the PSO against the huge amount of lipid oxidation, which might occur for the un-encapsulated oil after three months.

### 3.4. Optimization

In order to achieve the best conditions for a process, optimization which is an essential tool to obtain acceptable results from various processes, used. As the higher amounts of MEE and lower amounts of POV lead to lower deterioration of pumpkin seed oil by oxygen and lengthened storage time of the product[10], optimization performed to minimizing the Moisture content as a characteristic of the drying process, maximizing the MEE and minimizing the POV. Consequently, the ideal drying state for microencapsulation of PSO was suggested by RSM to be inlet air temperature of 140 °C, aspirator rate of 75 %, and peristaltic pump rate of 5% to offer moisture content of 0.27 (%W.b.), microencapsulation efficiency of 88.60%, and peroxide value of 13.97 meq/kg sample with the total desirability of 89%.

## 4. Conclusion

The research indicates that spray drying is the suitable method to obtain the high amount of MEE in microencapsulating of PSO under the studied process conditions. Spray drying conditions such as aspirator rate and peristaltic pump rate significantly affected the characteristics of PSO microcapsules. Inlet air temperature had no significant effect on alteration of output responses, which could be related to its low range of variation (140–180°C). Microencapsulation by a spray dryer could protect the PSO against the high amount of lipid oxidation according to POV analysis.

### **Abstract**

*Spray drying plays a crucial role in the processing of pharmaceutical products such as pills, capsules, and tablets as it is used to convert drug containing liquids into dried powdered forms. Nano spray drying is in particular used to improve drug formulation by encapsulating active ingredients in polymeric wall materials for protection and delivering the drugs to the right place and time in the body. The nano spray dryer developed in the recent years extends the spectrum of produced powder particles to the submicron- and nanoscale with very narrow size distributions and sample quantities in the milligram scale at high product yields. This enables the economical use of expensive active pharmaceutical ingredients and pure drugs. The present paper explains the concept of nano spray drying and discusses the influence of the main process parameters on the final powder properties like particle size, morphology, encapsulation efficiency, and drug loading. Application results of nano spray drying for the formulation and encapsulation of different drugs are reviewed.*

**Keywords:** *nano spray drying; pharmaceuticals; drug encapsulation; particle size; powder*

---

## 1. Introduction

Spray drying is a simple, fast, and scalable drying technology that is well established in the pharmaceutical industry. Many pharmaceutical products such as pills, capsules, and tablets are processed in dried powdered form. In the course of the rapid progress of nanocapsulation techniques, nano spray drying technology has developed to improve the formulation and administration of drugs with solid colloidal particles in the submicron size range. It enables the encapsulation of active ingredients in polymeric wall materials providing enhanced environmental protection (e.g. against oxidation, light, and temperature), stability, handling, storage, and controlled drug release properties. The nanonization and structural change improves the particle solubility and redispersibility of the final drug product in aqueous solutions. This study explains the concept of nano spray drying, the influence of the main process parameters on the powder properties (e.g. particle size, morphology, encapsulation efficiency, drug loading), and discusses different pharmaceutical applications. More detailed information on the formation of nanocapsules by nano spray drying can be found in several review studies [1–12], in particular in a recently published book chapter by Arpagaus et al. [1].

## 2. Process Parameters of a Nano Spray Dryer

Figure 1 shows the functional principle of a nano spray dryer and the adjustable process parameters and formulation variables. The droplet generation is based on vibrating mesh technology ejecting precisely sized droplets into the drying chamber.

Figure 1 Process parameters and formulation variables for a nano spray dryer [1].

With a 4.0  $\mu\text{m}$  spray mesh approximately 3 to 8  $\mu\text{m}$  water droplets are produced [1,8]. The dried particles are captured in an electrostatic particle collector providing high particle collection efficiency. The cooling effect of the evaporating solvent keeps the droplet temperature low, so that heat sensitive products can be dried with negligible degradation. Table 1 provides an overview of the main process parameters and their influence on the final powder product. The thickness of each arrow illustrates the strength of the relationship. The key parameters controlling the final particle size are the spray mesh size and the solid concentration. The submicron size is typically reached when a 4.0  $\mu\text{m}$  spray mesh and diluted solutions of 0.1 to 1% (w/v) are used.

**Table 1 Influence of the main process parameters in nano spray drying (▲/▼strong, †/‡weak increasing/decreasing influence, – minimal or no influence) [1].**

Process parameter	Outlet temperature	Droplet size	Particle size	Feed rate	Moisture content	Yield	Stability
Drying gas flow rate †	▲	–	–	–	▼	–	–

Solid concentration †	†	–	▲	▼	‡	†	–
Surfactant / stabilizer †	–	‡	‡	†	–	†	▲
Solvent instead of water	▲	‡	‡	†	▼	†	–

Depending on the application, an optimized set of process parameters can be found, e.g. by design of experiment studies [1]. Organic solvents like dichloromethane, acetone, ethanol, methanol, acetonitrile, ethylacetate, and mixtures thereof with water are typically used in nano spray drying of pharmaceuticals. The selection is based on the drug solubilization and the encapsulating wall materials, as well as on the required drying temperatures. For aqueous applications, the outlet temperatures range between 28 and 59 °C [2]. The optimal drying temperatures of for example poly(lactic-co-glycolic acid) (PLGA) dissolved in dichloromethane lies in a range of 29 to 32 °C [12].

Numerous excipients, dispersing agents, binders and stabilizers are applied in drug formulation studies, including water-soluble saccharides (e.g. arabic gum, alginate, chitosan, cyclodextrin, cellulose derivatives, modified starch, maltodextrin, pectin, mannitol, lactose trehalose), proteins (i.e. gelatin, serum albumin, whey protein, sodium caseinate, silk fibroin, leucine), water-soluble synthetic polymers (e.g. poly(vinyl alcohol), poly(ethylene glycol) or poly(acrylic acid) (Carbopol)), hydrophobic synthetic polymers (e.g. PLGA, poly( $\epsilon$ -caprolactone), poly(vinyl pyrrolidone) (Kollidon), Eudragit), and fats (e.g. stearic acid and glyceryl behenate (Compritol)).

The morphology of particles prepared by nano spray drying depends on the drying conditions and the feed properties. Dense, hollow, porous, composites, and encapsulated structures (i.e. single-core, multi-core, irregular, or multi-walled) with spherical, wrinkled, shriveled, or even doughnut-like shapes can be obtained [1]. Figure 2 illustrates some examples of nano spray dried particles including salbutamol, albuterol in mannitol, cyclosporine in PLGA, trehalose,  $\beta$ -galactosidase in trehalose, and bovine serum albumin.

**Figure 2** Examples of nano spray dried particles: **A:** Salbutamol sulfate (1% solid concentration, nano spray dried at 100 °C) [13]; **B:** Albuterol sulfate in mannitol, L-leucine and poloxamer 188 (30:48:20:2 mixing ratio, 0.5% in water-ethanol solution (80:20), 70 °C) [14]; **C:** Cyclosporin in PLGA (50:50, 15 kDa, dissolved in DCM, 29°C) [12]; **D:** Trehalose with addition of 0.005% polysorbate 20 (0.1%, 120 °C) [8]; **E:**  $\beta$ -galactosidase in trehalose (1:2 mixing ratio, 5%, 80°C) [11]; **F:** Bovine serum albumin with 0.05% Tween 80 (0.5%, 120 °C) [6].

In general, slow drying leads to more compact particles, while fast and high temperature drying favours the formation of hollow particles with thin shells. Surfactants balance the surface-to-viscous forces inside of the drying droplet and enable the formation of a smooth spherical surface. Composite particles prepared from suspensions and nano spray drying provide a high specific surface area. Most nano spray dried drugs tend to be amorphous due to the too short drying time to form crystalline structures. To prevent recrystallization, the dried powders are stored under dry and controlled conditions.

### 3. Applications of Nano Spray Dried Pharmaceuticals

The number of publications on nano spray dried pharmaceuticals has risen sharply after the market launch of the Nano Spray Dryer B-90 in 2009 [1]. The formulations contain drugs and excipients for the treatment of various diseases, including

- *asthma* (e.g. salbutamol, terbutaline, or fluticasone),
- *inflammation* (e.g. dexamethasone and azithromycin, or pain and fever reducer indomethacin and nimesulide),
- *cystic fibrosis* (e.g. antibacterial dexketoprofen in Kollidon and Eudragit nanoparticles, or azithromycin in leucine),
- *diabetes* (e.g. sitagliptin, vildagliptin, and metformin in mucoadhesive Carbopol and gelatin),
- *pulmonary arterial hypertension* (e.g. resveratrol in poly(caprolactone), or sildenafil in PLGA),
- *tuberculosis* (e.g. capreomycin or pyrazinamide in L-leucine, or ethambutol mixed with chitosan carrier particles),
- *Alzheimer's and Parkinson's diseases* (e.g. nanocrystals of calpain inhibitor steroids),
- *breast cancer* (e.g. simvastatin loaded PLGA particles), or *lung cancer* (e.g. methotrexate, carboplatin in gelatine, or paclitaxel),
- *bacterial infections* (e.g. amoxicillin, ciprofloxacin, gatifloxacin, clarithromycin, or levofloxacin),
- *fungal infections* (e.g. antifungal griseovulfin)
- *ophthalmic disorders* (e.g. calpain inhibitor nanocrystals or dirithromycin incorporated in Kollidon),
- *high blood pressure* (e.g. nimodipine in PLGA or pure nicergoline nanoparticles),
- *congestive heart failure and edema* (e.g. diuretic furosemide).

The drug-loaded nano spray dried particles are administered in various ways underlining the versatility of the applications, such as mainly *pulmonary* (e.g. optimized respirable particles of 1 to 5  $\mu\text{m}$  size) and *oral*, but also *intravenous* (e.g. simvastatin in PLGA as cancer chemotherapeutics, antipsychotic clozapine and risperidone in PLGA, or small interfering RNAs loaded in human serum albumin particles to treat genetic disorders), *topically* as creams to the skin (e.g. anti-inflammatory dexamethasone, antibacterial gentamicin in

gelatin-pectine, amoxicillin loaded chitosan, antifungal econazole in cyclodextrin, soy isoflavones for skin cancer treatment or as anti-ageing agent), or as nanoparticulate powder (e.g. as a wound dressing during surgery), *ophthalmic* (e.g. anti-inflammatory steroids in eye drop solutions, or dirithromycin to treat ocular bacterial infections), *intraperitoneal* (e.g. encapsulated paclitaxel as cytostatic in anticancer therapy), *intravesical* (e.g. as drug delivery system to treat local bladder diseases), and even *cerebral* (e.g. with nimodipine in PLGA regulating the dilatation of blood vessels).

Typical experimental process parameters for nano spray drying are listed in Table 2 and can be used as first guess values for applying identical or similar substances. The main organic solvents used to dissolve poorly water soluble drugs are ethanol, acetone, and DCM. With highly diluted solutions containing 0.1 to 1% (w/v) solids concentrations, finest solid particles down to 100 nm can be obtained by nano spray drying.

**Table 2 Typical experimental process parameters for nano spray drying of pharmaceuticals.**

Solvent	Inlet drying temperature [°C]	Outlet drying temperature [°C]	Drying gas type	Drying gas flow rate [L/min]	Solid concentration [% w/v]	Spray mesh size [µm]	Feed Rate [mL/h]
Water	60 to 120	30 to 60	Air	100 to 140	0.1 to 10	4.0	5 to 25
Ethanol	50 to 110	30 to 50	Air	100 to 120		5.5	20 to 65
Acetone	40 to 70	25 to 40	Inert gas	90 to 120		7.0	30 to 160
DCM	30 to 50	20 to 35	(N <sub>2</sub> /CO <sub>2</sub> )	80 to 120			

Pure drug particles in the nanosize dimensions and the amorphous state offer higher absorption rates and bioavailability, and encourage future developments in this research area. Nanocapsules, with their reduced size and large specific surface area, provide pronounced improvement in controlled drug release and bioavailability. This enables the generation of target drug delivery systems. Under optimized conditions uniquely high product yields of about 76 to 96% can be achieved to process small sample amounts of substances in the range of 10 mg to 2.5 g.

Variations in the yield may occur due to particle depositions around the spray cap and the chamber walls, nozzle blockage, or due to losses during the manual collection of the powder with a rubber spatula.

However, the ability to process small sample amounts makes a nano spray dryer very suitable for testing valuable biological materials such as for example monoclonal antibodies, recombinant proteins, or siRNA-based therapeutics. Moreover, nano spray drying enables the encapsulation of drugs in polymers with high efficiency of over 95% and adjustable drug loading.

## 4. Conclusions

Nano spray drying has been successfully applied for a wide range of pharmaceutical applications, such as increasing the bioavailability of poorly soluble drugs by nanoisation and structural modification, as well as the encapsulation of nanoparticles, nanoemulsions and nanosuspensions in biocompatible polymeric wall materials for sustained drug release. Encapsulation efficiencies of over 95% are achieved by adjustable drug loadings. Smallest sample amounts ranging from 10 mg to 2.5 g with uniquely high yields of over 95% can be processed, which enables the economical use of valuable active pharmaceutical ingredients.

Compared to conventional spray drying processes, nano spray drying relies on vibrating mesh technology to produce an ultrafine spray. A highly efficient electrostatic powder collector to extend the size spectrum of separable particles to the nanoscale.

The most important adjustable process parameters are the drying gas temperature, the drying gas flow rate, the spray mesh size, the solvent type, the solids concentration in the feed, and the selection of the corresponding excipients, stabilizers and surfactants. Depending on the application, an optimized set of parameters can be found. Submicron spray dried particles can be formed down to a size of only 100 nm with diluted solutions of 0.1 to 1% (w/v) solids concentration. Different particle morphologies can be created, including dense, hollow and porous particles with spherical, wrinkled, or donut shapes.

The drying process is gentle and contributes to maintaining the stability and activity of heat-sensitive materials, such as peptides, proteins, hormones and amino acids. The prepared drug loaded particles are administered in various ways, including pulmonary, oral, intravenous, topically, ophthalmic, intraperitoneal, intravesical, or even cerebral, which underlines the versatility of the nano spray drying technology.

To further explore the potentials of nano spray drying future research should focus on the further commercialization of this technology to an industrial scale. There is an increasing need for scale-up.

The main application trends are in the areas of pulmonary drug delivery, nanotherapeutics, the encapsulation of nanoemulsions with poorly water-soluble active ingredients and the formulation of nanocrystals for a higher bioavailability.

### **Abstract**

*Sprouting is a green technology contributing in improving cereals and pulses nutritional properties. However sprouts have a high water content limiting their shelf-life. This research focused on the impact of drying technology on physico-chemical, functional and nutritional properties of Tunisian landrace durum wheat (*Triticum durum*) “Chili” sprouts for their use as a functional ingredient. Three technologies were evaluated: lyophilisation, micro-wave vacuum drying and oven drying at 50°C. Sprouted seeds flour properties were significantly ( $p < 0.05$ ) affected by the drying methods used. Lyophilisation led to the highest preservation of bioactive compounds followed by micro-wave vacuum drying. The way of evolution of physico-chemical and functional properties depended on drying method used.*

**Keywords:** *Sprouts; drying; functional properties; bioactive compounds.*

## 1. Introduction

Consumers perception of eating has changed: food products are not only needed for satisfying hunger. They are also considered as a key factor in improving health and wellbeing [1]. To satisfy this need, food manufacturers are more and more interested in developing products with added nutritional value. Sprouting is an old practice used to enhance naturally seeds’ nutrients and bioactive compounds [2]. Sprouting process increases also seeds moisture content. Thus sprouts couldn’t have a long shelf life.

Drying is the simplest and the oldest method used for food preservation [3]. Several methods could be used to dry agricultural products, from home drying (oven, sun) to developed technologies. Depending on the used method, drying may lead to quality degradation [3]. Modifications affecting products’ components (proteins, carbohydrates, lipids...) occurring during drying contribute in a modification of dried products functional properties [4]. For food manufacturers, these properties are an important parameter to take into account in food formulation. Particularly, for functional foods development, added to functional properties nutritional ones have a high interest.

The aim of this study is to evaluate the effect of different drying methods (convective hot air, lyophilisation and microwave vacuum drying) on physico-chemical, functional and nutritional properties of “Chili” Tunisian landrace durum wheat sprouts for its further use as a functional ingredient.

## 2. Materials and Methods

### 2.1. Plant material

“Chili” Tunisian cultivar of durum wheat (*Triticum durum*) was used in this study. It was introduced from France, and the pure line was registered in 1953 [5]. Samples (Harvested in 2015) were kindly provided by the National Gene Bank of Tunisia (BNG, Tunisia).

### 2.2. In vitro sprouting

Durum wheat seeds (*Triticum durum*) were germinated for 48h after their disinfection with 1 % (V/V) hypochlorite sodium solution.

### 2.3. Drying

Three drying methods were tested: convective hot air drying (L-MIM 320, Hungary) at 50°C, lyophilisation (Christ freeze dryer alpha 1-4 LCS, Germany) after freezing at -80°C and intermittent microwave vacuum drying (MVD) (60s on/off power at 850W and a vacuum pressure of 1kPa) using custom-designed MVD dryer.

All drying experiments were performed in triplicate until reaching at least 15% water content. After drying, all samples were milled (Retsch Grindomix GM 200, Germany) and stored at 4°C until analysis.

## **2.4. Physico-chemical properties**

Moisture content of all samples was analyzed using the AOAC oven method [6]. Novasina LabMaster  $a_w$  (Switzerland) was used for water activity determination at 25°C. Color was measured with a Konica Minolta Chroma Meter CR 400 (Japan). The color parameters  $L^*$ ,  $a^*$  and  $b^*$  were evaluated. Bulk density was determined according to the procedure previously described [7].

## **2.5. Bioactive compounds**

Folin-Ciocalteu method was used for total phenol content assessment [8]. Total carotenoid pigments were determined [9]. DPPH (1,1-diphenyl-2-picrylhydrazyl) radical scavenging activity (DPPH RSA) was measured according to the suggested previously [8] with slight modification during extraction: Extraction was made with 80% (v/v) aqueous methanol solution, for 2 h at 37 °C. Samples were afterwards centrifuged at 6,000 rpm for 30min. The supernatant was used for the determination of antioxidant capacity.

Antioxidant activity was calculated according to the following formula:

$$\% \text{DPPH RSA} = (1 - A_{\text{Sample}/t=30} / A_{\text{Control}/t=0}) * 100$$

## **2.6. Functional properties**

Water absorbance capacity (WAC) and Oil absorbance capacity (OAC) were determined [10]. Swelling power was evaluated following the described procedure [7].

## **2.7. Statistical analysis**

Statistical analysis was carried out using the Minitab software (Minitab 17). All experiments were carried out in triplicate and the average values were reported together with standard deviations. Analysis of variance (ANOVA) was performed using the Fisher test. Significance was defined at  $p < 0.05$ .

# **3. Results**

## **3.1. Physico-chemical properties**

As shown in table 1, drying, regardless the method used, contributed to a significant decrease in water content and water activity. Results obtained show that shelf life may be extended as bacterial growth induced by sprouting could be stopped at the obtained levels of water activity.

Drying induced changes in color parameters: a decrease in lightness was observed after oven and micro-wave vacuum drying unlike lyophilisation. For redness and yellow index, sprouted micro-wave vacuum dried samples showed a significant increase while a significant decrease was observed after oven drying and lyophilisation.

**Table 1. Evolution of physico-chemical parameters of Chili's sprouted wheat flour (n=3)**

Treatment	Water content (%)	Water activity (a <sub>w</sub> )	Lightness index (L*)	Redness index (a*)	Yellow index (b*)
Raw	10.13±0.07 <sup>d</sup>	0.488±0.00 <sup>c</sup>	74.99±0.06 <sup>b</sup>	2.87±0.02 <sup>b</sup>	18.94±0.03 <sup>a</sup>

### 3.2 Functional properties

Results describing evolution of functional properties after sprouting and drying are summarized in table 2. Functional properties are a key factor in food conception. These properties are related to flour characteristics (composition, structure, crystallinity, polar groups...) [11]. Sprouting is a physiological event marked by degradation of macromolecules such as protein and starch [12, 13]. As shown in table 2, functional properties of Chili's sprouted wheat flour were affected not only by sprouting, but also by the drying method: a significant decrease ( $p < 0.05$ ), depending on the drying method used, was observed in bulk density and swelling power as found previously [7]. The decrease in swelling power could be linked to the degradation of starch molecules during sprouting [14]. A decrease in water absorbance capacity was observed after drying except for micro-wave vacuum dried samples. For oil absorbance capacity, both sprouting and drying, the method used, induced a significant increase if compared to raw seeds. These findings are in agreement with a previous study dealing with sprouted cereals [15].

**Table 2. Evolution of functional properties of Chili's sprouted wheat flour after drying (n=3)**

Treatment	Bulk density (g/ml)	Water absorbance capacity (WAC)(g/g)	Oil absorbance capacity (OAC)(g/g)	Swelling power (g/g)
Raw	0.77±0.01 <sup>a</sup>	0.92±0.00 <sup>b</sup>	1.02±0.00 <sup>d</sup>	6.11±0.05 <sup>a</sup>
Oven drying	0.74±0.00 <sup>b</sup>	0.90±0.01 <sup>b</sup>	1.05±0.02 <sup>c</sup>	3.74±0.08 <sup>c</sup>
Lyophilisation	0.74±0.00 <sup>b</sup>	0.84±0.00 <sup>c</sup>	1.28±0.01 <sup>b</sup>	3.71±0.05 <sup>c</sup>
Micro-wave vacuum drying	0.62±0.00 <sup>c</sup>	1.57±0.04 <sup>a</sup>	1.35±0.02 <sup>a</sup>	4.53±0.07 <sup>b</sup>

Means in same column that do not share same letters are significantly different, according to Fisher's test.

### 3.3 Nutritional properties

Comparing raw seeds flours to sprouted freeze dried ones shows a significant increase in bioactive compounds (+18.7% for carotenoids, +118.7% for total phenol content) and consequently in antioxidant activity (+31.6%). In fact, lyophilisation process is known by preserving products nutritional and sensory properties [16]. Our results about the role of sprouting in enhancing bioactive compounds are in agreement with previous studies [2]. Despite nutritional improvement induced by sprouting, micro-wave vacuum and convective drying decreased carotenoids and total phenol amounts significantly. Highest losses were obtained after oven drying, probably due to drying process duration if compared to micro-wave vacuum drying one.

**Table 3. Effect of drying method on bioactive compounds and anti-oxydant activity of Chili's sprouted wheat flour**

Treatment	Carotenoids (mg β carotene/kg dm)	Total phenol content (mg GAE/g dm)	DPPH RSA %
Raw	18.53±0.23 <sup>b</sup>	19.93±0.49 <sup>b</sup>	32.50±0.82 <sup>b</sup>
Oven drying	8.50±0.24 <sup>c</sup>	7.28±0.07 <sup>d</sup>	18.54±0.87 <sup>d</sup>
Lyophilisation	21.99±0.42 <sup>a</sup>	43.59±0.34 <sup>a</sup>	42.78±0.39 <sup>a</sup>
Micro-waves vacuum drying	18.06±0.18 <sup>b</sup>	13.00±0.06 <sup>c</sup>	24.99±0.45 <sup>c</sup>

Means in same column that do not share same letters are significantly different, according to Fisher's test

GAE: Gallic Acid Equivalent, dm: dry matter bases, DPPH RSA: (1,1-diphenyl-2-picrylhydrazyl) radical scavenging activity

## **4. Conclusion**

Results of this study showed that drying amplified modifications induced by sprouting Chili's durum wheat seeds. All tested drying methods led to a decrease in moisture content and water activity which may increase sprouts shelf life and promote their use in cereal products. However, only lyophilisation allowed preservation of nutritional improvement obtained by sprouting. Evolution of functional properties depends on drying process adapted.

### **Abstract**

*Process modeling of conveyer dryer for cellulosic fibre drying demands many fundamental insights. Present study highlights detailed cellulosic fibre drying aspects like mass transfer correlation relating mass transfer rate with process conditions, normalized drying curve and critical moisture content. Cellulosic fibre drying follows falling rate period, where rate of mass transfer decreases with moisture content. Conveyer dryer process model for commercial cellulosic fibre drying was developed and validated successfully. Moderate drying strategy derived based on developed process model and drying fundamentals was deployed at commercial scale which helped in reducing the moisture variability.*

**Keywords:** *Cellulosic fibre, Conveyor dryer, Process Model, Sherwood number, Moderate drying.*

---

## **1. Introduction**

Cellulosic fibres provide key attributes of comfort and softness to the final textile fabrics [1]. The widely used cellulosic fibres are cotton and man-made cellulosic fibres (viscose, lyocell, modal, etc.). Commercially all man-made cellulosic fibres are prepared by dissolving specific grades of pulp in a solvent, extruding into fibres followed by regeneration in a spin bath, cutting into specific lengths, web formation by steam/air sparging, treatment/washing and subsequently drying. The drying process is preceded by squeezing of fibre mat to remove excess water and opening the fibres in a mat opener. The drying process in case of cellulosic fibres, are pre dominantly carried out in hot air conveyer dryers to achieve desired moisture content in the final product [2]. Standard size (250 kg) bales are made out of dried fibres with a fibre meeting quality specs of 10.5- 11.5 wt. % (dry basis) moisture content.

Low moisture variability and low levels of wet and over-dried fibres are key drivers to get good processibility and yarn quality in the downstream industry of converting fibres to yarn [3]. Major factors imparting variability are dryer inlet moisture variation and methodology adopted during drying operation. Precise control over dryer inlet moisture variability in cellulosic fibre was very difficult to achieve whereas effective control over dryer operation was the most practically feasible option. Improvement in fibre opening, mat uniformity, over drying followed by conditioning and control of air flow distribution inside the dryer by modifying the internal dryer design have been attempted historically [4]. These improvements alone have a limitation to reduce the variability, if not coupled effectively with control of operational parameters like air temperature, humidity and air distribution over fibre web. Mathematical modeling supported by specific product drying fundamentals, understanding of heat, mass and momentum aspects have also helped in getting effective control over moisture and its variability [5, 6, 7]. Efforts towards understanding the cellulosic fibre drying fundamentals and its use in commercial scale conveyer dryer process modeling to control the fibre quality forms the basis of this study as it was not reported in the literature.

A process model for commercial scale cellulosic fibre dryer was developed in Aspen, supported with data from understanding of cellulosic fibre drying fundamentals like drying rate curve, fibre critical moisture content and mass transfer correlation relating process parameters. Main goal of this study was to reduce moisture variability of cellulosic fibre at commercial scale with precise control in a narrow range (10.5-11.5 wt. % on dry basis) and lower energy consumption during drying operation.

## **2. Materials and methods**

Cellulosic fibre, in the form of viscose staple grey fibre, was used in this study from a leading man-made fibre manufacturer in India i.e. GRASIM industries. Commercial samples with

standard fibre length (38 mm) and diameter (45  $\mu\text{m}$ ) were chosen for the experimental studies to avoid raw material variability factor.

## 2.1. Experimentation for fundamental understanding of drying

Two separate experimental set-ups were developed to gather information for viscose fibre drying. First set-up was used to find out the drying kinetics and the second set-up to develop the correlation between mass transfer co-efficient and diffusivity. Developed fundamental understanding about drying kinetics and mass transfer correlation was used in Aspen model.

### 2.1.1. Drying kinetics experiments

Experiments were performed at different air temperatures (80°C, 100°C, 120°C and 140°C) to find out the critical moisture content and drying rate curve of viscose staple fibre. Fully dried commercial viscose fibre samples were soaked in known water quantity for experimental purpose. Initial moisture of viscose fibre was at 300% and maximum overall sample weight in individual experiment was chosen to be around 2g based on analyzer limitations. Moisture analyzer continuously recorded moisture percentage and sample weight in every 30 seconds based on the thermo-gravimetric principle. Each experiment was repeated three times to check the repeatability.

### 2.1.2. Mass transfer correlation experiments

Drying kinetics is mainly driven by rate of mass and heat transfer coupled with momentum. A decreasing linear period with decreasing drying rate is generally happen after a critical point where drying rate is depended on drying conditions [8] similar to constant rate period. Therefore, mass transfer correlation was developed (Equation 1) using Sherwood number with air temperature ( $T_G, ^\circ\text{C}$ ), air absolute humidity ( $Y$ , kg moisture/kg dry air) and inlet fibre moisture content ( $X_{in}$ , kg moisture/kg dry fibre).

$$\text{Sh} = f(T_G, Y, X_{in}) \quad (1)$$

A separate set-up was developed where air of desired humidity (from air handling unit) was heated with the help of electric coils to raise the air temperature and wet viscose fibre sample was positioned at the bottom of the drying unit with cross-flow of hot air through fibre web/mat. Temperature and humidity sensors were placed in desired location of the setup to monitor the air quality. During experiments, air velocity was maintained at 0.6 m/s, similar to commercial dryer operation. Experiments were designed with three different air temperatures (60, 80 and 100°C), four different moisture content of fibre sample (20, 40, 70 and 100 wt. %) and three different absolute humidity conditions (0.022, 0.065 and 0.12 kg/kg dry air). A total of forty-five set of experiments were planned for developing the mass transfer correlation, which was validated with five more random experiments.

## 2.2. Development of process model

Fundamental understanding generated through experimental insights gave an idea about the preferable operational procedure. However, an optimum solution was essential to adopt in commercial plant operation. Aspen process simulation tool was used to predict the optimized solution with the help of experimentally generated basic data on viscose fibre drying.

Complete conveyor dryer (Fig. 1) was modeled with counter-current flow of air and viscose fibre, where each dryer zone was represented as a single dryer unit. Commercial conveyor dryer was divided into two sectional dryers, i.e. Dryer-A and Dryer-B, with further sub divisions of each sectional dryer. Fibre (solid) moved in axial (horizontal) direction with plug flow in each dryer, which operated at adiabatic saturation. NRTL (non-random two liquid) thermodynamic method was selected as a base method and STEAM-TA was opted for free water method as high pressure steam was used for air heating. A two stage heater-condenser arrangement was used to highlight the indirect air heating phenomena in Aspen.

*Fig. 1: Schematic representation of developed Aspen model: Multistage conveyor dryer*

Mass and energy balance equations for both gas (air) and solid (fibre) phases were used in the background, which are inbuilt in Aspen [9]. Experimentally generated fundamentals, like mass transfer correlation, critical and equilibrium moisture content [10] and normalized drying rate with shape factor of viscose fibre were incorporated as input to Aspen model.

## 3. Results and discussion

### 3.1. Drying curve: Viscose cellulosic fibre

Drying rate curves were generated based on moisture data, as shown in Figure 2 (a), for viscose fibre at four different temperatures as per the procedure explained in section 2.1. Increase in drying temperature shows increase in drying rate, which diminishes towards end of drying i.e. at an equilibrium moisture content. Equilibrium moisture content of viscose staple fibre was around 8-12 % for 30-60 % RH at 25°C [10].

Slope change of drying rate versus moisture content highlighted distinct periods like preheat zone, constant rate and falling rate period. Drying rate was observed to be very high at the preheat zone. Constant drying rate period typically follows preheat zone, due to continuous moisture availability at fibre surface where drying rate is controlled by heat transfer rate. Unavailability of moisture at the viscose fibre surface was observed in falling rate period where rate of moisture evaporation decreases with reduction in fibre moisture content. Transition from constant drying rate period to falling rate happens at a particular moisture content known as critical moisture content (Fig. 2a) which is ~ 130 % for viscose fibre. Whereas in commercial/ plant scale fibre dryer inlet moisture ~100% (< X<sub>C</sub>) which depicts drying occurs in falling rate period.

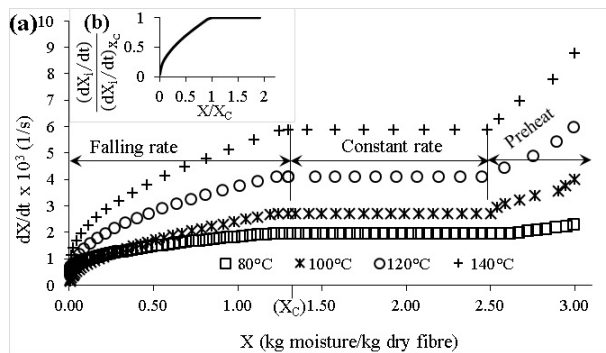

Fig. 2: Viscose staple fibre: (a) drying rate curve at different temperatures (Critical moisture content, X<sub>C</sub> = 130 %) and (b) normalize drying rate verses normalize moisture content

Drying rate specification in Aspen is typically provided in the form of normalized average drying rate curve where individual drying rate was normalized with constant drying rate (Equation 2) and the individual moisture content was normalized with critical moisture content. Figure 2 (b) showed average normalized drying rate for viscose staple fibre, which was temperature independent. Drying rate shape factor (F) [9], Equation 2, was found to be around ‘one’ for viscose fibre.

$$\vartheta(n) = \left( \frac{dX_i}{dt} \right) / \left( \frac{dX_i}{dt} \right)_{i=X_C} = 2. F. \left( \frac{X}{X_C} \right) - (2. F - 1) \left( \frac{X}{X_C} \right)^2 \quad (2)$$

### 3.2. Mass transfer correlation with process parameters

An attempt has been made here to understand the mass transfer rate aspects in commercial cellulosic fibre dryer. The rate of evaporation is proportional to moisture concentration gradient from fibre surface to air where proportionality constant is convective mass transfer coefficient where local mass transfer coefficient is proportional to Sherwood number

Mostly, Sherwood number used to explain convective mass transfer. In case of porous material drying, two scenarios have observed in commercial dryer, one side moisture removal from fibre surface to air through convective mass transfer and in other side transportation of moisture from materials capillary to the surface through diffusion mass transfer which may lead to decreasing wetted surface drying [8]. A single stage convective drying unit model was used in Aspen to calculate the Sherwood number for each experiment to match the extent of drying rate for different input process parameters. A simplified predictive mass transfer correlation:

$$\text{Sh} = a(T_G^b)(e^{gY})(e^{hX_{in}}) \quad (3)$$

Statistical tool was used to estimate the constants with regression coefficient,  $R^2$  value of 74%. Equation 4 shows a final version of mass transfer correlation using Sherwood number which was used in process model to estimate the local mass transfer coefficient of cellulosic (viscose) fibre and enhance the model robustness during optimization of drying.

$$\text{Sh} = \exp(-3.33) \cdot T_G^{(-0.095)} \cdot \exp(0.9 \cdot X_{in}) \cdot \exp(-9.5 \cdot Y) \quad (4)$$

Correlation clearly highlights proportional dependence on inlet fibre moisture content whereas air absolute humidity and temperature shows inverse with Sherwood number.

### 3.3. Model validation

Data from commercial production unit for outlet fibre moisture, steam/fibre ratio, exhaust air humidity, temperature, were used to validate the developed process model. Comparison of plant data and model predictions show maximum error of 7% whereas majority error numbers were <5 %. In addition, it has been shown that the process model predicts the plant operational drying curve (Fig. 3), and also increases confidence in developed cellulosic fibre drying process model. Multiple model validation strongly confirms that the developed model is capable of predicting temperature profile with other operational parameters to get the desired moisture quality.

### 3.4. Drying rate optimization for commercial conveyer dryer

Cellulosic fibre mat thickness, of around 200 mm, formed on the conveyer belt of the dryer significantly affects the moisture variation, as there exists no surface renewal mechanism in conveyer dryer except the effect induced by intermediate opener placed between Dryer-A and Dryer-B. Hot air flows in a cross flow manner through the moving fibre mat. Humidity starts occurring gain as air passes through the fibre mat with reduction in temperature and driving force for moisture removal. This phenomenon creates moisture variation within the mat and it continues till dryer end. Overall, drying rate has a potential to induce moisture variability at commercial scale and there is a scope for optimization of the same to reduce such variability. Commercially, first sectional dryer (Dryer-A) was operated at higher

temperature to remove approximately 75% moisture with fast drying rate (Figure 3), whereas second sectional dryer (Dryer-B) removes around 15- 20% of moisture at lower zone temperature. Mass transfer rate of moisture to the fibre surface along with available moisture carrying capacity of the hot air controls the overall drying operation.

Fig. 3: Drying curve: Plant and Aspen predictions for conventional and moderate drying strategy

In a few initial zones, due to high moisture content, convective mass transfer rates are high due to sufficient moisture present at the fibre surface and air temperature creates enough driving force to remove the moisture. This phenomenon observed typically at early stage of falling rate period. After few zones, transportation of moisture from capillary to fibre surface is dominated by diffusion where moisture evaporation happens at decreasing rate. Drying rate decreases with decrease of moisture content. Also, correlation (Equation 4) clearly shows higher Sherwood number at initial stage due to the impact of convective mass transfer and lower value of Sherwood number after few initial zones was due to lower convection mass transfer where impact of diffusion on drying process is high. Facilitation of the diffusion process to overcome capillary forces demands raising the fibre surface temperature. Overall fundamental insights along with multipoint validation provided confidence to deploy process model predictions of optimum parametric combination known as moderate drying strategy for targeting moisture variability reduction.

Figure 3 shows the comparison between drying curve of conventional (fast) and moderate drying strategy along with model predicted. In the moderate drying strategy, drying curve is shifted upwards compared to conventional due to lower temperatures adopted at the initial zones. Disappearance of this shift occurs at the start of Dryer-B due to higher temperatures adopted during start of Dryer-B which increases the fibre surface temperatures by  $\sim 10^{\circ}\text{C}$  higher than conventional. Developed moderate drying strategy is adopted in commercial

plant and improved in-spec bales by 18 % (from 63 % to 81 %) within narrow range (10.5-11.5 %) by reduction in moisture variability along with 9% reduction in steam consumption.

#### **4. Conclusion**

A fundamental understanding of cellulosic fibre (viscose) drying was obtained in terms of critical moisture content, normalized drying curve and mass transfer correlation. Commercial viscose fibre drying operation falls under falling rate period where convective mass transfer along with diffusion limits the moisture removal. Conveyor dryer process model for commercial viscose fibre drying was developed and validated successfully. Model suggested optimum process parameter combination maintained during drying operation at commercial scale reduced moisture variability by 18 % along with steam consumption reduction of 9 %.

### **Abstract**

*This work is based on the experimental study of the freeze-drying process to understand the impact of numerous factors on the survival rates of a model probiotic strain of Lactobacillus casei type. With the aim to find out if cell density in the matrix and survival rates are linked, we have studied the location of the cells after freeze drying inside a porous matrix composed of a lactose basis with a polymer, the polyvinylpyrrolidone (PVP) in various amounts. The best survival rate were obtained at slow freezing rate for a formulation containing 5% (m/V) of lactose and 5% (m/V) of PVP.*

## 1. Introduction

According to Food and Agriculture Organization of the United Nations and World Health Organization, probiotics are defined as “live micro-organisms which, when administered in adequate amounts, confer a health benefit on the host”<sup>[1]</sup>. Probiotics are generally temperature sensitive bacteria (with different degrees of sensitivity depending on the numerous strains), which loss a part of their viability and their favorable health properties during their dehydration processes and, next, during the storage and transport steps before their consumption. Many factors such as temperature, oxygen level, osmotic pressure and pH stresses have an important impact on their viability and, on their health promoting effect. Two types of methods are mainly used to stabilize and to maintain a long term activity level, namely the freezing and more or less soft drying techniques such as spray-drying, fluidized bed drying and freeze-drying. The freeze-drying is known as the method that usually leads to the best results in term of many quality factors of the freeze dried cake (viability rate, rehydration rate, etc.) despite various damaging effects generated by the freezing and sublimation/desorption phenomena (crystal growth; cryoconcentration, etc.)<sup>[2]</sup>. Nevertheless, this method has the major inconvenient to lead to the highest operating costs due to the very severe operating conditions of this discontinuous process which has to be carried out at very low levels of temperature and total gas pressure. During this long and complex soft dehydration process, three phase changes are taking place so that the living bacteria have to endure numerous stresses more or less interdependent and deeply understood (thermal, osmotic, pH, sub-cooling, intracellular crystallization...). Moreover, important differences exist between the different probiotic's species, sub-species and strains, particularly in terms of resistance to the severe process conditions generally encountered<sup>[3]</sup>. This is why the main objective of our work was to establish a rational protocol of optimization of freeze-drying cycles with a model probiotic strain, easily adaptable to other bacteria. This protocol is based on the reduction of stress effects in order to obtain the highest survival rates. Firstly we studied the cell immobilization by adsorption or inclusion inside a porous matrix. We have chosen to investigate on a formulation constituted of lactose (a popular effective cryoprotectant known for not influencing the cells content) and polyvinylpyrrolidone (PVP) which is a polymer widely used in the pharmaceutical industry due to its interesting properties of stabilization<sup>[4]</sup>. Indeed, PVP has been already used as cryoprotectants and has a higher glassy transition ( $T_g$ ) than most of the saccharides so that it can reduce the drying time by increasing the sublimation and desorption limit temperatures. The freezing protocol - especially the freezing rate - which could prove to be the key damaging step of the whole freeze-drying process, was investigated. Indeed, this step appeared to be the most lethal period for micro-organisms mainly because of osmotic phenomena occurring at the cell level. Then, we have investigated the influence of the total amount of each component in the formulation on the location of the bacteria in the solid matrix and on the survival rate.

## 2. Materials and Methods

### 2.1 Bacteria and growth conditions

The strain *Lactobacillus Casei* ATCC® 393™ (Alliance Bio Expertise, Guipry, France) was rehydrated from the Kwik-Stik® -containing the original dried strain- and then isolated on a MRS agar petri dish and finally incubated for 48h at 37°C. A single colony was collected from the plate and inoculated in 100mL MRS broth and finally incubated for 24h at 37°C under orbital shaking (150 rpm). Next a 1% diluted solution was prepared in 150 mL MRS broth and incubated under orbital shaking (150 rpm) during 30h.

### 2.2 Formulation composition

Once the stationary phase was obtained, the bacterial suspension was centrifuged at 7000 g during 10min at ambient temperature and next washed twice with saline buffer solution (0,85%NaCl (m/V)). Then the pellet was suspended again before processing. Various solutions were prepared with a Kollidon®30 (PVP) and monohydrate lactose basis in the range of concentration from 1% to 10% (m/V) or only with the saline buffer (Table 1).

*Table 1. Index of the formulation composition*

Nomenclature	Weight Lactose composition (m/V)	Weight Kollidon®30 composition (m/V)
<b>K5</b>	0%	5%
<b>L5</b>	5%	0%
<b>KL10-5</b>	5%	10%
<b>KL1-1</b>	1%	1%
<b>KL5-5</b>	5%	5%
<b>KL10-10</b>	10%	10%

### 2.3 Freezing and thawing protocol

Immediately after formulation, the solutions were poured into 6mL glass vials and next frozen from ambient temperature up to -45°C at different freezing rates, namely: 0.5; 1; 2; 5°C/min and a very fast rate by immersing directly the vials into liquid nitrogen. We investigated the effect of cold thermal stresses at the slowest rates by introducing, before the freezing step, a temperature plateau at 5°C during ½h. Then, the temperature was maintained during 2h before the thawing step which was performed by immersing the vials into distilled water at 37°C and next, immediately diluted for the enumeration.

### 2.4 Freeze-Drying process

A slow freezing rate was chosen, namely at 0.5°C/min with a temperature plateau at 5°C. The sublimation step (primary drying period) was performed slowly under vacuum at 150

Pa and around  $-40^{\circ}\text{C}$ . Next, the desorption step (secondary drying period) was achieved during 24h at  $20^{\circ}\text{C}$  under 50 Pa. All the vials were closed immediately inside the freeze-dryer chamber, hermetically sealed and finally stored at  $4^{\circ}\text{C}$ . Lyophilisates were rehydrated quickly at  $20^{\circ}\text{C}$  by addition of an adequate amount of saline buffer solution for enumeration of viable bacteria.

## 2.5 Enumeration and residual moisture

The rehydrated powder and the thawed solution were decimally diluted and next incubated at  $37^{\circ}\text{C}$  during 72h to enumerate the colony forming unit (CFU). Every enumeration was conducted in triplicate. The moisture contents in the freeze-dried vials were determined by the classical the Karl-Fisher method (860 KF Thermoprep - Metrohm). Samples of the freeze-dried cake (between 10 and 20 mg) were introduced into the Karl-Fisher oven at  $150^{\circ}\text{C}$ .

## 3. Results and Discussion

### 3.1 Effect of the addition of PVP and lactose on the bacterial viability

Fig. 1 Effect of polymer PVP and lactose on the viability of *Lactobacillus Casei* after freeze drying.

Bacterial suspensions were mixed with pure lactose (Ref. L5) or pure polymeric solution (Ref. K5) or a mixture of different concentration of these two components (KL10-5 Cf Table 1). No significant differences on bacterial viability were observed between these formulations after freeze-thawing. These results show that the presence of this polymer had not detrimental effects on the survival of bacteria, so that we concluded that it could be used as protectant of our formulation. After freeze-drying, survival rates exhibited light

differences between the different formulations of protectants (Fig.1). Just after process the concentration of viable bacteria decreases more when the polymer was the only protectant (**K5**). With the lactose formulation (**L5**), the survival of bacteria appeared to reach the highest values, even after one month of storage. However, the solution **KL10-5** seemed to present the highest stability after one month of storage even if the survival ratio right after the end of the whole freeze-drying process was slightly affected. This means that a formulation that combined lactose and PVP components could offer a high stabilizing effect for the storage. This favorable effect could be explained by the matrix vitrification phenomenon which could entrap and protect the cells during the process, by reducing the mechanical stresses induced by ice crystal growing, but also during the storage, by increasing the stability due to the high glassy transition values of the PVP<sup>[5]</sup>.

*Fig. 2 SEM photography of the repartition of dried *L. Casei* ATCC 393 in the porous matrix based on lactose and Kollidon® 30 or only lactose.*

Next, SEM photographs (Fig.2) allowed to observe the position of the bacteria located in the freeze-dried solid matrix. In the case of formulation **KL10-5**, the bacteria did not appeared at the pore's surface and seemed included inside the solid part of the freeze-dried matrix. On the contrary, for the **L5** formulation, as the relative amount of dry matter of lactose was smaller, the bacteria covered the pore's surface of the matrix. This behaviour could explain why the survival rate was lower with the **KL10-5** formulation than with the **L5** one. When the matrix was fixed during the freezing step, the bacteria may have suffered high local pressure levels due to Ostwald ripening phenomena during and just after the crystallization step. However, on a long time scale, the morphology and the structure of the solid matrix of the mixture could allow a higher survival ratio due to the formation of a

thick solid layer which can prevent the diffusion of water and oxygen up to the cells<sup>[6]</sup>. Experiments were carried out to find out the less damaging freezing kinetics. It appeared that a slow freezing rate around 0.5°C/min with a stabilization temperature step between 0.5 and 1h before the starting of the freezing at 5°C led to the best survival rate, with no significant reduction of viable bacteria. This could be related to a cold stress response from the bacteria, because, in reaction to the stress, the cells may produce Cold Shock Proteins allowing them to prevent damages<sup>[7]</sup>. Other hypothesis has been proposed on the dehydration rate of the cells, due to slow osmotic pressure variations preventing intracellular water crystallization due to cell water exit<sup>[8]</sup>. These results have to be compared with experimental data showing the influence of nucleation temperature.

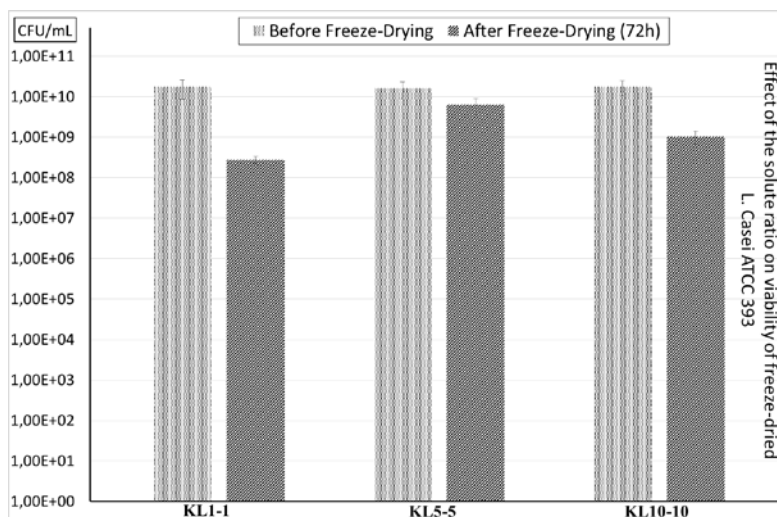

Fig. 3 Effect of the amount of solute on the viability of *L. Casei* ATCC 393

### 3.2 Influence of the amount of solute protectants on the bacteria location and viability

After observing the differences in the repartition of bacteria and morphology of the solid matrix with SEM pictures (as mentioned above), we characterized the influence of the amount of dry matter on the final viability of bacteria. We have chosen to investigate, at the same weight ratio, two extreme compositions and one central composition of the scale (Table 1). Some of the freeze-dried cakes were observed by SEM and the others were rehydrated for plate counting. For the lyophilisate that contained the lower solute concentration (**KL1-1**), we obtained approximately a 2-log reduction of the viable bacteria after freeze-drying while less than 0.5-log reduction for the **KL5-5** and around 1.2-log reduction for the **KL10-10** (Fig.3). The SEM photograph of Fig. 4 showed that the freeze-dried matrix network formed by **KL1-1** formulation was very thin with a high density of bacteria.

*Fig. 4 SEM photography of the repartition of dried L. Casei ATCC 393 in the porous matrix based on extreme lactose and Kollidon®30 content.*

The physical aspect with **KL1-1** at macroscopic scale was not enough consistent and the freeze-dried cake was difficult to analyze due to its fragility. Other experiments and photographs carried out with only buffered solutions and with only bacteria led to very low survival rates. The differences in bacterial location and on matrix structure for **KL5-5** and **KL10-10** formulation were more difficult to find out. In both cases we could observe a thick structure recovering the cells. Nevertheless, differences in the viability seemed to be linked to the mass ratio between dried excipients (lactose and PVP) and dried bacteria. In the case of low amounts of excipients, the bacteria were directly exposed to water during the rehydration process. Indeed, the rehydration rate had probably a great influence on the final viability ratio of the cells and the amount of solute exerted probably an important buffer effect on the mechanisms of water transfer to the cells. In another hand, a too important content of excipients could unbalance the osmotic equilibrium of bacteria with their surrounding solution during the formulation and freezing steps and, by the way, could generate too important water flows crossing the cells walls which resulted to important cell death ratios or viability losses<sup>[8]</sup>. That's why a balance should be established between too low content of protectant resulting in a loss of efficiency and a too high content, providing high stresses to the cells. Nevertheless, the **KL5** formulation presented the highest survival ratios with this soft freeze-drying protocol. Then, our forecoming work will focus on this formulation with the aim of parameters optimization and design space set up.

## 4. Conclusion

This study presents the effect of composition and of freezing parameters of a PVP Kollidon®30 and lactose based formulation on the viability of a *L. Casei* strain during a standard freeze-drying cycle. The polymer and cells were considered as compatible since no significant reduction was observed on the viability of the probiotic strain, even after one month of storage. The SEM photographs showed that the type and the concentration of solute in the cells preparation have an important impact on the cells location inside the freeze-dried matrix and, consequently, on the survival ratio. The KL5-5 formulation led to the best bacteria survival ratio with less than 0.5 log reduction after a standard freeze-drying cycle. Nevertheless, it is still difficult to conclude on the mechanisms explaining the best observed viability at this composition. These results indicated that the PVP can be used with this probiotic strain, and, moreover, it may preserve the viability of bacteria for long time storage in the freeze-dried form. Our next study will focus on the process optimization parameters and the design space set up allowing a viable and stable freeze-dried product.

### **Abstract**

*This study is aimed to improve the antioxidant property of instant coffee by using microencapsulation technique and spray drying. Concentrated coffee extract was mixed with Konjac glucomannan hydrolysate (KGMH) and Maltodextrin (MD). The mixture of coating material and coffee extract was then spray dried at 160 - 180 °C inlet air temperature and at 85-90 °C outlet air temperature. KGMH can preserve retention of phenolic compounds, DPPH scavenging activity and antioxidant activity of FRAP ( $p < 0.05$  of instant coffee better than other treatment.*

## **1. Introduction**

Coffee brews as one of the most popular beverages in the world has extensively studied for health concern. Moreover, many people choose coffee as their daily drink due to its effect to body health. Coffee brews are accepted as a rich source of compounds possessing antioxidant and radical scavenging activities. Coffee is high in phenolic compounds, especially chlorogenic acids and their degradation products such as caffeic, ferulic and coumaric acids, polyphenols, trigonelline and alkaloids including caffeine and also high amount of melanoidins which exhibit significant antioxidant activities [1, 2].

Comparing antioxidant capacity in one cup from different form of coffees, instant coffee accounted for the highest amount of essential substances which expressed antioxidant capacity that 3-4 times higher than ground coffee. During the manufacturing of instant coffee, antioxidant and other essential compounds are concentrated which resulted in enhancing of antioxidant capacity compare to roasted bean powder [3].

More advantages of instant coffee stimulate the research more deeply in its production. The conventional processes of instant coffee are spray drying and freeze drying, both techniques have some limitations regarding energy consumption and final product qualities. Freeze drying produces the best product quality in term of aroma recovery, but it uses high energy and time that affected the production cost. While, spray drying leads the high production capacity at low investment, but engender higher thermal impact and resulted in decreasing of essential compounds such as natural antioxidants. In fact, that spray drying is the most applicable process in instant coffee industry yet gives lower antioxidant and flavor compounds than other processing, thereupon considering other techniques to lowering thermal impact is proposed.

Microencapsulation offered as a solution to reduce the core reactivity from essential compounds with the environmental factor. Konjac glucomannan (KGM) is neutral polysaccharides with mannose residues as predominant monomer and glucose as secondary sugar. The deep exploitation of KGM and its derivatives has been paid considerable attention in recent year. What is more, KGM in form of flour and hydrolysate can be conveniently used to wider application in some fields such as food science, pharmaceutical science, chemistry and biotechnology [4]. One of the latest experiments that has been deeply studied is investigation of hydrolyzed KGM on spray drying microencapsulation. Previous study have shown that hydrolyzed KGM (KGMH) worked as wall material by spray drying technique in antimicrobial powder, flavor encapsulated powder and nutraceutical powder [5, 6, 7]. Therefore, the aims of this study were to investigate the utilization of hydrolyzed KGM on encapsulation efficiency and to obtain the suitable spray drying condition in the production of high antioxidant instant coffee microencapsulation.

## 2. Materials and Methods

### 2.1 Materials

Medium dark/roast of Arabica roasted was provided by. Mannanase 50,000,000 IU per gram enzyme, food grade (Bosar Biotechnology, China) was used. Maltodextrin (MD) DE 10-15 (Food grade) was purchased from Chemipan (Bangkok, Thailand).

### 2.2 Methods

#### 2.2.1 Coffee extract and coffee solution preparation for spray drying

Fine ground Arabica coffee (Green Net SE Co., Ltd, Bangkok, Thailand) (24 g) and 115 ml hot water are used in coffee extraction by using Moka Pot 22.5 x 10 cm (YAMI® YM-6007, China). Then coffee extract was evaporated by vacuum rotary evaporator (BÜCHI R-114, BÜCHI Labortechnik AG, Flawil, Switzerland) to get 10 °Brix of total solid. After that KGM hydrolysis is prepared by using Mannanase with 125 units per gram KGM is used for hydrolysis reaction. Modification method from previous study [6] was used to conduct KGM hydrolysis. All KGM hydrolysis was conducted under a controlled condition at  $40 \pm 1$  °C and 200 rpm of an overhead stirrer for 1 hour. Then KGMH solution was added by MD powder to adjust wall material concentration at 20% (w/w). For instance, 5% MD was added to 15% KGMH solution. Moreover, 20% KGMH was not added by MD, while 20 % MD solution (w/w) was used as control. Arabica coffee extract and wall material at ratio 2.2:1 (w/w) was mixed to obtain total solid mixture at 15% (w/w). Mixing process was done by magnetic stirrer for 5 minutes of stirring.

#### 2.2.2 Spray drying

Drying experiment was done in a co-current Mini Spray Dryer (BÜCHI B-290, BÜCHI Labortechnik AG, Flawil, Switzerland). with inlet temperature at 160-180 °C and outlet temperature at 85-90 °C by adjusting flow rate.

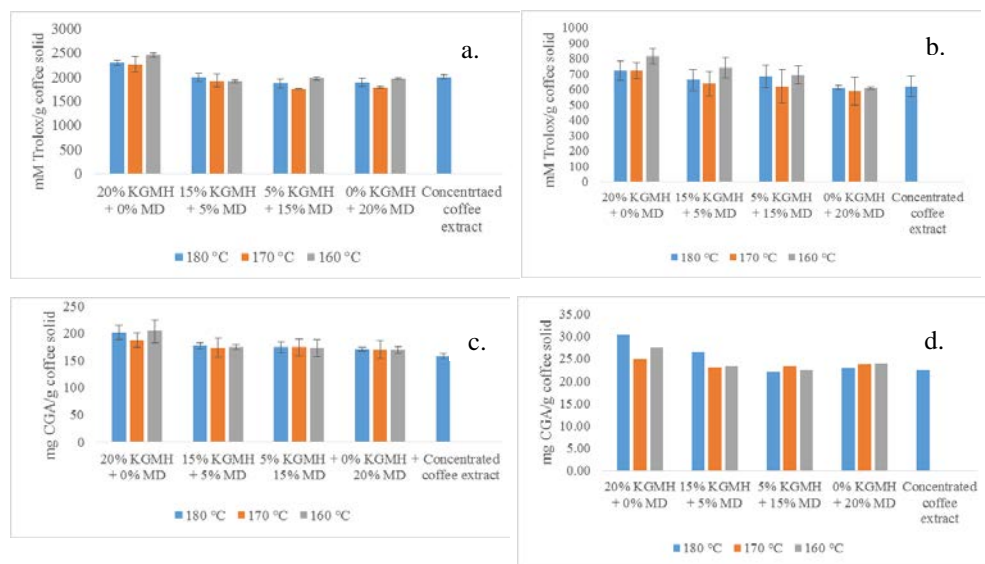

#### 2.2.3 Antioxidant properties analysis

Total phenolic compounds (TPC) was performed by Folin-Ciocalteu and calculated using gallic acid equivalent (CGA) [2]. Antioxidant activity was examined by DPPH scavenging ability method at 515 nm of spectrophotometric analysis [3]. Moreover, Ferric Reducing Antioxidant Power (FRAP) also used to examined antioxidant activity [2]. The FRAP measurement was done by spectrophotometry at 595 nm. Amount of chlorogenic acid was observed by using HPLC (Varian Prostar, USA) and the spectra were detected by Prostar 335 Photodiode Array Detector at 278 nm.

### 3. RESULTS AND DISCUSSION

#### 3.1 Antioxidant Property

Fig. 1 presented antioxidant activity and amount of phenolic compounds and chlorogenic acid based on coffee solid in coffee extract and instant coffee powder. The results have shown that spray drying microencapsulation process, especially when using KGMH as wall material, was able to shield phenolic and antioxidant compounds.

**Fig. 1** Antioxidant activity of instant coffee measured by (a) DPPH (b) FRAP (c) total phenolic content (d) chlorogenic acid

In TPC measurement (Fig. 1c), the highest phenolic content in instant coffee powder was the formulation of 20% (w/w) KGMH at 160 °C with 204.04±20.98 mg CGA/g coffee solid

( $p < 0.05$ ), while the coffee extract presented  $157.87 \pm 4.95$  mg CGA/g coffee solid. To confirm TPC result, a specific phenolic compound which is chlorogenic acid (Fig. 1d) was observed by HPLC. In the current study, amount of chlorogenic acid in concentrated coffee extract had  $22.49 \pm 1.35$  mg/g coffee solid, while instant coffee powder contained 22-30.60 mg/g coffee solid. Among the treated instant coffee powders, 20% (w/w) KGMH instant coffee powder produced at 180 °C presented the highest content. In general, increasing KGMH concentration and inlet temperature lead to the higher chlorogenic acid content. On the other hands, DPPH scavenging ability results (Fig. 1b) have shown a similar pattern with TPC experiment where the highest value was exhibited by 160 °C spray dried of 20% (w/w) KGMH instant coffee powder ( $813.30 \pm 100.89$  mM Trolox/g coffee solid) ( $p < 0.05$ ), while the extract presented  $619.21 \pm 130.91$  mM Trolox/g coffee solid. During spray drying, high temperature might trigger some reactions such as phenolic degradation and Maillard reaction which can create new compounds that possess higher antioxidant capacity. It is noted that in coffee mixture, antioxidant activity is contributed by phenolic compounds and melanoidins (non-phenolic). Since DPPH method has a wide range of mechanism, the new compounds created during drying could possibly be detected and express antioxidant capacity. Furthermore, in FRAP method (Fig. 1a), the similar formulation in TPC and DPPH methods was noted to have the highest value which accounted for  $2,453.23 \pm 122.50$  mM Trolox/g coffee solid ( $p < 0.05$ ).

### 3.2 Physical properties

The effects of spray drying conditions and wall material solutions on physical properties of microencapsulated instant coffee were observed including moisture content, water activity, water solubility index (WSI), water absorption index (WAI) and surface morphology shown in Table 1. The results pointed out that increasing KGMH concentration while decreasing MD concentration was tending to produce a lower yield. The increasing of inlet temperature was contributed to better production yield but it was inconsistent. The highest yield was produced by wall material of 20% (w/w) MD at 160 and 180 °C of inlet temperature ( $p < 0.05$ ) which accounted for  $65.27\% \pm 4.67$  and  $64.00\% \pm 8.03$ . In all inlet temperature, 20% (w/w) KGMH alone was exhibited comparable results with the mixture of KGMH and MD as wall materials. This result was in line with Tolun *et al.* (2016) [8] which have a similar wall material design with current study and concluded that MD (DE 17-20) alone produced the highest yield at 52.77%, while when MD was mixed with gum Arabic the results had a contrary influence on the yield. During spray drying, instant coffee with KGMH was had more loses because of KGMH properties. KGMH solution is stickier than MD solution, therefore, the amount of adhered sample in drying chamber after drying was found higher in KGMH instant coffee sample.

**Table 1. Product yield, moisture content, and water activity of instant coffee**

Inlet temperature (°C)	Wall material	Product yield (%)	Moisture content (% w.b.) <sup>ns</sup>	Water activity <sup>ns</sup>
160	20% (w/w) KGMH	53.66±4.81 <sup>a</sup>	3.73±0.52	0.24±0.02

ns: non-significant

WSI is an important property to reveal powder behavior in aqueous and its reconstitution ability. Table 2. presented the WSI of microencapsulated instant coffee powder from different spray drying condition and formulation. In general, the value of WSI was in contrary to the amount of KGMH used but correlated with increasing of inlet temperature. The most solubilize powder was come from instant coffee produced from 20% (w/w) MD at 180 °C (98.98±0.87%) while the lowest WSI was 20% (w/w) KGMH powder at inlet temperature 170 and 160 °C (89.03±3.68 and 88.95±5.16%) ( $p < 0.05$ ). Similar finding from Jafari *et al.* (2017) [9] who found that juice powder with 25-45% (w/w) MD as drying aids

have WSI above 90%, while Adamiec *et al.* (2012) [5] noted that by using combination KGMH and gum Arabic at wall material concentration at 9% (w/w) presented WSI at 67-69%. Even though KGMH instant coffee exhibited the lowest WSI, the value of WSI was still above 88% which mean that all instant coffee powder still have a good solubility.

**Table 2. Water solubility index (WSI) and water absorption index (WAI) of instant coffee**

Inlet temperature °C	Wall material	WSI (%)	WAI (%)
160	20% (w/w) KGMH	88.95±5.16 <sup>a</sup>	8.94±1.51 <sup>c</sup>
	15% (w/w) KGMH	91.89±4.10 <sup>abc</sup>	3.07±0.76 <sup>a</sup>

#### 4. CONCLUSIONS

Antioxidant property of instant coffee can be enhanced by microencapsulation using KGMH as an appropriate natural wall material. KGMH concentration affected antioxidant and other physicochemical properties. Increasing KGMH concentration leads to the better antioxidant properties including TPC, antioxidant capacity by DPPH and FRAP and chlorogenic acid content. The wall material was able to shield almost all antioxidant component and resulted in the excessive retention percentage. The application of KGMH alone as wall material exhibited the best retention percentage compare to microcapsule made from KGMH-MD in all ratio and MD alone. The inlet temperature of spray drying was showing an important role in antioxidant properties. The increasing of inlet

temperature was correlated with lower retention of antioxidant properties except for chlorogenic acid that was increased. In general, the lowest inlet temperature (160 °C) produced better overall antioxidant properties than spray drying at 170 and 180 °C. The best condition of producing instant coffee from this study is 20% (w/w) KGMH as wall material at 160 °C inlet temperature of spray drying.

### **Abstract**

*High quality drying of therapeutic protein-solution is important in medical and pharmaceutical processing. Freeze-drying is mostly used, but it takes a long drying-time and causes damages of protein structures. In order to improve the drying quality, we propose a microwave vacuum drying performed at ambient temperatures under low-pressure conditions. We are focusing on the Parma-Zyme method for the evaporative drying of protein solutions such as egg white or lysozyme with vitrification. Circular dichroism (CD) spectroscopy is used to detect protein conformation changes due to the drying, and it is found that the ambient temperature drying can preserve the protein conformation.*

**Keywords:** *Microwave vacuum drying; Freeze-drying; Therapeutic protein; Egg white; Lysozyme*

## 1. Introduction

In recent years, with the progress of biotechnology, the development of pharmaceutical products using biopolymers such as proteins has been rapidly developed. However, it is difficult to stably stored in solution state, many proteins preparations are preserved by freeze-drying (FD). Generally, FD takes a long time (about 1 to 3 days) due to drying accompanied by sublimation of ice, and requires large energy. In addition, changes in the hydration state due to freezing and concentration may result in deactivation and aggregation of proteins. Therefore, studies are under way to prevent denaturation by adding compounds and additives to protein formulations [1]. Considering the situation, we propose a method using a microwave vacuum drying (MVD) as a new method instead of FD. MVD promotes evaporation of water under reduced pressure condition and supplies only latent heat of vaporization by microwave, resulting in the drying at room temperature. It is possible not only to prevent protein damage but also to drastically shorten the dering time. We are focusing on the Perma-Zyme method for the evaporative drying with vitrification, because it has a possibility to increase the vitrification temperature up to the room temperature [2]. Figure 1 shows a solid/liquid state diagram of sucrose water system [3]. In the method of FD, the long process (A-B-C-D) must be followed to get the glassy state for the vital preservation. On the other hand, if the direct phase transition from liquid to solid (glass) at room temperature (A-D), it would have great advantages in the bioindustries. In this study, drying experiments of egg whites and lysozyme protein solutions were carried out using three drying methods of FD, MVD, and a combination of FD and MVD. After the drying, preservation of protein structure/activity, drying time, and solubility were evaluated.

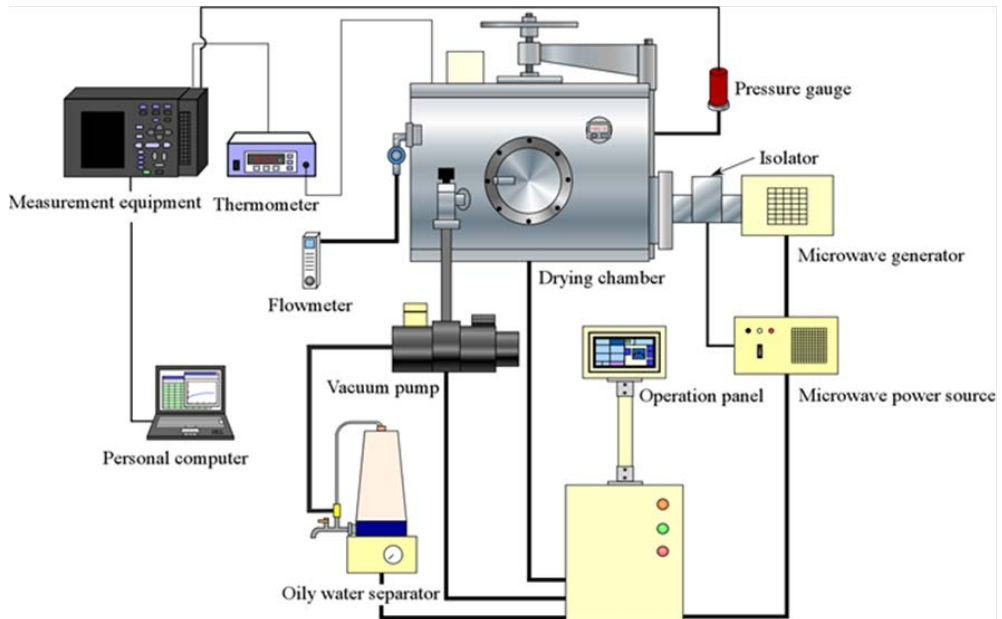

**Fig.1 Solid/liquid state diagram of the sucrose water system.**

## 2. Experimental Apparatus and Methods

### 2.1. Drying methods

The experimental apparatus for the microwave vacuum drying is shown in Fig. 2. The drying system consists of the vacuum drying container, vacuum pump, and microwave irradiation equipment [4, 5]. The drying chamber is a cylinder made from stainless steel, which has an inner diameter of 590 mm and a height of 345 mm. The microwave is introduced into the chamber from the side. The microwave generator has a magnetron with a 3 kW irradiation power at 2.45 GHz. We can select some intermittent irradiation patterns with a different power as well as a continuous irradiation. In order to irradiate the sample uniformly, a turntable is set at the bottom of the chamber. During the experiment, the samples on the table are rotated at a rate of 3rpm.

As experimental samples, 5 g of egg whites (albumin) and 5 g of lysozyme aqueous solution (0.5 g of lysozyme + 4.5 g of purified water) were used as a model of protein solution. The sample is placed in a PFA Petri dish of 50mm in inner diameter. In MVD, four set of samples were placed in a vacuum container, and drying was performed with a microwave output of 50 to 100 W at a pressure of 20 kPa. In FD, the sample was frozen in a freezer at  $-25\text{ }^{\circ}\text{C}$  for more than 12 hours, then the frozen sample was set in a vacuum container and dried at a temperature of  $5\text{ }^{\circ}\text{C}$  under a pressure of 200 Pa.

*Fig.2 Microwave vacuum drying system.*

## **2.2. Evaluation method of protein conformation changes**

Molecular structure analysis was performed using a circular dichroism spectrometer (CD; JASCO Corporation J-820) in order to confirm the denaturation of proteins by drying. Three kinds of dried egg white by MVD, FD and their combination were subjected to the tests. As a reference sample showing thermal damage, the egg white heated at 98 °C for 10 minutes was examined as well as the raw egg white. Ultraviolet visible spectrophotometer (Hitachi High-Tech Science U-3310) was used to adjust to the same concentration, and ultra pure water was used as a solvent.

## **2.3. Measurement of the residual activity of protein**

It is most important to confirm the residual activity of the protein. Therefore, the degradation activity of lysozyme was measured using the UV spectrophotometer. *Micrococcus luteus* was added to 50 mM phosphate buffer solution so that the absorbance at a wavelength of 600 nm was 1.0 Abs in a 1 cm glass cell to prepare a substrate solution. The aqueous solution of lysozyme of 20 µl was dropped into 2980 µl of the substrate solution, and the time change in absorbance at 600 nm due to substrate degradation of lysozyme was measured. The activity of lysozyme was evaluated assuming that the absorbance immediately after the dropping was 100% and the absorbance after the decomposition was 0%.

## **2.4. Solubility test**

Solubility is important factor for a practical use in medical area. In this study, 0.05 g of dried egg white was dissolved in 5 ml of water and time change of concentration of albumin was measured.

# **3. Results and Discussions**

## **3.1. Drying of egg white**

Figure 3 shows appearances of egg white before and after the drying. The raw egg white is transparent as in (a), it is seen in (b) that dried egg white is a transparent film even after the MVD drying. On the other hand, in the FD of (c) and 1h-MVD+FD of (d), it became a porous state like a sponge cake. In the FD, since ice crystals are dried by sublimation, the ice crystal parts become voids and porous. In 1h-MVD+FD, it is considered that ice crystals became smaller by first 1-hour drying by the MVD, and the porosity decreased. Also, we can see many large cracks in (d).

**Fig.3 Photographs of egg white before and after drying.**  
 (a) Raw white egg, (b) MVD, (c) FD, (d) 1h-MVD+FD

**Fig.4 Time transients of moisture content ratio.**

Figure 4 shows the time transient of the relative moisture content in each drying process. Drying was carried out until water contents became 0.05 or less. In MVD, the drying temperature was kept below 25 °C. Compared to FD, MVD was able to reduce drying time by about 50% and MVD+FD by about 20%.

### 3.2. Molecular structure analysis of egg white (albumin)

The results of structural analysis on dried egg albumin by CD are shown in Fig.5. It is known that the albumin has two negative peaks at 210 nm and 218 nm in the CD signal. The present results for FD, MVD and MVD+FD indicate two negative peaks similar to the raw egg albumin [6]. However, the CD intensity of the 98 °C-heated sample decreased in wide ranges, and the negative peaks shifted to shorter wavelengths of 207 nm and 217 nm, which indicates that alpha-helix structure of albumin has changed due to heating. It is

confirmed from the results that the room temperature dryings can preserve the albumin without any structural damages.

Fig.5 CD spectral analysis of albumin aqueous solution.

### 3.3. Residual activity of lysozyme

Figure 6 shows the residual activity of lysozyme measured using UV, where the absorbance at 600 nm of wave length was measured by dropping lysozyme into the substrate solution at 150 s. It can be seen that the absorbance of lysozyme heated at 98 °C has not changed. This is because lysozyme was inactivated and could not decompose micrococcus luthus. In contrast, lysozyme processed by FD, MVD, MVD+FD has decreased absorbance after 150s, indicating that the activity of degrading micrococcus leutus can be preserved. The results of calculating the decomposition rate are shown in Table 1. There is no clear difference in the drying method compared to lysozyme.

Fig.6 Remaining activity measurement of lysozyme aqueous solution.

**Table 1. Decomposition rate**

	Lysozyme	MVD	FD	MVD+ FD
Decomposition rate (Abs/s)	0.003791	0.003924	0.003517	0.003192

### 3.4. Comparison of solubility

Figure 7 compares the time transient of concentration when 0.05 g of dried egg white is dissolved in 5 ml of ultrapure water. It can be seen that the sample by FD treatment dissolved in approximately 10 minutes, while the sample by MVD took about 40 minutes. About 80% or more of sample by MVD + FD has dissolved in the first 20 minutes and it can be said that it is more soluble than MVD. This indicates that ice crystal formation during the freezing contributes the faster solubility.

*Fig.7 Comparison of solubility of MVD, FD and MVD+FD.*

## 4. Conclusions

The protein aqueous solutions, egg white (albumin) and lysozyme, were dried using three kinds of drying methods, i.e. the freeze-drying (FD) and the microwave vacuum drying (MVD) and their combination, and the conformation change and the activity of preserved protein were examined. Circular dichroism (CD) spectrometer is used to detect protein conformation changes in the drying of albumin, which indicates that the MVD at room temperature can preserve the protein conformation. Also, the UV measurement of the residual activity of lysozyme with use of the micrococcus luteus shows that the room temperature drying shows good performance for the residual activity. It is concluded that the MVD at room temperature enables a less damages and a rapid drying compared to the

FD. It should be noted that MVD is inferior in solubility compared with the FD. The combination of MVD and FD has a possibility for better performances in solubility and drying time.

### Abstract

*Candida rugosa* lipase (LCR) was immobilized on low-cost supports (by-products) and dried using a spouted-bed system. The yields of immobilized derivatives were in the range 61.5–78.7%. Lipase immobilized on rice husk showed the best results, presenting 94.1% of the original activity, followed by sugarcane bagasse (90.3%) and green coconut fiber (87.3%). Moisture content in the obtained powders varied between 4.7 and 5.6% and the water activities were in the range 0.21–0.35. Among all the tested biocatalysts for aroma production the lipase immobilized on rice husk showed the highest activity towards the formation of isoamyl caprylate (62.40 g.L<sup>-1</sup>).

## 1. Introduction

Lipases (triacylglycerol acylhydrolase - EC 3.1.1.3) are serine hydrolases formerly characterized by the ability to reacting with a wide range of substrate with a high enantio and regio selectivity.<sup>[1]</sup> However, the commercialization of enzymes with potential industrial applications, including lipases, depends on their stability during enzymatic reaction and/or storage period.<sup>[2]</sup> In fact, the water presence in enzyme formulations is the mainly drawbacks for protein stabilization and consequently, for enzyme application.<sup>[3]</sup> Drying technologies can be utilized to obtain dehydrated and stable thermosensitive products like microbial enzymes.<sup>[4]</sup> On the other hand, enzyme immobilization are other mechanisms used to improve enzymes properties (like stability, activity, inhibition by reaction products and selectivity toward non-natural substrates), and allows recovery and reuse of the biocatalyst.<sup>[2]</sup> In this work, we associated the benefits of drying and immobilizing processes and performed them in a single step employing a spouted bed system. Furthermore, we used eco-friendly supports like coconut fibers, rice husk and sugarcane bagasse to prevent emergence of environment ethical issues and cut down the production costs of immobilization processes. Additional information on the catalytic activity was obtained by testing the immobilized derivatives obtained in synthetic applications, that is, in the esterification reaction of isoamyl alcohol with caprylic acid.

## 2. Materials and Methods

### 2.1 Enzymatic activity of the free and immobilized lipase

*Candida rugosa* lipase from Sigma-Aldrich was used in the immobilization assays. Lipase activity assay was performed using *p*-nitrophenyl palmitate (*p*-NPP) as substrate according to Mayordomo et al. (2000).<sup>[5]</sup> The mixture was incubated at 40°C for 30 min and then 0.5 mL of 2% trizma base was added.<sup>[6]</sup> The optical density was measured at 410 nm. Enzymatic activity is given as  $\mu\text{mol}$  of *p*-NPP produced per minute per mg of enzyme (IU).

### 2.2 Lipase Immobilization on agricultural byproducts

“In natura” Agricultural byproducts supplied by local farmers, were oven dried, ground and sieved to obtain particles with sizes between 50 and 150 mesh - Figura 1.

*Fig. 1. Agricultural by-products used as support for lipase immobilization: (A) rice husk, (B) sugarcane bagasse, (C) green coconut fiber.*

The supports were activated using glutaraldehyde prior to the covalent immobilization method. *Candida rugosa* lipase was immobilized in the by-products previously activated by covalent binding in the presence of polyethylene glycol as a stabilizing agent.<sup>[8]</sup>

### 2.3 Spouted Bed Drying of Immobilized Lipase

Immobilized *C. rugosa* lipase was dried using a homemade conical–cylindrical spouted bed, with an internal angle of the conical base of 40° and inlet orifice diameter of 15 mm. A cylindrical column with a diameter of 85mm and height of 300mm was connected to the conical base. Concave cylindrical Teflon particles with a mean diameter of 5.45mm and density of 2,160 kg/m<sup>3</sup> were used as inert material. Table 1 shows the operating parameters of the spouted bed dryer.

**Table 1. Spouted bed parameters set for drying of enzyme-support system.**

Spouted bed drying parameters	
Inlet gas temperature (T <sub>gi</sub> ), °C	100.0
Drying gas flow rate (Q), m <sup>3</sup> /min	0.660
Feed system position	top spray
Mass feed flow rate (Ws), g/min	5.5
Static bed height (H <sub>0</sub> ), cm	5.5
Mass of inert material (M <sub>i</sub> ), g	255.0

### 2.4 Dryer Performance and Product Properties

The spouted bed drying performance and physicochemical product properties were assessed by the following assays: **A. Enzymatic activity:** The lipase activity assay was performed using *p*-NPP as the substrate according to Mayordomo et al.<sup>[5]</sup> using an immobilized derivative (10 mg) in 50mM of phosphate buffer, pH 6.5. **B. Product stability:** The stability of the immobilized derivatives was assessed by determination of the enzyme activity of dried powder during 3 months of storage at 5 °C. **C. Reuse cycles:** Residual enzymatic activity determination for immobilized lipase after each batch of reaction was determined. The immobilized derivative was recovered by centrifugation and washed with buffer (sodium phosphate buffer 50mM, pH 6.5) for the next reaction test. **D. Product moisture content (X<sub>p</sub>):** The moisture content of the spouted bed–dried product was determined by the oven drying method at 105 °C up to a constant weight and was calculated from triplicate analyses. **E. Water activity (aw):** Water activity was determined using an AQUALAB 4TEV-Decagon according to the method of Norenã et al.<sup>[9]</sup> **F. Efficiency of powder production:** The product recovery (R<sub>E</sub>) was defined as the ratio between the total mass of the product recovered to the mass of immobilized enzyme composition fed to the system (dry basis).

## 2.5 Synthesis of Isoamyl Caprylate using the immobilized *Candida rugosa* lipase

Reaction systems consisted of isooctane (20 mL), isoamyl alcohol (0.30 mol/L), caprylic acid (0.30 mol/L) and immobilized lipase derivatives (30 units activity/mL of substrate). The mixture was incubated at 40 °C for 48 h with continuous shaking at 150 rpm. The consumed isoamyl alcohol and the formed product were determined by gas chromatography using a 5% DEGS CHR-WHP 80-100 mesh 6 ft 2.0 mm ID and 1/8" OD column (Restek, Frankel Commerce of Analytic Instruments Ltd, SP, Brazil) and octanol as an internal standard.<sup>[10]</sup> Caprylic acid concentrations were titrated with 0.02 mol.L<sup>-1</sup> potassium hydroxide solution using phenolphthalein as an indicator. The alcohol molar conversion (X, %), the productivity (P, g.L<sup>-1</sup> isoamyl caprylate h<sup>-1</sup>) and initial reaction rates (A, μM isoamyl caprylate min<sup>-1</sup>.g<sup>-1</sup> catalyst) were calculated based on Perez et al. (2007).<sup>[11]</sup>

## 3. Results and Discussion

Table 2 shows the effect of different supports and glutaraldehyde concentration on outlet drying gas temperature (T<sub>go</sub>), temperature inside the spouted bed dryer (T<sub>in</sub>), process yield (R<sub>E</sub>), and residual enzyme activity (R<sub>EA</sub>) of the product.

*Table 2. Effect of support and glutaraldehyde concentration on outlet drying gas temperature, bed temperature, process yield and residual lipase activity.*

Support	GLU (%)	T <sub>go</sub> (°C)	T <sub>in</sub> (°C)	R <sub>E</sub> (%)	R <sub>EA</sub> (%)
Rice husk	0.5	81.5±0.6	59.1±0.6	61.5	48.5±0.7
	1.5	78.1±0.4	58.5±1.1	76.2	94.1±0.4
	2.5	79.9±1.2	60.1±0.2	73.0	71.9±1.2
Sugarcane bagasse	0.5	80.8±0.5	59.4±1.3	66.4	53.6±1.1
	1.5	79.3±0.9	58.1±0.9	78.7	90.3±1.4
	2.5	81.8±0.3	60.8±0.2	73.5	62.0±0.9
Green coconut fiber	0.5	82.1±0.5	61.4±1.3	65.1	44.9±1.3
	1.5	79.3±0.9	59.1±0.9	74.6	87.3±0.9
	2.5	81.8±0.3	60.8±0.2	70.8	51.0±1.2

The residual enzymatic activity of all drying formulations used in this study was in the range 44.9-94.1%. Among all preparations evaluated, those containing 1.5% of glutaraldehyde showed the best result because they exhibited the highest retention of enzyme activity after spouted bed drying in all assays. *Candida rugosa* lipase immobilized in rice husk acted with 1.5% of glutaraldehyde showed the best result maintaining 94.1 % of initial enzyme activity. The inlet gas temperature used during the drying process was 100 °C, a temperature

that theoretically could provoke enzyme denaturation. However, the spouted bed dryer mechanism and the cooling effect caused by water evaporation prevents the loss of enzymatic activity. Indeed, the average temperature inside the spouted bed ( $T_{in}$ ) was 59.7 °C, a condition more appropriate for termosensitive biomaterials comparatively to the inlet temperature applied. The immobilized derivatives recovery rate was compatible with the expected production when a home-made spouted bed is used. Efficiency of powder productions were in the range 61.5–78.7%, depending on the support used. Table 2 shows the moisture content, water activity and residual lipase activity after storage period and five reuse cycles for the lipase immobilized on byproducts actived with 1.5 % of glutaraldehyde. The moisture content in the obtained powders ranged from 2.3 to 5.7% while the water activities of the immobilized derivatives were in the range 0.18–0.33. These values are considered safe to avoid microorganisms growth.<sup>[12]</sup> Stability tests were performed for all spouted bed dried samples which were stored at 5°C for up to 3 months. The immobilized derivatives obtained had decreased enzyme activity with an average of only 12.4%, whereas the free enzyme form lost 51.7% of its initial activity in the same period. It can be observed that the biocatalysts prepared retained an average of 67.3% of the initial activity after five reuse cycles. Lipase immobilized in rice husk showed the best result maintaining 71.4% of initial enzyme activity. The enzyme activity retention after reuse cycles is very important parameter related to the feasibility of applying on industrial scale.

**Table 2. Moisture content, water activity and residual lipase activity after storage period and five reuse cycles for the lipase immobilized on byproducts actived with 1.5 % of glutaraldehyde.**

Support	Xp (%, d.b.)	A <sub>w</sub> (-)	Storage R <sub>EA</sub> (%)	Reuse R <sub>EA</sub> (%)
Sugarcane bagasse	5.0 ± 0.93	0.25 ± 0.09	88.5 ± 1.13	68.6 ± 1.12
Green coconut fiber	5.6 ± 1.20	0.35 ± 0.05	82.4 ± 0.79	62.1 ± 0.93
Rice husk	4.7 ± 0.85	0.21 ± 0.03	91.7 ± 0.58	71.4 ± 1.03

To verify the behavior of the biocatalysts in non-aqueous media, additional information on the catalytic activity was obtained by testing the immobilized derivatives in synthetic applications, that is, in the esterification reaction of isoamyl alcohol with caprylic acid. This reaction has been successfully used to screen the best source of lipase to mediate the synthesis of aroma ester using fusel oil and caprylic acid, being the *Candida rugosa* selected as the most suitable lipase. The results for the tested immobilized lipases are shown regarding consumption of the starting materials and ester formation as a function of time (Figure 2), being the results summarized on Table 3. For all tested lipase immobilized derivatives, the reaction was driven towards to completion (molar conversion higher than 80%) at 48 h. For all runs, no reverse reaction was observed and both starting material were simultaneously consumed with the correspondent ester formation. Under these conditions, productivities

(1.12 - 1.30 g.L<sup>-1</sup> isoamyl caprylate h<sup>-1</sup>) were similar for all immobilized derivatives though different initial reaction rates were found (192 to 617 μM min<sup>-1</sup>.g<sup>-1</sup>) depending on the support used to immobilize the *Candida rugosa* lipase (LCR). The highest initial rate was found for the LCR immobilized on rice husk and the lowest for LCR immobilized on green coconut fiber.

Fig. 2. Performance of *Candida rugosa* lipase immobilized on different matrixes in the synthesis of isoamyl caprylate (○) from isoamyl alcohol (●) and caprylic acid (▲) at equimolar ratio (40°C, 150 rpm, 0.30 mol.L<sup>-1</sup> of each starting material in the presence of isoctane as solvent).

Among all the tested biocatalysts the LCR immobilized on rice husk showed the highest activity towards the formation of isoamyl caprylate (62.40 g.L<sup>-1</sup>). This is an expected behavior compared with published data, since rice husk is considered among several matrixes derived from lignocellulosic materials the most suitable support for immobilizing lipases due to its high silica contents.<sup>[8]</sup>

**Table 3. Values for initial reaction rate, productivity (P) and molar conversion in the synthesis of isoamyl caprylate by *C. rugosa* lipase immobilized on different matrixes at 40 °C.**

Immobilized Lipase	Reaction rate ( $\mu\text{M}\cdot\text{min}^{-1}\text{g}^{-1}$ )	P <sup>a</sup> ( $\text{g L}^{-1} \text{h}^{-1}$ )	Molar conversion <sup>a</sup> (%)
Sugar cane bagasse	263	1.16	83.87 ± 0.56
Rice husk	617	1.30	88.71 ± 2.20
Green coconut straw	192	1.12	82.25 ± 2.28

<sup>a</sup> Calculated at 48 h reaction

#### 4. Conclusions

The high values of enzyme activity retention and low water content of immobilized derivatives obtained showed that the use of agricultural by-products (eco-friendly supports) combined with the spouted-bed system is a promising technology to be applied for immobilization and stabilization of enzymes of commercial appeal. The tested immobilized lipases showed potential to catalyze the esterification reactions although at different rates. The highest performance was attained by the LCR immobilized on rice husk.

#### 5. Nomenclature

A <sub>w</sub>	Water activity	( - )
H <sub>0</sub>	Static bed height	(cm)

### **Abstract (100 words)**

*Active ingredients can be supplemented into a bakery product to produce functional food. However, the preservation of the functionality of these active ingredients during baking remains a challenge for food industry. A deeper understanding of the underlying interactions between functionality and baking is highly desired for developing innovative functional bakery products with significant health benefits and high product quality. In this work, recent advances in the development of functional bakery products are reviewed. The interactions between the baking process and the functionality of the supplemented active ingredients are discussed and the perspective of future research is addressed.*

**Keywords:** *baking; active ingredients; probiotics; inactivation kinetics; functional food*

---

## 1. Introduction

A functional food can be defined as a modified food or food ingredient that may provide a health benefit to the consumer beyond its basic nutrients. Bakery products can be fortified with health-promoting active ingredients to produce non-dairy-based functional food. The viability of the active ingredients such as probiotics in the final products should be sufficient to confer beneficial influence on consumer health. However, for baking process it is a challenge to maintain the functionality of these heat-sensitive active ingredients as high temperatures are involved.

This review aims to illustrate recent advances and challenges in the development of functional bakery products. The interactions between the baking process and the functionality of the active ingredients are discussed, as well as new technologies such as microencapsulation to preserve the active ingredients during baking. Manufacturing of functional bakery products of good quality and sufficient health-promoting properties leads to interesting research questions and the perspective of future research is addressed.

## 2. Recent advances in the development of functional bakery products

The father of modern medicine Hippocrates declared 2500 years ago that food intake may be beneficial to health: “*Let food be thy medicine and medicine be thy food.*” In modern food industry, a new food category called “functional foods” emerged as a result of the increasing awareness of the link between personal health & well-being and diet. To date, there is no unitary accepted definition for functional foods, nevertheless three main concepts are involved in most of the proposed definitions in literature, i.e., health benefits, nutritional functions and technological processes <sup>1</sup>. Among these concepts, ‘technological processes’ refer to i) the development of functional foods by optimizing traditional food processing technologies, e.g. fortification of foods with dietary fibre; ii) technologies designed to prevent the deterioration of active ingredients, e.g. microencapsulation; iii) technologies aimed to design personalized functional foods, e.g. application of nutrigenomics; 3D food printing. To simplify, functional foods can be defined as modified food or food ingredients that can provide health benefits to the consumers beyond its basic nutrients.

Functional foods introduced into the market include for example beverages, dairy products, confectionery products, bakery products and breakfast cereals <sup>2</sup>. The category of functional bakery products is newer and received increasing attention in scientific studies. Bakery products are not only nutritious plant-based foods containing macronutrients (e.g. starch and dietary fibre) and micronutrients (e.g. antioxidants and minerals), the transportation and storage of bakery products is also less demanding compared to liquid-form products such as yoghurt. In addition, the worldwide consumption of baked goods on a daily basis makes

these products interesting to serve as potential vehicles to deliver health-promoting ingredients to the human diet.

Table 1 lists some recent studies of functional bakery products with a special focus on bread which is one of the most-consumed staple foods. The main active ingredients supplemented to bakery goods include probiotics and prebiotics (dietary fibres), antioxidants and phenolic compounds <sup>3</sup>. Other functional ingredients are oils and lipids, minerals and salts, and vitamins <sup>2</sup>. Among these ingredients, probiotics and prebiotics are important in human nutrition because of their influences on the gastrointestinal (GI) microbiota. Probiotics are defined as ‘live microorganisms which confer a health benefit on the host when administered in adequate amounts’ <sup>4</sup>. Prebiotics are short chain carbohydrates which are non-digestible by digestive enzymes in the upper GI tract of humans, but are ‘consumed’ selectively by some types of bacteria (typically bifidobacteria and/or lactobacilli). Prebiotics can therefore enhance the activity of those beneficial bacteria <sup>5</sup>. The alleged health-promoting benefits of the aforementioned functional bakery products are diverse, e.g. reducing serum cholesterol and blood pressure, reducing the risk of coronary heart diseases, lowering the glycaemic response after food consumption, treating human intestinal barrier dysfunctions <sup>6-10</sup>.

**Table 1. An overview of scientific studies focusing on functional bakery products.**

Ingredient	Product	Incorporation strategy	Baking condition	Functionality
<b>Probiotics</b>				
<i>Lactobacillus rhamnosus</i> R011 <sup>11</sup>	biscuit	mix microentrapped cells in whey protein isolate into dough	baked at 280 °C for 5 min	4.5×10 <sup>5</sup> CFU/g (initial viability 1.3×10 <sup>7</sup> CFU/g)
<i>Lactobacillus acidophilus</i> <sup>12</sup>	bread	apply edible coating layers onto the surface of part-baked bread	baked off at 180 °C for 16 min	~7 log CFU/70 g bread
<i>Lactobacillus reuteri</i> DSM 17938 <sup>13</sup>	chocolate Soufflé	supplement cells into microcapsules dough	70 g dough; frozen at -18 °C; 2 h; baked at 180 °C; 10 min	~3-6 log CFU/g sample from core
<i>Bifidobacterium lactis</i> Bb12 <sup>14</sup>	bread	mix cell suspension into dough	60 g dough; baked at 165, 185 or 205 °C for 12 min	~2-3 log CFU/g (initial viable counts in dough 2.1×10 <sup>6</sup> CFU/g)
<i>Lactobacillus rhamnosus</i> GG <sup>15</sup>	bread	apply probiotic containing film solution on the surface	air dry the prebaked bread at 60 °C; 10 min or	7.6-9.0 log CFU/30-40 g bread slice

		of prebaked pan bread	180 °C; 2 min		
(Continued)					
<i>Bacillus coagulans</i> MTCC 5856 <sup>16</sup>	muffin	mix bacteria batter	spray-dried powder into	baked at 205 °C for 20-25 min	7.14 log CFU/g (initial viable counts in batter) 6.99 log CFU/g
<b>Prebiotics</b>					
carob fibre/inulin/pea fibre <sup>17</sup>	bread	add 3% fibre to dough		100 g dough; baked at 190 °C for 20 min	total dietary fibre in bread: carob fibre 5.06 %; inulin 5.14 %; pea fibre 5.38 %;
β-glucans & arabinoxylans <sup>18</sup>	flat bread	substitute wheat flour with 20 % barley fibre-rich-fractions		diameter of circular dough sheet 20 cm; baked at 540 °C for 70 s	total β-glucans 3.0 g, arabinoxylans 4.2 g per flat bread
hemicellulose B <sup>19</sup>	bread	add hemicellulose B to dough		baked at 200 °C, baking time N/A	3.87 % dm dietary fibre in baked bread
bacterial nanocellulose (BNC) <sup>20</sup>	bread	disperse BNC gel in water and mix with other ingredients		70 g dough; baked at 195 °C for 23 min	N/A
<b>Others</b>					
tea catechins <sup>21</sup>	bread	mix green tea extract into dough		baked at 215 °C for 11 min	tea catechins content: 0.53 mg/g bread
phenolic antioxidants <sup>22</sup>	bread	substitute wheat flour with fruit phenolic extracts		baked at 155 °C for 60 min	the phenolic recovery ranged from 9 % to 39 %; total antioxidant activity increased
anthocyanin <sup>23</sup>	bread	mix anthocyanin-rich black rice extract powder into dough		50 g dough; baked at 200 °C for 8 min	79 % of cyanidin-3-glucoside was retained in bread crumb after baking

### 3. Bread baking process

Bread is one of the most-consumed staple foods worldwide. Bread making is a complex process involving dough mixing, proofing (i.e., fermentation), baking and cooling. Among these steps, baking is of great importance because heat and mass transfer occurs simultaneously and interdependently inside the dough during baking, along with a series of physical and chemical changes, e.g. water evaporation, gas cell expansion, starch gelatinization, protein coagulation, dough-crumbs transition and crust formation<sup>24</sup>. These changes are dominated by heat and mass transfer mechanisms inside the oven chamber as well as in the product, and interact in a complex manner, which significantly influence the

product quality. A deeper understanding of the bread baking process is necessary to better control the quality of the final products.

During baking, the heat transport in the dough is dominated by the classic 'evaporation-condensation' mechanism<sup>25</sup>. Hence, the temperature in the crumb reaches a plateau of 100 °C while the moisture content remains similar to that of the dough (40 w/w%); the temperature in the crust keeps increasing to the oven temperature (if the baking time is long enough) and the moisture content reduces more significantly (to 20 w/w%) compared to the crumb<sup>26</sup>. These distinct temperature and moisture content histories in the inner part and the outer layer of the dough result in bread with unique macroscopic features, i.e., soft and porous crumb and crispy and dense crust. In addition, the brown colour of the crust and the flavour/aroma of the bread are formed during baking due to the Maillard reactions.

#### 4. Factors influence the functionality of active ingredients

The development of functional bread is challenging for the food industry because active ingredients may fully or partly lose their bioactivity or bioavailability during manufacturing due to either the high baking temperature or their interaction with other ingredients, e.g. decreased bioavailability of water-extractable arabinoxylan in bread due to ferulic acid-protein cross-links<sup>27</sup>. Therefore, it is important to investigate the interactions between the bread making process and the addition of active ingredients.

On the one hand, the baking process can influence the bioactivity of heat-sensitive ingredients supplemented to bread e.g. probiotics<sup>14</sup>. Although certain probiotic strains (i.e., *Bacillus coagulans*) may show high heat resistance due to their ability to form spores (see Table 1)<sup>16</sup>, several strategies have been investigated to preserve other probiotic strains (i.e., lactic acid bacteria) under stressful conditions, e.g. micro-entrapment or encapsulation, edible film, coatings, and micro-beads<sup>28-30</sup>. However, application of these technologies may alter quality-attributes of bread. For example, starch based coatings containing probiotics changed the crispness of the bread crust<sup>12</sup>. Nevertheless, data available for the wide application of microencapsulation of active compounds in thermal-processed foods are still rare<sup>31</sup>. Furthermore, a recent study on the inactivation kinetics of *Lactobacillus plantarum* showed that the moisture content of the bread matrix influenced the survival of the embedded bacteria<sup>26</sup>. The survival of this bacterium after baking appeared higher in the crust compared to the crumb for certain baking conditions, which was attributed to the lower moisture content and denser matrix structure in the crust. New strategies to enhance survival of probiotics during baking could therefore benefit by lowering moisture content of the close environment in which the cells are embedded, e.g. via encapsulation or embedded in a thin dried film at the surface of the bread.

On the other hand, incorporation of active ingredients into bread can influence the product quality in either a positive or a negative manner. For example, sourdough fermentation can produce bread with increased specific volume and softer crumb, and some of the added lactic acid bacteria (LAB) produce metabolites with antimicrobial activity, which prolong the shelf-life of bread<sup>32-34</sup>. However, supplementation of some other active ingredients can compromise the organoleptic properties of the products, therefore the modern food industry is seeking for techniques to resolve this problem<sup>35</sup>. For example, encapsulation technology is employed to reduce off-flavours caused by the incorporation of omega-3 fatty acids<sup>36</sup>. Another example is that the substitution of wheat flour with fibre-rich-fractions negatively influences the aesthetic properties of the bread (e.g. dark discolouration, harder crumb with lower loaf volume)<sup>37</sup>, which consequently lowers the acceptance of the fortified bread by consumers<sup>38</sup>. In this context, enzymatic pre-treatment of the fibre-rich-fractions might be done to modify their baking properties<sup>39</sup>.

## **5. Conclusion and future perspectives**

To develop functional bread that contains sufficient active ingredients without compromising product quality, systematic study on the interactions between the functional ingredients and the baking process is of great importance. Several questions for future research are identified: i) develop kinetic models for the inactivation of active ingredients during baking based on experimental data, which can be coupled to heat & mass transfer models of baking. The combined model may be used to optimize the baking process to better retain the functionality of active ingredients; ii) further explore the encapsulation of the active ingredients to enhance their resistance against moist-heat during baking; iii) investigate the functionality of the active ingredients during digestion, and the health-promoting properties of those ingredients in clinical trials.

### **Abstract**

*The aim of this study was to investigate the effect of convective and vacuum drying on properties of biodegradable films. The film-forming solutions were prepared with bovine gelatin and carrageenan. The films solutions were dried in convective and vacuum dryers at temperatures of 40, 50 and 60 °C. The results of convective drying kinetics of biofilms showed a constant drying rate period followed by a falling drying rate period. The results of thickness showed dependence with moisture content present in films. Carrageenan films showed promising results, with high values of tensile strength and elongation for convective drying at 60 °C.*

**Keywords:** *gelatin; carrageenan; drying; biofilm*

---

### **1. Introduction**

The resulting environmental impact of the high consumption of plastic materials in the food industry has encouraged packaging industry to develop biodegradable packaging materials

that can be used as substitutes for the current synthetic polymers [1]. The biopolymer based packaging films offers several advantages due to their good biodegradability, biocompatibility, environmentally-friendliness, and even edibility [2]. Biopolymer films have been generally classified according to the source of the original polymer utilized. Among the main raw materials, the polysaccharide-based or protein-based materials are the most widely used [3].

Gelatin is an animal protein extracted from skins, bones and connective tissue of animals by controlled hydrolysis of the fibrous insoluble collagen [4;5]. It is well known that gelatin has been widely used in food industries due to its film-forming ability and its use as an outer film to protect food from drying and exposure to light and oxygen [6]. Carrageenans are natural and water soluble sulfated polysaccharides extracted from red seaweeds [7]. The differences in the chemical structure of carrageenans are essential for their physicochemical properties and the helical structure formation leading to varied applications [8]. Park (1996) [9] reported that Kappa-carrageenan is able to produce a clear film with excellent mechanical and structural properties with high tensile strength.

In order to produce efficient packaging films, the properties of films must be optimized for commercial applications. The formation of polymeric films occurs during solvent evaporation and includes complex heat and mass transfer phenomena and polymeric chain reorganization [10]. Several researchers reported on the influence of drying conditions on the mechanical and barrier properties of alginate, whey protein, chitosan, gelatin biofilms [11; 12; 13; 14]. However, the literature does not show results of impact of drying on carrageenan films. The aim of this study was to investigate the effect of convective and vacuum drying on properties of biodegradable films produced from bovine gelatin and carrageenan.

## **2. Materials and Methods**

### **2.1 Materials**

Gelatin from bovine skin and kappa-carrageenan were used as biopolymeric matrix while glycerol (analytical grade) was used as a plasticizer. All reagents were obtained from Sigma-Aldrich (USA); distilled water was available in the laboratory for preparation of all solutions.

### **2.2 Biofilm formation and Drying**

Gelatin and carrageenan films were produced by the casting method, using the methodology proposed by Martiny [15]. The convective drying of films was performed in a custom made laboratory convective hot-air dryer. The perpendicular air flow coming from the blower was heated by an electrical heater. The inlet and outlet air temperatures were measured outside the shielded cavity using type-T thermocouples. The convective drying conditions were 40, 50 and 60 °C at an air velocity of one m/s. The drying curves  $((M-M_e)/(M_0-M_e))$  as a function of time) were obtained. The equilibrium moisture content was assumed as the final moisture

content, when the drying rate was practically null, at each drying condition. The drying rates were determined using Equation 1.

$$R = -\frac{L_s}{A} \cdot \frac{dM}{dt} \quad (1)$$

where, R is the drying rate ( $\text{kg}\cdot\text{h}^{-1}\cdot\text{m}^{-2}$ ),  $L_s$  is dried solids mass (kg), A is drying area ( $\text{m}^2$ ), M is the moisture content ( $\text{kg}\cdot\text{kg}^{-1}$ , d.b.) and  $t$  is time (h).

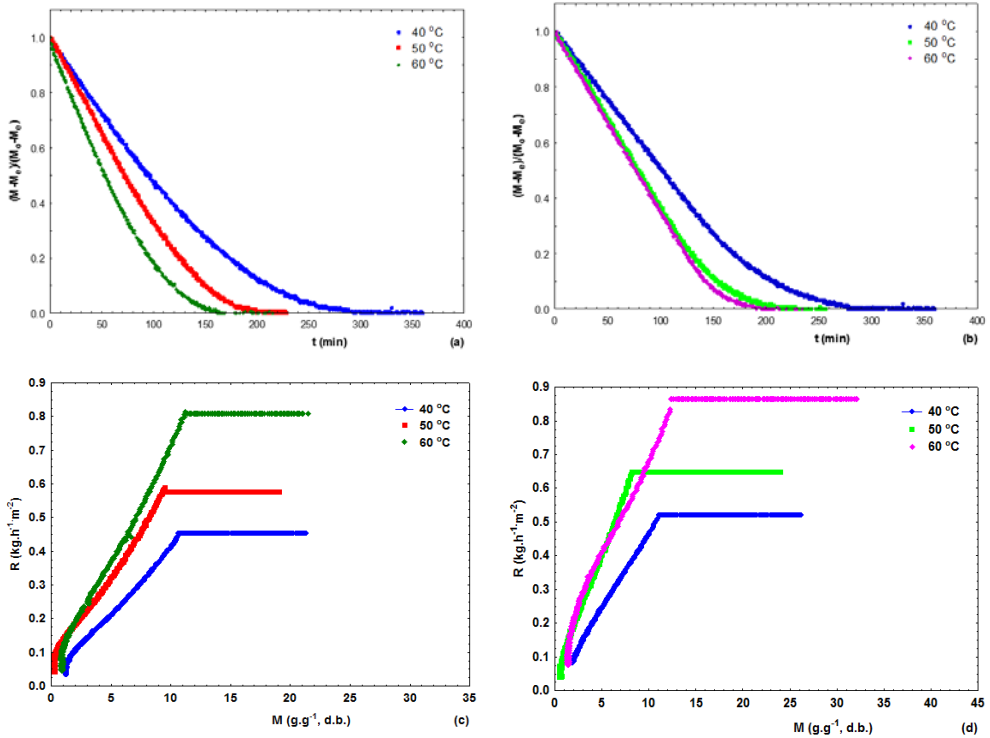

The vacuum drying of films was performed in a vacuum oven (StableTemp, Cole-Parmer, USA) with controlled temperature connected with vacuum line (25" Hg) for 48 h. The same temperatures studied in convective dryer (40, 50 and 60 °C) were applied for vacuum drying.

## 2.4 Biofilm characterization

The biofilm thickness was measured using an electronic digital micrometer (Marathon Co, CO030025, Canada) with 0.001 mm of resolution. Mean thickness was calculated from ten measurements taken at different locations on biofilm samples, according to Ferreira et al. [16]. Water vapor permeability (WVP) of biofilms was determined gravimetrically using the ASTM standard method E96/E96M-05 [17]. Tensile strength (TS) and elongation percentage (E) at break point were measured uniaxially by stretching the specimen in one direction using a Universal Testing Machine (50 N load cell - Instron 4502, USA) according to the ASTM standard method D-882-02 [18]. Scanning electron micrographs (SEM) of the film samples submitted to different drying temperatures and methods were obtained using a scanning electron microscope (Hitachi, TM 3000, Japan). Experimental data were analyzed by Statistica 7.1 software. Mean comparisons were carried out by Tukey test ( $p < 0.05$  was considered as significant).

## 3. Results and Discussion

Typical drying curves obtained are illustrated in Figure 1. Overall drying kinetic curves obtained for biofilms samples under different drying conditions showed the same behavior. In all experiments, the drying kinetics of biofilms showed a constant drying rate period followed by a falling drying rate period. The drying of high moisture materials typically presents a constant drying rate period and one or two falling rate periods [19]. The moisture contents of the samples at the end of the drying process were in the range of 0.2 to 1.8  $\text{g}\cdot\text{g}^{-1}$  (d.b.) and the time taken to reach the final moisture content ( $M_e$ ) increased from 234 min to 360 min.

**Fig. 1** Drying curves of biofilms at diferent operation conditions: (a) and (c) gelatin films; (b) and (d) carrageenan films.

As the moisture content of the samples was very high during the initial phase of the drying, higher drying rates were observed. As the drying progressed, the moisture loss (solvent-water) from the product resulted in the fall of drying rate. Various studies also reported that drying curves of polymers dispersed in solvents showed an initial period of constant drying rate before the falling rate period [19; 20; 21]. During the falling rate period, water movement may occur in the films via liquid diffusion, which is driven by moisture gradients, and vapor diffusion. This is enhanced by the vapor partial pressure gradients induced by the temperature gradients. Because pores were not observed in the SEM micrographs of film (Figure 2), liquid movement via capillarity is less probable [22; 19].

Table 1 shows the values obtained for thickness, water vapor permeability (WVP), tensile strength (TS) and elongation (E) of the gelatin and carrageenan biofilms.

Average±deviation (n=10 for thickness, n=2 for WVP, n=3 for mechanical properties)

Different letters in the same column (separated gelatin (G-) and carrageenan (C-) films) indicate significant differences between samples ( $p < 0.05$ )

The film thicknesses were in the range of 0.074 to 0.128 mm and showed significant difference ( $p > 0.05$ ) regarding films obtained from diferents drying methods and temperatures. Ahmad et al. [23] reported that the thickness depends on the components and the water content in film structure. Gelatin biofilms obtained showed properties similar to those published by other authors. Nishihora [24] reported a thickness of 0.086 mm and WVP of  $1.82\cdot 10^{-10} \text{ g}\cdot\text{m}^{-1}\cdot\text{s}^{-1}\cdot\text{Pa}^{-1}$ ; Albertos et al. [25] reported WVP of  $2\cdot 10^{-10} \text{ g}\cdot\text{m}^{-1}\cdot\text{s}^{-1}\cdot\text{Pa}^{-1}$ ; Bertan [26] showed thickness values between 0.075 and 0.128 mm; Musso et al. [27] reported a WVP from  $6.5\cdot 10^{-10}$  to  $7.9\cdot 10^{-10} \text{ g}\cdot\text{m}^{-1}\cdot\text{s}^{-1}\cdot\text{Pa}^{-1}$ , tensile strength from 3.4 to 4.6 MPa and elongation between 159 to 206 %.

Martins et al. [28] produced carrageenan films and obtained thickness of 0.052 mm, 16.18 % elongation and 19.95 MPa for tensile strength. Several studies with carrageenan films have shown WVP from  $5.8 \cdot 10^{-11}$  to  $2.18 \cdot 10^{-8}$  g. m<sup>-1</sup>.s<sup>-1</sup>.Pa<sup>-1</sup> [28; 29; 30; 31; 32; 33], tensile strength from 11.64 to 26.29 MPa and elongation from 2.54 to 45 % [28; 31; 33; 34].

The data reported in the literature for tensile strength and elongation are smaller than those obtained in this work. This was attributed to the differences in the preparation, composition and proportions of the film-forming solutions. Results for carrageenan films looked promising. Normally, a high tensile strength in the formulated film is common, however the flexibility of the film, indicated by the elongation is a very important parameter. This enables better applicability of this film in packaging [35].

There were no significant difference ( $p < 0.05$ ) between the WVP, tensile strength and elongation of carrageenan biofilms obtained from convective drying. Also, gelatin biofilms obtained from convective drying did not show significant difference for tensile strength and elongation. This is a desirable since the convective drying can be faster when the temperature is 60 °C.

SEM images of gelatin and carrageenan films are shown in Figure 2. Among the films, the gelatin films were more homogeneous and transparent, while the carrageenan film had the highest density of clusters and the highest opacity. These images show smooth and homogeneous surfaces for gelatin films. Despite the carrageenan films showing a heterogeneous surface, it was not possible to see defects and cracks. The non-uniformity of carrageenan films was attributed to the early gelation during casting [31].

**Fig. 2 SEM micrographs of surface of films obtained from (a) gelatin-convective drying at 50 °C, (b) gelatin-vacuum drying at 50 °C, (c) carrageenan-convective drying at 50 °C, (d) carrageenan-vacuum drying at 50 °C.**

#### 4. Conclusions

The development of this research allowed to investigate the effect of convective and vacuum drying on properties of gelatin and carrageenan films. The convective drying kinetics showed a constant drying rate period followed by a falling drying rate period, which is typical of materials with high moisture content. The results of thickness showed dependence with

moisture content present in films. Carrageenan films showed promising results, with high values of tensile strength and elongation even for those made in the convective dryer at 60 °C.

### Abstract

*Drying kinetics of *Saccharina latissima* (raw and blanched) at low temperatures (10.0, 25.0 and 38.0 °C) was studied. The effective moisture diffusivity coefficient varied due to temperature alterations in the range between 1.4 and 4.5 10<sup>-10</sup> m<sup>2</sup>/s for raw and 0.91 and 2.56 10<sup>-10</sup> m<sup>2</sup>/s for blanched seaweeds. Significant changes in structural properties and chemical composition resulted in a much longer drying time of blanched seaweeds, when compared with raw. Drying temperature of 38.0 °C resulted in more brown color, when compared with other samples. Sorption characteristics of dried raw seaweeds depended on salt content and showed high accumulation of moisture at relative humidity of air of 80.0 %. The blanched seaweeds showed linear accumulation of moisture within increasing of relative humidity of drying air from 20.0 to 80.0 %, but high level of hysteresis was determined between sorption and desorption isotherms. The shrinkage development within dewatering of blanched and raw samples was also studied.*

**Keywords:** brown seaweeds, drying kinetics, sorption isotherms, color

---

## 1. Introduction

As much as 36 % (30 million tons of total harvest) of seaweed is used as a direct food source<sup>[1]</sup>. The main representatives of the food-grade seaweeds are: *Laminaria japonica* (Kombu) and *Saccharina latissima* (Royal Kombu)<sup>[2]</sup>, which are mostly produced and consumed in Asia. At the same time the key advantage (and the main potential) of the seaweed industry in Europe is its independence from three main resources, that limit conventional agriculture: land, water and fertilizers<sup>[3]</sup>. The brown seaweeds *Saccharina Latissima* are cultivated now in Norway with the aim to produce food-grade products. However, the harvesting season is short and raw material has a very low stability. Thus, the effective stabilization method is required.

Drying is the common way to preserve food products like seaweed and most of the seaweeds are sold in a dried form<sup>[4]</sup>. Solar and natural drying of seaweeds is a cost-effective method. At the same time climate conditions can result in a high final moisture content in dried product<sup>[5]</sup> due to high moisture absorption ability<sup>[6]</sup>, also, the process 5 or 7 days<sup>[7]</sup> and this is not a feasible and safe to apply the method for food graded seaweeds for European market. The demand for traceability and safety appears, when the drying process is used for food production. Drying of seaweeds for long time and/or at high temperature influences negatively on their carbohydrates, amino acid composition and vitamin content<sup>[8]</sup>. The recent study of *Saccharina Latissima* revealed that decreasing of the drying temperatures results in the increasing of quality<sup>[9]</sup>

The task of this study was the determination of the main process dependencies for the low temperature drying of *Saccharina Latissima* after frozen storage with the aim of implementation this knowledge into the sustainable drying process.

## 2. Materials and Methods

### 2.1 Characterization of raw material

The brown algae *Saccharina latissima*, which is commonly referred as kelp (Sugar kelp or kombu) was used for the experiments. The seaweeds was cultivated for one year in an aquaculture farm, which is situated in Sør-Trøndelag (Norway). Harvesting season was 3 days in May 2016 to maintain the best quality of the seaweeds and avoid high amount of biofouling. The seaweed was harvested into nets (75-150 kg). The nets were buffered in the seawater at the farm for up to 1 weeks before processing. Then the seaweeds were sorted to remove seaweed of a bad quality. Afterwards, the seaweed was weighed out and packed inside vacuum bags with high barrier properties (2.0 kg each). Freezing was at -46 °C for 20-25 min until the temperature inside the bag reached -18.0 °C. The bags were packed in cardboard boxes, put on pallets and placed in freeze storage at -18 °C. The freezing process was applied to stabilize the product, because harvesting season is short (few days) and high

amount of biomass is difficult to process before deterioration will start. Chemical composition of the aquaculture seaweeds is given in the Table 1.

**Table 1. Chemical composition of *Saccharina latissima* at harvesting season (analysis performed by accredited analytical laboratory Kystlab preBIO, Frøya, Norway).**

<b>Chemical composition</b>	<b>%, d.b.</b>	<b>Minerals , mg/kg d.b.</b>	
Proteins	11.2	Potassium	84000
Fats	2.9	Sodium	52000
Carbohydrates	55.3	Calcium	10000
Incl. Dietary fiber	46.6	Magnesium	7500
Ash	37.9	Sulfur	7300
Incl. Salt (NaCl)	14.6	Iodine	3670
Water	900.0	Phosphrus	1700

## 2.2 Experiment description

The frozen seaweeds were divided into two groups: one was blanched seaweeds another group was raw seaweeds without any processing. Frozen seaweeds were defrosted at +5.0 °C in refrigeration cabin to avoid significant degradation of tissues. The blanching took place in a boiling water (100.0 °C) for 1.0 min. The blanched seaweeds were immediately cooled in water (5.0 °C). The drying took place on shelves in drying chamber with a closed loop air circulation. The following parameters were varied during drying experiments: air temperature: 10, 25 and 38 °C; amount of seaweed's layers: 1 layer, 2 and 3. The seaweeds were placed in a drying chamber on shelves parallel to the air flow. Relative humidity of drying air for all cases was 16.0 ±4.0 %. Drying air velocity 1.5±0.5 m/s. The drying process was stopped when the moisture content was in the range between 20.0 and 10.0% d.b.

## 2.3 Determination of drying kinetics

The drying behaviors were modelled using Newton model. The drying behavior itself was characterized via determination of the effective moisture diffusivity. This material property was derived from the drying kinetics via analytical solution of the Fick's second law of diffusion (infinite slab).

## 2.4 Determination of sorption and desorption properties at different temperatures

Sorption isotherms were determined for dried blanched and dried raw seaweeds at 10.0, 25.0 and 38.0 °C. Desorption properties were determined by drying of raw seaweeds at 25.0 °C 20.0 % RH.

## **2.5 Determination of color**

Color was analyzed with the assistance of ColorFlex EZ Spectrophotometer (HunterLab, USA) using CIE L\*C\*h\* scale. The lightness L\* varies from black (L\*=0) to perfect white (L\*=100). The chromaticity C\* reflects the colorfulness; when C\*=0, the object is considered to be colorless. Hue is an attribute of a visual sensation, according to which an area appears be similar to one of the perceived colours or to a combination of two of them. It is measured in degrees from 0 to 360°, rose (h\*=0°), yellow (h\*=90°), green-blue (h\*=180°), and blue-violet (h\*=270°).

## **2.6 Statistical analysis**

The analysis of variance (ANOVA: single test and two-factor test with replication) was applied to analyze the obtained data. The difference was considered significant at  $p < 0.05$ . All the experimental points were done in six parallels, except of desorption isotherm determination, where each point represents a single experiment. A regression analysis was done with a software DataFit 8.1 program (Oakdale Engineering).

# **3. Results and Discussion**

## **3.1. Influence of pretreatment and drying modes on color of seaweeds**

The blanching process alternated the lightness (L\*), chrominance (C), and hue (h) of the seaweeds ( $p < 0.05$ ). The typical brown-olive color (by human eye perception) of the seaweeds visually changed to green, this was reflected by increasing of hue by 12° and alteration of chrominance by 71.0 %, Table 2. The lightness of dried raw samples were significantly higher when compared with dried blanched ( $p < 0.05$ ). This might be possible due to deposits of salts and other water soluble compounds (for example, mannitol) on the surface of the dried blades of *Saccharina latissima*, which created a layer on surface with high reflective properties. Chrominance of dried raw seaweeds was also higher ( $p < 0.05$ ). Some interesting observations were found regarding the influence of temperature on the hue-value of the dried seaweeds. The drying temperature of 38.0 °C resulted in a slight decreasing of the hue-value, so the color became more “orange (brown)” (in terms of L\*C\*h\* color space), while the seaweeds dried at 10.0 °C showed more “yellow-green” color. This was valid both for raw and blanched seaweeds. One of the possible explanation may be a higher oxidation rate of the pigments by oxygen at a higher temperatures <sup>[10]</sup>.

**Table 2. Color parameters of raw and blanched seaweeds before and after drying**

Type of seaweeds	Before drying (Color parameters)								
	L*, (-)	C, (-)	h,°	a*, (-)	b*, (-)				
Raw seaweeds	9.78 (0.96)	8.08 (1.97)	80.23 (1.45)	1.39 (0.43)	7.96 (1.94)				
Blanched seaweeds	11.54 (1.29)	13.84 (1.63)	92.00 (4.04)	-0.13 (1.25)	14.74 (1.39)				
After drying (Color parameters)									
	L*, (-)		C, (-)		H,°				
	Temperature, °C								
	38.0	25.0	10.0	38.0	25.0	10.0			
Blanched seaweeds	23.1 <sup>a</sup> (1.54)	23.7 <sup>a</sup> (2.19)	23.83 <sup>a</sup> (1.23)	6.4 <sup>c</sup> (2.84)	5.76 <sup>c</sup> (1.89)	6.59 <sup>c</sup> (1.32)	81.39 <sup>e</sup> (5.66)	82.85 <sup>e</sup> (4.57)	86.86 <sup>f</sup> (3.3)
Raw seaweeds	25.86 <sup>b</sup> (1.12)	27.25 <sup>b</sup> (2.78)	27.91 (2.46)	8.71 <sup>d</sup> (1.33)	8.39 <sup>d</sup> (1.02)	8.42 <sup>d</sup> (1.09)	83.39 <sup>e</sup> (3.07)	86.00 <sup>f</sup> (2.53)	86.73 <sup>f</sup> (3.03)

### 3.2 Sorption-desorption characteristics of *Saccharina latissima*

The dried raw and blanched seaweeds behave differently during absorption of moisture from the ambient air (Fig. 1). Dried blanched seaweeds showed higher accumulation of moisture at low relative humidity of air (from 20.0 to 40.0 % RH) for all the investigated samples, when compared with raw seaweeds ( $p < 0.05$ ). While, the trend was changed at 60.0 % RH. Further increasing of the relative humidity in the climate chamber to 80.0 % resulted in a sharp alteration of moisture content in dried raw seaweeds for all the investigated temperatures ( $p < 0.05$ ), while dried blanched seaweeds showed almost linear trend of moisture increasing in the range of RH between 20.0 and 80.0 %. The temperature variation between 10.0 and 38.0 °C did not influence on the sorption characteristic of the blanched seaweeds.

The similar behavior was observed by Sappati et al., [11] studied the sorption isotherms of *Saccharina latissima* at 20.0 °C. The sharp increasing of the equilibrium moisture content of raw seaweeds at 80.0 % and relatively low water absorbance at RH below 60.0 % can be explained by hygroscopic point of salts, which occupy the significant share among other compounds. For example, hygroscopic point of NaCl appears at 75.5 % RH at 25.0 °C, KCl at 82.0 % RH. The salt concentration in raw seaweeds was determined at 14.4 % d.b., while blanched seaweeds were almost salt-free (below 0.5 % d.b). Desorption isotherms were determined at 25.0 °C and compared with sorption profiles at the same temperature. It is interesting to note, that hysteresis phenomena was relatively small for raw seaweeds, while blanched seaweeds showed a significant change in structural properties during drying. It may happens due to freezing and blanching process when the cell membranes were broken and water soluble compounds were easily washed out and replaced by a free water. Thus, significant irreversible shrinkage appears during drying process of blanched seaweeds.

Figure 1. Sorption characteristics of *Saccharina Latissima*

### 3.3 Shrinkage of raw and blanched seaweeds during dewatering

Figure 2. Shrinkage of raw and blanched seaweeds during drying

The drying processes resulted in a significant reduction of blade thickness for raw and blanched seaweeds, Fig. 2, while surface area reduced only by 20.0..25.0 %.

The thickness reductions was much more developed for blanched blades, when compared with raw samples ( $p < 0.05$ ). Also, raw seaweeds retained their thickness much longer during

dewatering when compared with blanched. The first traces of the thickness decreasing were detected at MR of 0.6 and 0.8 at 25.0 °C for raw and blanched seaweeds respectively.

### 3.4 Drying kinetics of seaweeds

The drying kinetics was investigated for raw and blanched seaweeds. The raw seaweeds showed initial moisture content at 900.0 (50.0) % d.b. The moisture content of the blanched seaweeds was found at 2079.0 (100.0) % d.b. Dehydration of raw seaweeds was much faster, when compared with blanched. This can be explained by the higher moisture content of blanched seaweeds and also may be linked with the changes of their structure after blanching. The increasing of temperature accelerated the dewatering of the seaweeds both raw and blanched, and the highest dewatering rate was observed for 38.0 °C.

Newton model was implemented to obtain the regression equations for all the drying temperatures ( $R^2 > 0.98$ ;  $\text{Prob}(F) < 0.000014$ ;  $F(\text{Ratio}) > 700$ ). The empirical drying coefficient  $k$  was found in the range between 0.008 and 0.22 1/min due to the influence of temperature and variation of thickness of the sample.

Table 3. Coefficients for Newton equation and effective moisture diffusivity

Type of seaweeds	Drying temp., °C	Drying coefficient, 1/min			
		1 layer	2 layers	3 layers	
Raw seaweeds	10.0	0.07(0.01)	0.015(0.01)	0.016(0.001)	
	25.0	0.13 (0.01)	0.033(0.01)	0.021(0.001)	
	38.0	0.22 (0.01)	0.055(0.01)	0.036(0.001)	
Blanched	10.0	0.035 (0.001)	0.017(0.002)	0.008(0.002)	
	25.0	0.051 (0.001)	0.025(0.003)	0.013(0.002)	
	38.0	0.060 (0.001)	0.031(0.004)	0.015(0.001)	
<b>Effective diffusivity, <math>D \text{ m}^2/\text{s} \cdot 10^{10}</math></b>				<b>Average</b>	
		1 layer	2 layers	3 layers	
Raw seaweeds	10.0	1.50	1.20	1.50	<b>1.4 (0.17)</b>
	25.0	2.80	2.60	2.60	<b>2.7 (0.11)</b>
	38.0	4.50	4.00	5.00	<b>4.50 (0.5)</b>
Blanched seaweeds	10.0	0.95	0.90	0.90	<b>0.91 (0.03)</b>
	25.0	1.10	1.50	1.10	<b>1.2 (0.23)</b>
	38.0	2.50	2.60	2.60	<b>2.56 (0.05)</b>

The average values of effective moisture diffusivity (Table 3) increased with increasing of the drying temperature and reached the highest value of  $3.5 \cdot 10^{-10} \text{ m}^2/\text{s}$  at 38.0 °C. The effective moisture diffusivities of blanched seaweeds were relatively lower, when compared with raw seaweeds. The results of this study were in agreement with the resent study on *Saccharina latissima* [11], when the effective moisture diffusivity was determined at  $2.95 \cdot 10^{-10} \text{ m}^2/\text{s}$  at 40.0 °C and 25.0% RH.

## 4. Conclusions

Drying kinetics of *Saccharina latissima* (raw and blanched) at low temperatures (10.0, 25.0 and 38.0 °C) was studied. The effective moisture diffusivity coefficient varied due to temperature alterations in the range between 1.4 and 4.5  $10^{-10}$  m<sup>2</sup>/s for raw and 0.91 and 2.56  $10^{-10}$  m<sup>2</sup>/s for blanched seaweeds. Significant changes in structural properties and chemical composition resulted in a much longer drying time of blanched seaweeds, when compared with raw. Drying temperature of 38.0 °C resulted in more brown color, when compared with other samples. Sorption characteristics of dried raw seaweeds depended on salt content and showed high accumulation of moisture at relative humidity of air of 80.0 %. The blanched seaweeds showed linear accumulation of moisture within increasing of relative humidity of drying air from 20.0 to 80.0 %, but high level of hysteresis was determined between sorption and desorption isotherms. The shrinkage development within dewatering of blanched and raw samples was also studied.

### **Abstract**

*The main objective of this work is to encapsulate and dry the bacterium probiotic Lactobacillus casei applying three different drying techniques (lyophilization, fluidized bed and flash freeze drying) as well as to evaluate their viability during storage in the dark at 20°C and 34% relative humidity for 28 days. In addition, to compare viability of the bacterium processed with flash freeze drying with cryoprotectant (skim milk) and without cryoprotectant.*

*In the case of flash freeze drying, the final level of viability shows the potential of this drying technique with much less operating costs than lyophilization.*

**Keywords:** *Encapsulated, probiotics, lactobacillus, casei, drying*

---

## 1. Introduction

Encapsulation and drying techniques are alternatives which try to protect probiotics microorganisms of the effect of environmental agents that may affect their viability, during processing, storage and consumption and their passage through the gastrointestinal tract by allowing them to maintain their viability and functionality over time [1, 2] by reducing cell damage to retain cells within encapsulation materials that generate their isolation [3, 4].

Probiotic bacteria are live microorganisms which when administered in adequate amounts confer health benefits to the host, beyond their inherent nutritional contribution [5, 6]. The bacteria are encapsulated, dried and converted into powder for use in food and pharmaceutical applications, as the powder is easy to handle, transport and store. Different drying techniques can be used for the encapsulation of probiotics.

In this project we evaluated flash freeze drying, lyophilization and fluidized bed.

Flash freeze drying (FFD) process is developed by the freezing of the product through the application of vacuum. Then, a considerable fraction of water is removed by vaporization during freezing and once frozen the rest by sublimation, obtaining in this way a dry paste which favours the preservation of the product [7]. This technology enables the encapsulation of biological materials to reduce the rate of chemical reactions and degradation by heat [8].

Many factors responsible for microbial survival have been reported during and after the freeze-dried, among them, the bacterial species, the physiological state, cell density, effect of protectors [9], freezing rates and other process parameters, as well as rehydration [10].

Lyophilisation is a technique which also is developed by the freezing of the product and after the application of vacuum, the water is removed only by sublimation while Fluidized Bed Drying is a process in which heated gas is, usually conditioned air with controlled velocity, is passed through a bed of suspending solid particles, dragging the removed water.

The main objective of this work is to encapsulate and dry the bacterium probiotic *Lactobacillus casei* applying different drying techniques as well as to evaluate their viability during storage. In addition, to compare the viability of the bacterium *L. casei*, processed with Flash Freeze Drying with cryoprotectant (skim milk) and without cryoprotectant.

## 2. Materials and Methods

*Lactobacillus casei* 431 biomass was produced using Man Rogosa Sharpe (MRS) culture medium. The final probiotic required an encapsulation treatment with alginate and chitosan in a Jet-cutter equipment, and then dried by three different treatments: Flash freeze drying (FFD), lyophilization and fluidized bed.

Probiotics were packaged in vacuum, stored in the dark at 20°C and 34% relative humidity for 28 days. Measurements of water activity and microbiological analysis were performed on the 7<sup>th</sup>, 14<sup>th</sup>, 21<sup>st</sup> and 28<sup>th</sup> days of storage.

### **2.1. Obtaining of microbial biomass**

Strains of *L. casei* 431 were supplied by Christian Hansen & Cia and kept in their original packaging at temperature of - 80°C. They were activated in MRS broth and incubated at 37 °C for 24 hours under aerobic conditions with moderate stirring (200 rpm). Biomass recovered by centrifugation (4000 rpm at 15°C). The centrifuged fraction presented a concentration of cells around of 10<sup>9</sup> units forming colonies (CFU) per gram and the supernatant was discarded. Finally, the cells were washed with sterile water, and preserved in refrigeration (6±2°C) until used.

### **2.2. Encapsulation**

For encapsulation process, we suspended the bacteria in alginate and received it in a bath of Chitosan using a Jett Cutter at following operations conditions: flow 25 g/s, 170 nozzle, pressure 1.5 bar and motor 4,000 rpm. Then, the mass of microcapsules were divided in three groups: a) fluidized bed drying b) lyophilization and c) flash freeze drying. In addition, we divided flash freeze drying in two groups: c.1) with cryoprotectant (skim milk sterile) and c.2) without cryoprotectant.

### **2.3. Drying techniques**

Fluidized bed drying (FBD) was made in a Glatt GmbH dryer, model Uni-Glatt, with the following conditions: temperature in air 30°C, temperature out air 24°C and temperature product 12°C. The process drying was carried out until to obtain the required water activity in the product.

Lyophilization was carried out in a Telstar Lyo beta 25 equipment, with fluid temperature of 5.1 °C, condenser temperature - 76.3 °C and heating temperature of 23.1°C, with full cycle of 48 hours, beginning at a freezing temperature of - 40°C to 0.1 mbar during 4 hours, followed by a 24 hour primary dried at 40°C and 4 hours of secondary drying at 20°C and at 0.05 mbar, 10 hours more.

For Flash Freeze Drying (FFD), we used a Telstar Lyo Quest equipment in which pressure was reduced from atmospheric to 0.02 mbar in 30 min with the heating device at 30 °C during sublimation.

Dried material was packed in polyethylene bags and stored in controlled temperature (20±2 ° C) store and moisture relativity of 60 %.

## 2.4. Study of bacteria survived and stability

To determine the effect of the agent cryoprotectant (sterile skim milk) on viability of encapsulated microorganisms, the number of viable cells was determined before and after freeze-drying and drying, every 7 days during storage at  $20\pm 2^\circ\text{C}$  for 28 days. We used as criteria of stability: the viability during storage (CFU/g) and water activity. These parameters were determined every seven days by triplicate.

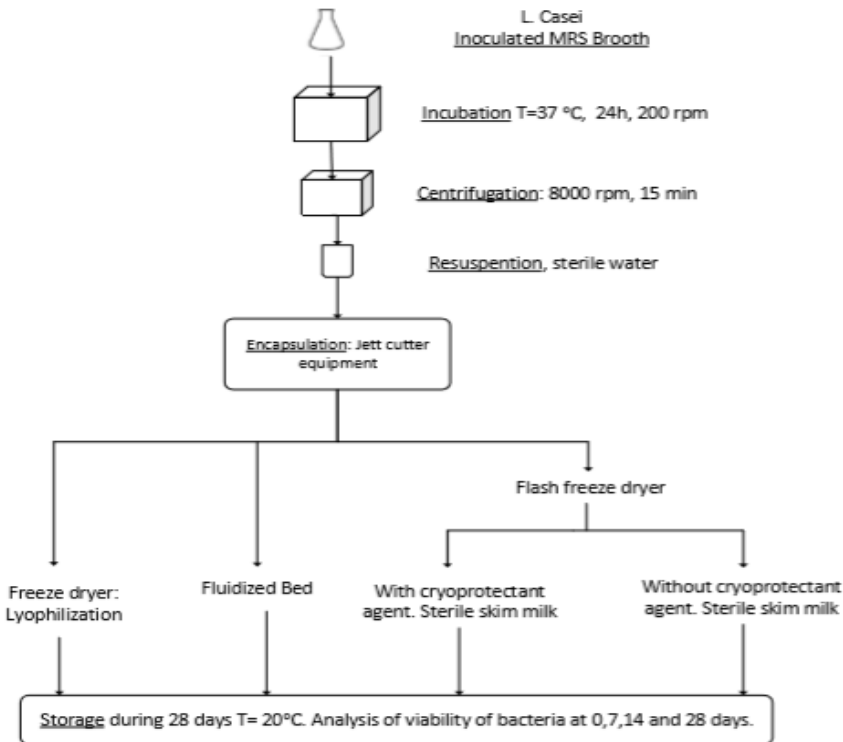

Figure 1. Flowchart with the methodology used for encapsulation and drying *L. casei*

## 2.5. Viability

Analysis of viability was made taken a gram of encapsulated material, soaked in 10 ml of buffered 0.1 sterile water, homogenized with vortex. A volume of 100  $\mu\text{L}$  of dilution it was sown surface on MRS medium and incubated under aerobic conditions at  $37^\circ\text{C}$  for 48 hours. Counts were performed in duplicate and expressed as cfu g<sup>-1</sup> (dry basis), for each experimental condition [11]. The figure 1 show flowchart with the methodology used for encapsulation and drying of *L. casei*.

## 2.6. Physicochemical characterization

Water activity ( $a_w$ ) was determined in a hygrometer Novasina, Bab master aw, Switzerland.

## 2.7. Experimental design and statistical analysis

An experimental design was applied with a factor (storage time) with repeated measurements where the experimental units were followed over time. The results correspond to the average of three replicates and are presented as mean  $\pm$  standard deviation. An analysis of variance (ANOVA) and Tukey test with a level of significance to  $p < 0.05$  was applied to the data analysis.

## 3. Results and discussion

### 3.1. Drying techniques effect

The results show significant differences between the results of feasibility among the three treatments, presenting the Fluidized Bed Drying (FBD) the lower viability. Besides, there were significant differences between the water activity of capsules treated in three treatments, showing freeze-dried capsules the lower water activity.

After FFD, see Table 1, the bacterium presented a viability level of  $5.3 \times 10^{10}$  CFU/g, which is equivalent to 84.49% survival, only a little less than by lyophilization, in which the viability test gave  $7.9 \times 10^{10}$  CFU/g or an 86.19% survival.

In the case of FFD, although a certain decrease in viability during storage was observed, from  $5.1 \times 10^{10}$  CFU/g (7<sup>th</sup> day) to  $4.7 \times 10^9$  CFU/g (28<sup>th</sup> day), or a survival variation from 99.8 to 90.3%, the final level of viability is important because shows the potential of this technical drying.

*Table 1. Cell survival after drying and during storage for the three drying techniques. The values of  $a_w$  (20 °C) correspond to the end of drying*

Drying technique	Cell viability* - Drying		Water activity ( $a_w$ )	Cell viability** - Storage	
	Before	After		7 <sup>th</sup> day	28 <sup>th</sup> day
Lyophilization	4.4 E12	7.9E10 (86.19)	0.0993	7.2E10(99.6)	6.2 E9 (90.19)
FBD	5.1 E12	7.1E8	0.3075	8.1E7	0
FFD	4.92 E12	5.3E10 (84.49)	0.0775	5.1E10(99.8)	4.7 E9 (90.3)

\* Cell viability values are expressed in CFU/g, numbers between brackets are the survival percent respect to the cell content before drying.

\*\* In the case of storage, numbers between brackets are the survival percent respect to the cell content after drying.

### **3.2. Storage**

Respect to the dried stored samples the results show that the L. Casei lyophilized presented at the end of the 28th day of storage a viability level of  $5.3 \times 10^{10}$  CFU/g, which is equivalent to 84.49% survival, only a little less than by lyophilization, in which the viability test gave  $7.9 \times 10^{10}$  CFU/g or an 86.19% survival.

In the case of FFD, see Table 1, although a certain decrease in viability during storage was observed, from  $5.1 \times 10^{10}$  CFU/g (7<sup>th</sup> day) to  $4.7 \times 10^9$  CFU/g (28<sup>th</sup> day), or a survival variation from 99.8 to 90.3%, the final level of viability is important because shows the potential of this drying technique with much less operating costs than lyophilization. [12]

### **3.3. Physicochemical properties**

Water activity values are considered critical parameters for the survival of micro-organisms and on the stability of microcapsules during storage. Measurements were made at the beginning and end of storage, and they are reported in the Table 1.

Some authors claim that the adverse effect or not, of the drying techniques is related to aspects as the bacterial species, the addition of protective substances, initial cell concentration, physiological state of microorganisms, rate of freezing by the generation of osmotic stress, temperature and conditions of rehydration, among others [13]. In this study FBD presents the lowest water activity, which encourages the preservation of probiotic material.

## **4. Conclusions**

Flash Freeze Drying (FFD) is set to become a promising drying technique with similar results to lyophilization but with much less process time and operating costs.

The use of milk as a protectant showed advantages on the results of feasibility, so its use is recommended.

The importance of these results reveal that, under adequate drying treatment, it is possible to stabilize probiotic material with Flash Freeze Drying (FFD) process in viable conditions for extending its shelf life.

## 5. Nomenclature

g/s	grams per second
mbar	milibar
ml	millilitre
μL	microlitre
°C	Celsius degrees
rpm	revolutions per minute
CFU/g	colony forming units per gram
a <sub>w</sub>	Water activity

### **Abstract**

*The present study aims to find the best drying method to minimize the duration of the operation while respecting the nutritional value of the product. Experiments of convective drying and microwave radiation were respectively carried out with a convective dryer (heat temperature: 65 °C and air velocity: 1.3 m/s) and a microwave oven (power level: 100 W and frequency: 2450 MHz). Six coupling tests between the convective drying and microwave radiation were conducted. The only variable condition is the time output of tomatoes from the convective dryer or the microwave oven corresponding to an intermediate mass ratio (IMR) 0.5, 0.4 and 0.3. The microwave drying removes the bound water faster than convective drying. This explains the observed time savings due to convection-microwave and microwave-convection combined drying. The combination of convection drying and microwave drying to an IMR 0.5 preserved better the red color and the antioxidants of the tomato. Thus, the convection-microwave combined drying (IMR 0.5) proved most suitable for preserving the quality of tomatoes.*

**Keywords:** convective drying; microwave; coupled drying; color.

## **1. Introduction**

Tunisia is ranked among the top ten countries in the world in terms of tomato processing, with a local production of 1.2 million tons of tomatoes in 2013, fifty thousand tons of which are destined for processing [1]. Furthermore, the export of dried tomatoes has shown remarkable growth in recent years. Tomato is an herbaceous climacteric fruit, which belongs to the order of Solanale, the family of Solanaceae and the genus of Lycopersicon. It is native to the northwestern South of America and it is grown in warm and temperate countries around the world. According to some studies, regular consumption of tomatoes or tomato products can reduce the risk of cancer, as well as cardiovascular diseases, diabetes and osteoporosis [2],[3]. Indeed, Tomato is a fruit which is rich in antioxidant compounds, and more particularly, in polyphenols and vitamin C. The transformation processes involve one or more heat treatments which can affect the levels of antioxidants and thus the nutritional quality of the products. In fact, these micro-constituents can be partially degraded under the effect of heat and light. In this context, our study aims to find the best mode for drying tomatoes by combining convective drying and microwaves in order to minimize the duration of the operation while respecting the nutritional value of tomatoes.

## **2. Materials and Methods**

### **2.1. Raw material**

The tomato samples used for drying are "round" varieties grown under a greenhouse and supplied from the "AGRIFOOD" Tunisian company.

### **2.2. Determination of drying kinetics**

#### *2.2.1. Convective drying experiments*

The drying kinetics of the tomatoes were performed using the convective drying loop of the research group GP2A (ENIS). After setting the air flow, the controller starts to heat up to the set temperature. Once the experimental conditions are stable, the samples to be dried are washed and cut into quarters. Then, the samples are placed on a suitable support; this support is suspended in the horizontal test vein by a hook located below a precision balance. The drying kinetics are determined through the measurements of the mass variation of the samples over time by means of a digital precision electronic scale. This balance is linked to a computer and equipped with a data output enabling the acquisition of the mass over time by means of a suitable software. The experimental conditions carried out with the convective drying loop are fixed at a temperature of 65 ° C., an air velocity of 1.3 m / s and a final mass ratio of 0.2, imposed by the manufacturer.

#### *2.2.2. Microwave drying experiments*

The drying experiments were carried out in a domestic microwave oven at a frequency of 2450 MHz and three power levels (100, 300 and 600 W) for a cycle of 15 seconds. The

drying end criterion is also the final mass ratio of 0.2. Preliminary tests at different power levels were carried out and led to the choice of the lowest power (100 W) for subsequent experiments based on the visual appearance of tomatoes during drying.

### 2.2.3. Experimental protocol of convective and microwave coupled drying

Six coupling tests were carried out under the same drying conditions as: a temperature of 65 ° C., an air velocity of 1.3 m / s, a power of 100 W and a final mass ratio of 0, 2. The only variable condition is the intermediate output time from the convective dryer or the microwave oven corresponding to an intermediate mass ratio (IMR) of 0.5; 0.4 and 0.3. This ratio corresponds to the breaking point and the change from one drying mode to another:

- 3 assays of coupling convective drying (Co) to microwave radiation (Mo) at 3 IMR: 0.5; 0.4 and 0.3.
- 3 other coupling tests by switching from microwave drying (Mo) to convective drying (Co) at 3 IMR: 0.5; 0.4 and 0.3.

## 2.3. Physicochemical analysis

### 2.3.1. Preparation of extracts

The extraction is carried out using an ultrasonic bath. One gram of crushed tomatoes is mixed with 50 ml of pure ethanol for 2 hours. The solvent was evaporated on a rotary evaporator. Dry extracts stored at 4 ° C are obtained until use.

### 2.3.2. Water content

The water content, X (kg of water / kg M.S.) is calculated using the following equation:

$$X = \frac{m - ms}{ms} \quad (1)$$

with: m: mass of the wet sample (kg), ms: mass of the dry sample (kg).

### 2.3.3. Ascorbic acid analysis

The ascorbic acid content is measured by the 2,6-dichloroindophenol titration method [4].

### 2.3.4. Color analysis

The color is measured using a colorimeter (Konica Minolta CR 300) with CIE Lab system (L \*, a\*, b\*). Statistical analysis was performed using SPSS software (version 13, Inc. SPSS, Chicago, USA) at a confidence interval of 95%.

### 3. Results and discussion

#### 3.1. Kinetics of convective and microwave drying

Figure 1 shows the evolution of the reduced water content as a function of the drying time for the convective (65 ° C. and 1.3 m / s) (FIG. 1 a) and for microwaves drying (at 100 W) (FIG. 1b). The drying time needed to obtain a final mass ratio of 0.2 (i.e. a final water content of 0.25 kg water / kg DM) is 5 hours and 21 minutes. The water content decreases rapidly at the first time and then more and more slowly at the end of the drying. Indeed, at the beginning of drying, the mechanism of water displacement through the pores walls of the solid towards the surface is carried out in an accelerated manner. At the end of the drying process, increasing the temperature in the center of the product and decreasing its water content result in a new state of equilibrium in the product. Thus, water is increasingly hard to migrate into the product and the internal transfer of matter becomes a limiting phenomenon [5].

**Figure 1: Evolution of the reduced water content as a function of the drying time by: (a) forced convection drying at 65 ° C and 1.3 m / s ( $X_0 = 24.263$  kg water / kg M.S); and (b) microwaves radiation at 100 W ( $X_0 = 24.258$  kg water / kg M.S)**

Microwave drying at a relatively low power (100 W) allows to achieve the same mass ratio of 0.2 (i.e. a final water content of 0.25 kg of water / kg DM) in 25 minutes; that means a gain of 4 hours and 56 minutes compared to convective drying. Despite the short duration of microwave treatment and the visual aspect, the sample had a softer texture and showed intense yellowing of the skin that we did not notice for convection dried samples; hence, the idea of combining convective drying with microwaves seems to be interesting.

### 3.2. Coupled drying

Figure 2 shows the evolution of the reduced water content as a function of time for the various alternating convection / microwave and microwave / convection drying modes. In the early stages of drying, the kinetic rates obtained by convection-microwave coupled drying at different IMR are similar to that of convective drying. After that, the water content decreases rapidly under the effect of microwave radiation compared to the convective drying applied alone.

**Figure 2: Evolution of the reduced water content as a function of the drying time obtained by (a) convection-microwave coupled drying, (b) microwave-convection coupled drying.**

Thus, microwave drying allows removing the weak bonded water more rapidly than convection drying. In the beginning, the kinetic rates obtained by microwave-convection coupled drying at different IMR are similar to that of microwave drying; while at the end of drying, they are comparable to that of convective drying. Microwave radiations permit to reduce the water content of the product more quickly than convective drying. This fact results in a remarkable reduction of the drying time compared to that of convection drying and convection-microwave coupled drying.

#### 3.2.1. Drying for an intermediate mass ratio of 0.5

The evolution of the reduced water content as a function of drying time is shown in Figure 3 for different convection / microwave and microwave / convection coupled drying and at each IMR. It is noted that microwave radiations followed by convective drying (Mo 0.5 Co) reduce the drying time by 3 hours and 13 minutes compared to convective drying (Co). While convective drying followed by microwave radiation (Co 0.5 Mo) allows decreasing the duration by 2 hours and 33 minutes.

Figure 3: Evolution of the reduced water content as a function of time for the convection / microwave and microwave / convection dryings at: (a) IMR of 0.5; (b) IMR of 0.4 and (c) IMR of 0.3

### 3.2.2. Drying for an intermediate mass ratio of 0.4

The coupled drying which starts with microwave radiation (Mo 0.4 Co) lasts 1 hour and 55 minutes, ie a gain of 2 hours and 4 minutes compared to the convective-microwave drying (Co 0.4 Mo) and 3 hours and 25 minutes compared to convective drying applied alone. The convection-microwave coupled drying lasts 3 hours and 59 minutes, thus reducing the drying time of 1 hour and 21 minutes compared to the convective drying.

### 3.2.3. Drying for an intermediate mass ratio of 0.3

The drying duration obtained by microwave-convection drying (Mo 0.3 Co) is 54 min, giving a gain of 4 h 26 min with respect to the convective drying. The convection-microwave drying (Co 0.3 Mo) allows a gain of 1 h 42 min compared to the convective drying (drying time is equal to 3h 38 min). Based on the drying time criterion, which is the most important for the manufacturer, we can opt for microwave-convection drying at this stage. However, the visual appearance of dried tomatoes by convection- microwave mode seems to be better. Therefore, biochemical analyzes were carried out on dried tomatoes.

### 3.3. Determination of quality parameters

#### 3.3.1. Color analysis

Measurement of color by referring to the CIE Lab coordinates ( $L^*$ ,  $a^*$  and  $b^*$ ) shows that luminance ( $L^*$ ) of dried tomatoes is lower than that of fresh tomato (Figure 4). This fact can be explained by the non-enzymatic browning during drying. The values corresponding to the convection-microwave drying with a transition mass ratio of 0.5 and 0.4 are close to that of fresh tomato. Regarding the ( $a^*$ ) index, it is noted that the values obtained after convective-radiative drying of tomatoes at transition ratios of 0.5 and 0.4 are significantly greater than those obtained for fresh tomato. The ( $b^*$ ) values obtained after microwave, microwave-convective drying and convective drying of tomatoes increase significantly with respect to that of fresh tomato.

Figure 4: Effect of drying on the color of tomatoes

#### 3.3.2. Ascorbic acid

The ascorbic acid contents of the dehydrated tomatoes are summarized in Table 1. As a result of the heat treatments undergone by the tomato, the vitamin C content is reduced in comparison with that of fresh product. The convective-microwave dryings, for IMR of 0.5; 0.4 and 0.3, lead to vitamin C loss due to tomato exposure to heated air (65 ° C). After microwave-convective drying, vitamin C loss was greater in dried tomatoes than in other samples. Thus, convective-microwave (Co 0.5 Mb) drying better preserves ascorbic acid in tomatoes.

## 4. Conclusions

Microwave drying eliminates weak bonded water faster than convection drying. This explains the saving in time observed after convection-microwave and microwave-convective drying. Based on the nutritional quality attributes of the tomato, the convection-

microwave combined drying (IMR 0.5) proved most suitable for preserving the quality of tomatoes.

**Table 1: Ascorbic acid contents of tomatoes (mg / 100g DM)**

<b>Drying conditions</b>	<b>Ascorbic acid content</b>
Fresh	384.441 $\pm$ 0.175
Co 0.5 Mo	234.375 $\pm$ 0.022
Mo 0.5 Co	111.877 $\pm$ 0.023
Co 0.4 Mo	136.491 $\pm$ 0.021
Mo 0.4 Co	102.387 $\pm$ 0.011
Co 0.3 Mo	130.293 $\pm$ 0,011
Mo 0.3 Co	97.286 $\pm$ 0.000
Co	109.905 $\pm$ 0.011
Mo	81.394 $\pm$ 0.023

### **Abstract**

*The aim of this work was to study the combination of osmodehydration (OD), coupled with Ohmic Heating (OH) and Pulsed Vacuum (PV) and to introduce natural compounds from a cryoconcentrated pomegranate juice (47°Brix) at 30, 40 and 50 °C into apple matrix, during 180 min. PV was performed at 50 mbar for 5 min at the beginning of the process and OH generates an electric field of 6.6 V/cm. The results indicated that treatments reduced water content and increase polyphenol content of apples, evidencing that the osmotic treatment improve mass transfer, especially when they are applied together at higher temperatures.*

**Keywords:** *Ohmic heating; pulsed vacuum; cryoconcentration; enriched; pomegranate.*

## **1. Introduction**

As consequences in a change of lifestyle and eating habits diseases such as obesity, cardiovascular problems, diabetes type II, hypertension, cancer among others have increased (1). These adverse effects have developed the interest in healthy food and the consumption food functional food (2). Functional foods include bioactive compounds (BAC), which have health benefits as well as their nutritional value. Vitamins, polyphenols, and minerals are found in BAC (2).

Pomegranate (*Punica granatum L.*) has gain interest in the past few years for its nutritional and antioxidant activities (3). Pomegranate juice is a potential source of anthocyanins, flavonoids, organic acids, ellagic acid (4). Therefore, its health benefits are associated with those chemical characteristics. Therefore, its health benefits are associated with those chemical characteristics.

Freeze concentration (also called cryoconcentration) as mention before, is an emerging technology, which consists on entirely or partially freezing the liquid food solution for later separation of the ice fraction from the liquid. Vitamins as polyphenols are thermolabile compounds, by using FC the high nutritional value and organoleptic characteristics can be protected (5).

The ohmic heating (OH) is a thermal process, in which energy is generated by the passage of an alternating electrical current that diffuses through the food (2). The PV has been widely used to obtain a rapid penetration of compounds in vegetable tissues and enriches fruits and vegetables with antioxidants, vitamins, minerals, among others (6).

Osmotic dehydration (OD) is the process in which water is partially removed from the cellular material when it is exposed to a concentrated solution of solutes. The type of osmotic agent used and its molecular weight or ionic behavior affects the kinetics of water elimination and the gain of solids (7), during the OD mass transfer occurs through semipermeable cell membrane making substantial changes in the tissue structure (8).

The aim of this work was to study the combination of osmodehydration (OD), Pulsed Vacuum (PV), Ohmic Heating (OH) and to introduce natural compounds from a concentrated pomegranate juice at 30, 40 and 50 °C into an apple matrix, during 180 minutes.

## **2. Materials and Methods**

### **2.1. Sample preparation**

Pomegranate (cv. Wonderful) and apples (cv. Granny Smith) were acquired in the local market (Chillán, Chile) and stored under refrigeration (5 °C) until processing. The

pomegranates were cut in half and removed the seeds manually for juice extraction and filtered to eliminate any residue.

## 2.2. Osmotic agent

To obtain the osmotic agent, freeze concentrated pomegranate juice, block freeze concentrated as described by (9) with modifications. Samples were frozen -20 °C for 12 h and place in a refrigerated centrifuge (Eppendorf 5430R) operated at 15 °C for 15 min for the first cycle and 10 min for the second and third cycle at a speed of 1878 RCF.

## 2.3. Osmodehydration treatments assisted by pulsed vacuum and ohmic heating.

Osmodehydration (OD) at atmospheric pressure and pulsed vacuum (PVOD) with conventional and ohmic heating (OH) at 30, 40, 50 °C, using a thermoregulated bath as described by (10). The freeze concentrated pomegranate juice was exposed to an alternating current at 60 Hz and 50 V, generating an electric field E of 6.66 V/cm.

## 2.4. Total phenolic content (TPC)

The total phenolic content was determined through a colorimetric method by Folin-Ciocalteu (FC) reagent (11) using gallic acid as standard. Treated samples extracts (100 µL) were mixed with 7900 µL distilled water, 500 µL FC reagent and 1500 µL sodium carbonate. The sample was incubated 120 min before measurement at 760 nm in a spectrophotometer (Shimadzu Scientific 1600 UV/VIS, USA). Results were expressed mg of gallic acid equivalents in 100 g of dry matter (mg GAE/ 100 g d.m.).

## 2.5. Compositional analysis

Soluble solids and moisture content were determined the effect of osmodehydration time over water loss, mass loss, solid gain and water activity ( $a_w$ ). Moisture content was determined according to the method defined by the AOAC, 2000 (12). The solute gain was determined as described by Moreno et al., (2016), the solid content was measured using a digital refractometer (Leica Mark II, Buffalo, NY, USA). The  $X_{ss}$  and  $X_w$  content were determined for both fresh and treated, the compositional changes were calculated through the following equations. Samples water activity ( $a_w$ ) was determined using a dew point hygrometer (Aqua Lab Model 4TE, Pullman, USA). Measurements were executed in triplicate and the mean values are informed.

## 2.6. Physical properties

The firmness of the samples was evaluated with a Texture Analyzer TA-XT (Stable Microsystems, Haslemere, UK), using a slice shear blade the mechanical parameter was considered as maximum peak force and reported as N. Apple slices color, fresh and treated, was measured with a spectrophotometer (Konica Minolta CM-500). The CIE  $L^* a^* b^*$

coordinates used a  $D_{65}$  illuminant and  $10^\circ$  observer as a system reference. The color was measured in triplicate.

### 3. Results and Discussion

#### 3.1 Total phenolic content (TPC)

The phenolic content of the treated apple samples is expressed in mg gallic acid equivalent (GAE) in 100 g of dry matter. As Fig. 1 shows the apples treated with PVOD/OH at  $30^\circ\text{C}$  had higher retention of TPC throughout the processing time (180 min), followed by PVOD/OH  $50^\circ\text{C}$ ; the samples with the lowest phenolic retention were the PVOD  $40^\circ\text{C}$  OD/OH  $50^\circ\text{C}$ .

**Fig. 1 Total phenolic content (TPC) kinetics of osmodehydrated apple using cryoconcentrated pomegranate juice for 180 min. OD: osmotic dehydration at atmospheric pressure, PVOD: osmotic dehydration with vacuum pulsed vacuum, OH: ohmic heating (OD/OH and PVOD/OH) at 6.66 V/cm**

Furthermore, the total phenolic content decreases for all treated samples after 30 min of the process except PVOD/OH  $30^\circ\text{C}$ ; this may be due to the kind of treatment, temperature and time. Also after de processing time most of the treatments retained at least the same amount of TPC as in time 0, except PVOD  $40^\circ\text{C}$ , such finding differs with (10); in which the fresh sample had a significant difference in the TPC compare to the treated.

### 3.2 Compositional changes and water activity

Table 1 shows the compositional changes between the fresh and different treatments of osmodehydration after 180 min of processing. According to previous findings, osmotic dehydration with concentrated juice is more significant compared to osmotic dehydration with sucrose (13). The combination of PVOD/OH 40 and 50 °C, and PVOD 30 °C had the highest solute gain had more significant water loss and solid gain, due to the diffusion and convection forces, both which facilitate the mass transfer process. Application of pulsed vacuum eases the osmotic agent into the matrix pores and facilitates the water loss and has a beneficial effect on the kinetics, reaching equilibrium easily (10). Also, the combination of OD/OH encouraged more substantial concentration levels in samples than OD.

*Table 1. Composition parameters of fresh and processed samples (processing time: 180 min) water mass fraction ( $X_w$ ), soluble solids mass fraction ( $X_{ss}$ ), water loss ( $\Delta M^w_t$ ), solid gain ( $\Delta M^{ss}_t$ ) and water activity ( $a_w$ ).*

Treatments	$X_w$	$X_{ss}$	$\Delta M^w_t$	$\Delta M^{ss}_t$	$a_w$

PVOD/OH 50°C	$0.49 \pm 0.01^{a,b}$	$0.81 \pm 0.01^{d,e}$	$-0.35 \pm 0.01^a$	$0.65 \pm 0.03^d$	$0.87 \pm 0.00^a$

Different letters (a, b, c, ..., g) in each column indicate significant differences at  $p \leq 0.05$ , according to a LSD test.

In this case, the mass transfer in PVOD and PVOD/OH in comparison to the OD is due to the unsteadiness of particles in the juice. Likewise, inadequate dissemination of the components may occur when gradients pressure in the vegetable tissue provoke the irregular flow of the osmotic agent through the structure and consequently accumulate bioactive components in some areas (14); making the mass transfer harder in OD. The most significant water activity reduction was in PVOD/OH 50 °C, followed by OD/OH 50 °C in contrast to the fresh sample. This difference is attributed to temperature, pH, and

electroporation which promote the gain of freeze concentrated pomegranate juice and water loss (15).

### 3.4 Changes in physical properties

Table 2 shows the values obtained for the fresh and treated apple, the hue angle ( $h^*ab$ ), chrome ( $C^*ab$ ) and change in color ( $\Delta E$ ). Previous studies have demonstrated L increases with the osmotic treatments (15). However, samples with the combination of PVOD and PVOD/OH have reduced L, due to the concentration of anthocyanins from the pomegranate juice, this same effect reported by (9) treated sample had lower L than the fresh one. The  $\Delta E$  was higher in the same treatments as the L, this due to the content of anthocyanin pigments present in the cryoconcentrated pomegranate juice. The firmness values acquired from the mechanical test (Table 2). A sample of PVOD 30 °C had the firmness highest value which indicates a higher resistance. Fresh sample differs significantly from the samples treated at 50 °C. Although, values from treatments at 40 °C had no difference with the fresh sample, as well as OD/OH and PVOD at 30 °C.

**Table 2. Firmness and color determination in fresh and treated apples with three temperatures (30 C, 40 C, 50 °C).**

Treatments	Firmness (N)	Color

Different letters (<sup>a...g</sup>) in each column indicate significant differences at  $p \leq 0.05$ , according to a LSD test.

#### 4. Conclusion

The combination of pulsed vacuum and ohmic heating in the osmodehydration of apple slices at 30 °C affected the retention of total phenolic content positively during processing time (180 min). Osmotic dehydration combined with pulsed vacuum and ohmic heating at 50 and 40 °C intensifies the solid gain and water loss due to the diffusion and convection forces which accelerated the mass transfer process. PVOD/OH and OD/OH 50 °C had the most significant water activity mainly cause by the electroporation and temperature. The changes in color were significant in C\*ab (chrome) in L\* (lightness), and values in treated apple slices with PVOD and PVOD/OH due to retention of anthocyanins from the freeze concentrated pomegranate juice. The highest firmness was observed in a sample of PVOD 30 °C. Therefore, our results suggest that PVOD/OH process at 50 °C by 180 min is the optimal treatment for osmodehydrated apples with freeze concentrated pomegranate juice.

### **Abstract**

*The tomato (*Lycopersicon esculentum*), widely consumed fresh fruit but also in processed form, is recognized for its nutritional qualities, rich in micro components, such as carotenoids (lycopene in particular), phenolic compounds and vitamin C.*

*The goal of this work is to valorize the tomato; in the form of paste, seeds, peel and mixture of seeds-peel; in order to obtain a powder rich in antioxidant constituents. Convective drying of the various tomato by-products (paste, seeds, peel and mixture) is an essential process in the valorization of the studied products. The results obtained, showed that our analysed samples are rich in phenolic compounds. The mixture seeds-peel has slightly higher total polyphenol content (190.65 mg EAG / ml), peel (157.36 mg EAG / ml), seeds (140.56 mg EAG / ml) and the paste (120 mg EAG / ml).*

*The evolution of the color of dried by-products (method L, a, b), shows that the mixture (seeds-peel) has a better result of parameter "a" (indicates the red color and signifies the presence of Lycopene).*

**Keywords:** *tomato, drying, antioxidant, polyphenols.*

---

## **1. Introduction**

Tomatoes are a major source of lycopene, which helps in the prevention of many chronic diseases such as cancer and heart diseases [1]. They also contain various nutritional (Vitamin A, C, and E), non nutritional (beta-carotene, carotenoid, flavonoids, flavone and total phenolic), minerals, and dietary fiber [2-3].

The very high water content of tomato (approximately 90%) favors its degradation in the fresh state and its physical-chemical's and microbiological deterioration.

According to the Food and Agricultural Organization (FAO), the global production of tomato, in 2016, exceeds 177 million tons of which 1280570 tons were produced in Algeria.

The aim of this work is to valorize the tomato; in the form of paste, seeds, peel and mixture of seeds-peel; in order to obtain a powder rich in antioxidant constituents.

## **2. Materials and methods**

### **2.1. Drying experiments**

Drying experiments were performed on tunnel dryer (Fig.1) installed in the mechanical engineering laboratory, Ouargla University, Algeria. The dryer is a forced convection dryer intended for the drying of food products. Four removable stainless steel plates that can be placed in a channel (drying chamber) of dimension (250 cm x 50 cm x 50c m). The drying chamber is thermally insulated with polystyrene (thickness = 3cm), the outer part of which is covered by four galvanized sheets. The drying of the different samples of tomatoes is carried out on a tray (surface of 620 cm<sup>2</sup>) and exposed to air flow, serves on the one hand to heat the product to be dried, and on the other hand, to evacuate the quantity of releasing moisture. The mass loss of product is controlled by a digital scale. The temperature and relative humidity of the air are detected by a combined temperature and humidity sensor. An additional sensor serves to measure the velocity of the air flow.

The air coming from the external environment is preheated by an electrical resistance. Under the effect of a fan with adjustable speed, drying air circulates in the drying chamber, passes through the product at a constant drying temperature and comes out at a lower temperature and high humidity.

### **2.2. Sample preparation**

Fresh local tomatoes were bought from local market in Ouargla, Algeria. They were separated using a visual criterion like color, size, absence of physical damage and uniform maturation degree. The samples of different by-products were prepared according to the following steps : Fresh tomatoes were washed with water to eliminate dust, bacteria, dirt and insect larvae. Tomatoes were crushed using a Star Mix blender. The by-products: paste,

seeds, peel and mixtures of seeds and peel were separated using a sieve (2 mm thickness) and dropped in a permeable bag for a few hours.

*Fig. 1. Drying system*

### **2.3. Moisture measurements**

Water content of different samples was determined using a moisture Analyzer (Sartorius MA 45, accuracy  $\pm 0.01$ ), operating in the following conditions:

Sample weight (3g); temperature analysis (105 °C). The device stops automatically once the weight of the sample becomes constant. Moisture content is expressed on a dry basis, kg water/kg dry matter.

### **2.4. Total polyphenols analyses**

Total phenolic content of the samples was measured by the spectrophotometric method [4]. 5 g of the powder of each by-product is macerated in 100 ml of a hydroalcoholic mixture MeOH (methanol-water) (80/20 : v/v) for 48 hours at room temperature, after the methanol is evaporated by rotavapor at 65 °C and the mixture is filtered by wattman paper to obtain a crude hydroalcoholic extract, finally the phenolic extract is kept at 6 °C until it is used. For the determination of total polyphenol, we introduce in a test tube 0.2 ml of extract of each by-product of tomato (prepared in distilled water with suitable dilutions), 1 ml of Folin-

Cicalteu reagent (10 times diluted) and 0.8 ml of the solution  $\text{Na}_2\text{CO}_3$  at 7.5 % (7.5 g in 100 ml). The mixture is incubated at ambient temperature for two hours. The reading is performed against a blank without extract using a spectrophotometer at 765 Nanometer (nm).

## 2.5. Antioxidant activity

The evaluation of the antioxidant activity is based on the reduction reaction of ( $\text{Fe}^{+3}$ ) present in the potassium ferrocyanide complex in ( $\text{Fe}^{+2}$ ), the reaction is revealed by the yellow-colored transfer of ferric iron ( $\text{Fe}^{+3}$ ) in green blue color of ferrous iron ( $\text{Fe}^{+2}$ ), the intensity of this coloration is measured by spectrophotometer at 700 nm. The experimental protocol [5] used is that of 0.5 ml of sample of our extract at different concentrations is mixed with 1.25 ml of a 0.2M phosphate buffer solution (pH 6.6) and 1.25 ml of a solution of potassium ferricyanide  $\text{K}_3\text{Fe}(\text{CN})_6$  at 1% (1 g of  $\text{K}_3\text{Fe}(\text{CN})_6$  in 100 ml of distilled water). Incubation of the prepared mixture in a water bath at 50 ° C for 20 minutes then the mixture is cooled. 2.5 ml of 10 % trichloroacetic acid is added to stop the reaction. 1.25 ml of the supernatant is added to 1.25 ml of distilled water and 0.25 ml of a freshly prepared solution of 0.1% ferric chloride. The reading is against a white at 700 nm.

## 2.6. Color measurements

The color of fresh and dried by-products was measured using a Minolta CR-400 colorimeter [6] allowing the acquisition of the Hunter  $L$ ,  $a$ ,  $b$  color scale values.  $L$  is lightness/darkness parameter,  $a$  the redness/greenness one and  $b$  the yellowness/blueness one. Where  $L_0$ ,  $a_0$  and  $b_0$  refer to the color values for the fresh by-products of tomato.

## 3. Results and discussion

Fig. 2 illustrates the amount of total phenolics (TP) in various by-products of tomato. Our results showed that all the by-products of tomato are a good source of TP compounds.

The peel powder contained the highest level of TP compared to the powders of seeds and paste. The amounts of TP in peel powder increase 16,8 % and 20,56 % respectively to the seeds and paste powders. These results of this study are in accordance with Ramandeep et al. [7], who reported that the highest levels of total phenolics were detected in the peel of three tomato cultivars (Excell, Tradiro and Flavourine). In addition, this study has also identified the by-product of peel tomato as an important reservoir of TP compounds.

Fig. 2 shows also that the mixture (consisting of peel and seeds of tomatoes) powder contained the highest levels of TP compared to those of peel, seeds, and paste, powders.

This result shows that the mixture powder (peel and seed) is an important contributor to the major antioxidants of tomatoes. Therefore, removal of tomato peel and seeds during their fresh consumption or home cooking present a significant loss of the antioxidants. Similarly,

the discard of tomato slurry (consisting of peel and seeds of tomatoes) during tomato processing industry means a loss of antioxidants.

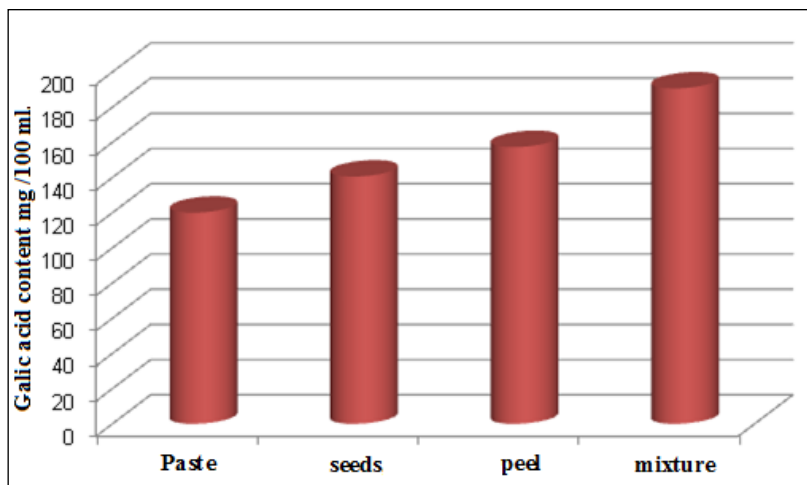

Fig. 2. Total polyphenol content of different by-products of tomato

The presence of the reductants in the extracts causes the reduction of iron  $\text{Fe}^{3+}$  ferricyanide complex to the ferrous form. Therefore,  $\text{Fe}^{2+}$  can be evaluated by measuring and monitoring the increase in green, blue colour density in the reaction medium at 700 NM. In other words, the  $\text{FeCl}_3 / \text{K}_3\text{Fe}(\text{CN})_6$  system confers on the method, the sensitivity for the determination of the polyphenol concentrations, which participate in the redox reaction [8]. According to the ascorbic acid curve, the reducing power of the four extracts is measured according to their absorbance.

The values presented in Figure 3 show the reducing power of the four extracts at different concentrations. From our results of the four extracts tested, an increase in iron reduction (increase in absorbance) is proportional to the concentrations used.

All our extracts have significantly lower antioxidant activity than that of the reference (ascorbic acid), for the latter the reduction is almost total from a concentration of 0.5 mg / ml. The extracts of the mixture powder (seeds and peel) is more active compared to the powders of the peel, the seeds, and the paste. The reducing power of the four extracts is due to the presence of lycopene and hydroxyl group in the phenolic compounds that can serve as electron donors. Therefore, antioxidants can be considered as reducing and inactivating oxidants.

Fig. 3. Reducing power of the four extracts and ascorbic acid.

Figure 4 demonstrates the evolution of the coordinates (L, a, b) for the four by-products. It should be noted that the mean value of the a parameter ; indicates the red color and signifies the presence of Lycopene; in the mixture (S-P) was 40. Rosa et al [9]. reported that the increase of a parameter is directly associated with lycopene synthesis and a significant correlation was observed between lycopene and a. Marcos et al. [10] also, have found highly significant and exponential correlations between lycopene and a parameter. Based on the literature previously cited, it should be conclude that the lycopene content in the mixture (S-P) presents a better result compared to the other by-products.

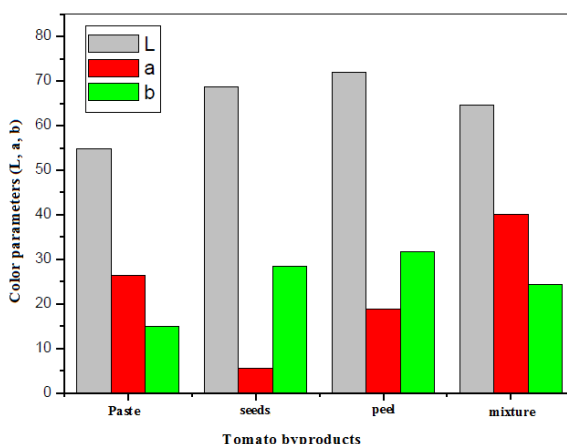

Fig. 4. Evolution of coordinates (L, a, b) for the four by-products

## 4. Conclusion

The valorization of the tomato; in the form of paste, seeds, peel and mixture of seeds and peel; to obtaining a powder rich in antioxidant constituents have been studied.

The convective drying of the various tomato by-products presents an indispensable step for the valorization of the tomato in powder form.

The results obtained showed that our analyzed samples are rich in phenolic compounds, whose mixture of seeds and peel has a slightly higher total polyphenol content (190.65 mg EAG / 100ml) compared to that of peel, seeds and paste which have 157.36, 140.56 and 120 mg EAG / 100ml respectively. This result confirms their high antioxidant potency which was proportional to different concentrations. This result has been confirmed by the color analyzes and the antioxidant

### **Abstract**

*Solar ovens have become a very popular technology for cooking, specially, in underdeveloped countries where access to firewood is scarce, time consuming and expensive. The benefits of solar cooking are multiple, such as saving money, as this device requires no fuel, as well as having an important impact in the environment, decreasing carbon dioxide emissions and decreasing deforestation.*

*One challenge for food industry is to get to know the behaviour of food cooked with solar technology. The aim of this study was to model the drying process of white and red grape in solar oven using thermodynamics and spectrophotometry measurements, controlling the irradiation effect blocking the Ultraviolet radiation using a polarized vinyl film*

**Keywords:** sun radiation; thermodynamics; solar oven; drying.

---

## **1. Introduction**

Grape is the second most widely cultivated fruit in the world after the orange and it is of great commercial interest [1]. It contains large amounts of phytochemicals including phenolics, flavonoids, anthocyanins and resveratrol, which offer health benefits. Antioxidant compounds include vitamins, phenols, carotenoids, and flavonoids. Among the last group, flavones, isoflavones, flavanones, flavonols, anthocyanins and catechins are the most important, and exhibit substantial antioxidant activity [2]. The high content of grapes in phenolics, flavonoids, and anthocyanins have been suggested to be responsible for their health benefits [3] and these benefits have been well described [4].

Other benefits, as described by Meng et al (2017) [5] such as Melatonin, which was recently reported to be present in wine in 2008, as well as resveratrol and hydroxytyrosol, are regarded as bioactive compounds in grapes and wines and have positive effects for human health.

Regarding the drying of this fruit, it is a slow and energy intensive process because the waxy peel has low permeability to moisture [6]. Nevertheless, Peinado et al. (2013) [7] reported that Pedro Ximenez grapes, exposed to sunlight, presented a higher antioxidant capacity than fresh grapes. Thus it is reasonable to infer that both UV radiation and temperature bring about changes in the phenolic profile when fresh grapes are processed into raisins by sun drying.

Drying is one of the most commonly followed methods of preservation for fruits, vegetables and fruit products [8]. Natural sun drying of fruits is still practiced largely unchanged from ancient times in many tropical and subtropical countries. This method is the cheapest and is successfully employed in grapes producing countries. In many of these countries, more than 80% of food is being produced by small farmers in developing countries. These farmers dry food products by natural sun drying, an advantage being that solar energy is available free of cost, but there are several disadvantages which are responsible for degradation and poor quality of the end product [9].

In many rural locations in Africa and most developing countries, grid-connected electricity and supplies of other non-renewable sources of energy are either unavailable, unreliable or, for many farmers, too expensive. Thus, in such areas, crop drying systems that employ motorised fans and/or electrical heating are inappropriate. The large initial and running costs of fossil fuel powered dryers present such barriers that they are rarely adopted by small scale farmers. The traditional open sun drying utilised widely by rural farmers has inherent limitations: high crop losses ensue from inadequate drying, fungal attacks, insects, birds and rodents encroachment, unexpected down pour of rain and other weathering effects. In such conditions, solar-energy crop dryers appear increasingly to be attractive as commercial propositions [10].

In pursuit of achieving the Sustainable Development Goals (SDGs) – and previously the Millennium Development Goals – introducing clean cooking technologies remains a popular option for development actors. One such technology is the solar cooker (SC), a device that makes direct use of sunlight to cook food or pasteurize drinks. While there are multiple designs, the general principle is that these devices channel and concentrate sunlight through mirrors, which is then converted to heat and used for cooking [11].

Thermodynamically, multiple studies were carried out by this research group regarding structural changes of meat as consequence of drying process. The infrared thermography (IRT) has shown to be a valuable tool to carry out studies regarding the infrared spectrum, as it is a non-contact and non-destructive method that provides temperature information of the whole body and not only one point [12, 13, 14].

The aim of this study was to model the drying process of white and red grape in solar oven using thermodynamics and spectrophotometry measurements, controlling the irradiation effect by blocking the Ultraviolet radiation using a polarized vinyl film.

## 2. Materials and Methods

### 2.1. Materials

Experiments were carried out using two different types of grapes (*Vitis vinifera*): red table grape “Red Globe” and white table grape “Regal”. Both types of grapes were bought at local commerce in Valencia, Spain, and selected according to their homogeneity in size and color. They were stored at 8°C until usage in sample cups, sealed with Parafilm® in order to avoid water losses.

### 2.2. Physicochemical Determinations

Mass was determined by using a Mettler Toledo Balance ( $\pm 0.0001$ ) (Mettler-Toledo, Inc., USA).

The water activity ( $a_w$ ) was determined by a dew point Hygrometer Decagon (Aqualab®, series 3 TE, Decagon Devices, Pullman, WA, USA), with precision  $\pm 0,003$ . Moisture was determined by drying in a vacuum oven at 60 °C until constant weight was reached (AOAC Method 934.06, 2000). Soluble solids content of the pulp liquid phase was determined by the refractometric index (°Brix) with a refractometer calibrated with distilled water at 25 °C (ABBE, ATAGO Model 3-T, Japan).

### 2.3 Drying process

A solar oven (model Suntaste Compact, SunOK, Portugal) of 52x43x32 cm was used for the drying. Samples were placed in the described order in the middle of the oven, close to the door, in order to favor its drying. The door of the oven was not fully closed, leaving a 10 cm space at the upper surface to enable drying and images from an infrared camera Optris PI®

160 thermal imager (Optris GmbH, Berlin, Germany). This setup was located approximately at 20 cm of the sample surface and at an angle of 45° relative to the plane in which the samples were placed. The camera was connected to a computer to record. A certified emissivity label of 25 mm diameter ( $\epsilon = 0.95$ ) (Optris GmbH, Berlin, Germany) was used as a reference emitter to calculate the reflected energy received by the infrared camera.

Temperatures during drying were controlled by 5 K-thermocouples and 2 radiofrequency sensors connected to an Agilent multiplexer 34972A data acquisition system (Agilent Technologies, Malaysia) and registered by Agilent.

At the same time as the drying started and the registering of temperatures, radiofrequency and infrared images were recorded, manual analysis were carried out every fifteen minutes: the air velocity was measured inside the oven and outside with a digital anemometer (Proster® RoHS, Model PST-TL090 series, wind accuracy  $\pm 5\%$  China). Air humidity was also registered in and out with a humidity meter (TRACKlife, RoHS, Model HM01, accuracy  $\pm 3\%$  RH at 25 °C, 20%-80% RH,  $\pm 3.5\%$  RH at other ranges, China) and thirdly, day light intensity and in the solar oven was registered with a digital luxometer (D-LUXmeter, RoHS, accuracy  $\pm 4\%$ , resolution 0.1 lx, range 0,1-200,000 lx, resolution 0,1 lx, China).

Procedure difference was that on one of the days, a window vinyl film with control heat and 96% UV rays blockage was placed over the solar oven's glass (Rabbitgoo®, A023-45B, China) and on the other day the oven's glass had no vinyl. The vinyl is PVC electrostatic film plus a back with PET release film.

## **2.4 Solar Oven**

The solar oven (SunTaste, SunOk©, Portugal) is made out of cork agglomerate with water based varnish to diminish UV effects. It also contains aluminium and an ultra-clear glass cover of 4mm thickness with a UV transmittance ( $T_{uv}$ ) of 84.5%.

A solar box cooker basically consists of an insulated box with a transparent glass cover and reflective surfaces to direct sunlight into the box. The inner part of the box is painted black in order to maximize the sunlight absorption.

## **2.5 Infrared measurements**

Thermal images were acquired using the Optris PI® 160 thermal imager (Optris GmbH, Berlin, Germany). It uses a two-dimensional Focal Plane array with 160 x 120 pixels, a spectral range of 7.5-13  $\mu\text{m}$ , resolution of 0.05 °C and an accuracy of  $\pm 2\%$ . The camera covers a temperature range of -20 to 100 °C. It has a field view of 23° x 17° with a minimal focus distance of 0.02 m. The camera is supported by the software Optris PI Connect (Optris GmbH, Berlin, Germany).

### 3. Results and discussion

The heating process of the red and white grape surface was produced by a combined effect of absorption of photon energy in the solar spectrum and by convection heat transmission with the air inside the solar oven. Figure 1 shows a sequence of treatment monitored by IRT, where it is possible to observe how the samples are heated by IRT (thermal infrared).

**Figure 1. Sequence of grapes heating analyzed by IRT, for treatment with whole thermal infrared and for same range without the ultraviolet range.**

Figure 2a and b show the surface temperature of the samples and of the air temperature with respect to the treatment time, where it is possible to observe how the temperature of the samples is always above that of the air. This behaviour occurs in both treatments, with ultraviolet spectrum and without this section of the spectrum. However, analyzing the internal and external measurements of light intensity in figure 2c and d, it is possible to observe how the effect of the solar oven mirrors cause an increase of the internal intensity in the treatment that include the ultraviolet range but this does not occur in the other treatment, when the ultraviolet spectrum is blocked.

Applying an energy balance on the surface of the samples, it is possible to calculate the amount of thermal energy accumulated as the addition of the heats received by radiation and by convection, see equation 1.

$$\frac{dE}{dt} = q_{rad} + q_{conv} \quad (\text{eq. 1})$$

Only the internal energy will accumulate because most of the sun spectrum that receives the surface is the thermal spectrum (IR, VIS and UV), with small radiation at lower frequencies (RF and MW) and nil at higher frequencies. Therefore, it is possible to estimate the temperature increasement by time measured by TIR, mass of sample and specific heat estimated by Chen model.

$$\frac{dE}{dt} = \frac{dU}{dt} = MC_p \frac{dT}{dt} \quad (\text{eq. 2})$$

For a natural convection (measuring the air velocity and relative humidity) it is possible to calculate the individual heat coefficient, and with the temperature difference between the surface and the air it is possible to estimate the heat loss to the environment.

$$q_{conv} = h (T_s - T_{amb}) \quad (\text{eq. 3})$$

**Figure 2.** a) and b) represents the air temperature (●), red grape surface temperature (●) and white grape surface temperature (●), and c) and d) the light intensity express in lm/m<sup>2</sup> for external (●) to the solar oven and internal (●). Where a) and c) represents treatment with whole thermal range radiation and b) and d) for same range radiation without the ultraviolet spectra.

Figure 3 shows the accumulation energy in the samples, the heat losses to the air and the heat gain by radiation, where it is possible to observe how the infrared and visible range are the most important for the warming because differences are not appreciated between both treatments.

Finally, the results of the drying process are shown in table 1, where it is possible to observe how dehydration occurs in the high moisture isotherm section, where small variations of water activity (in this case not significant) represent high variations in moisture (in this case very significant) producing a 20% of weight loss in all samples. However, there are no differences between treatments with or without ultraviolet spectrum.

Figure 3. represents the energies (kJ/s) explained on equation 1 applied in white grape; where (●), represents the convection heat (eq. 3); (●) represents the accumulated internal energy (eq. 2) and (●) represents the radiation heat. a) represents treatment with whole thermal range radiation and b) for same range radiation without the ultraviolet spectra.

Table 1. Initial and final physical and compositional values of samples in both treatments.

		initial			final			
		xw (kg <sub>w</sub> /kg <sub>T</sub> )	zs (°Brix)	a <sub>w</sub>	xw (kg <sub>w</sub> /kg <sub>T</sub> )	zs (°Brix)	a <sub>w</sub>	ΔM (kg/kg)
thermal range	Red grape	0,870 ± 0,002	9,70 ± 0,14	0,984 ± 0,002	0,83 ± 0,05	11,7 ± 1,1	0,980 ± 0,005	-0,20 ± 0,08
	White grape	0,807 ± 0,002	16,80 ± 0,15	0,977 ± 0,003	0,76 ± 0,02	21 ± 2	0,971 ± 0,004	-0,20 ± 0,08
non-UV range	Red grape	0,870 ± 0,002	9,70 ± 0,14	0,984 ± 0,002	0,85 ± 0,02	11,9 ± 0,7	0,9849 ± 0,0010	-0,21 ± 0,05
	White grape	0,807 ± 0,002	16,8 ± 0,15	0,977 ± 0,003	0,785 ± 0,009	20,4 ± 0,8	0,9741 ± 0,0006	-0,20 ± 0,03

#### 4. Conclusions

It has been shown that it is possible to remove the irradiating solar spectrum or ultraviolet range, which generates food oxidation, with no decrease of the heating capacity or dehydration of a solar oven.

### **Abstract**

*This study aims to investigate the complex microstructural changes in plant-based food materials during drying by using X-ray micro-computed tomography (X-ray  $\mu$ CT) along with the image analysis. The apple samples were dried at 60 °C and tested using X-ray  $\mu$ CT at different stages of drying. The porosity, cell and pore size distribution were determined from the micro-CT data set. It was observed that significant changes in porosity, cell and pore size distribution take place at different drying times and moisture contents. X-ray  $\mu$ CT can serve as a very promising tool to elucidate the evolution of the food microstructure during the drying process.*

**Keywords:** Food drying, characteristics, X-ray microtomography, nondestructive evaluation.

## **1. Introduction**

Drying of fruits and vegetables is a complex process as their structures are heterogeneous and changes in microstructures significantly affect the drying process<sup>1-3</sup>. Plant-based food material consists of cells and intercellular spaces. The major component of plant-based food materials is the water which is distributed in the cells and intercellular spaces<sup>4-5</sup>. Therefore, it is crucial to understand the evolution of microstructural characteristics to make an accurate prediction of energy requirement and the physical quality during drying of plant-based food material.

There are several methods such as Scanning electron microscope, light microscope, X-ray microtomography reported in the literature for the investigation of cellular structure in the fresh food sample<sup>6-7</sup>. However, very limited research has been conducted to investigate the evolution of the microstructural characteristics during drying of food material. The researchers have anticipated the cell breakdown under certain drying condition<sup>8-9</sup>. Cell collapse depends on internal thermal stress that first develops near the surface and gradually penetrates to the center of the sample during convective drying<sup>8</sup>. In other words, entire food sample does not reach breakdown temperature at a time. Therefore, it is critical to investigate the evolution of the cellular level structure during the drying process.

The proper microstructural information regarding the changes of cellular structure and porosity of the plant-based food is required to improve the physical quality of the dried food<sup>10</sup>. Most of the microstructural investigation techniques used by the researchers are destructive and invasive<sup>11-13</sup>. Therefore, these methods are not suitable for the structural characterization of the plant-based food material during drying<sup>14-15</sup>. The limitations of the destructive and the invasive methods justify the importance of high resolution non-destructive and non-invasive methods. There is a major gap in the literature regarding the application of the non-invasive method to investigate the micro level structural changes during drying of food material<sup>14</sup>. Hence, the evolution of microstructural characteristics during the drying process is still not clear to the food engineers. To address this research gap, X-ray  $\mu$ CT can be a very useful technique to elucidate the cellular level structural changes during food drying<sup>16</sup>. Therefore, the main aim of this work is to experimentally investigate the change in microstructural characteristics (Cells and pore size distributions) during drying of apple tissue.

## **2. Materials and Methods**

### **2.1 Sample preparation and the drying experiment**

Drying was carried out in a laboratory-scale temperature-controlled convective dryer. Granny Smith apple was taken as a sample for this experiment. The fresh apples were collected from the local market and stored in a refrigerator at 4°C to keep them fresh before the drying

experiment. Prior to the drying test, the samples were taken out from the refrigerator and kept at the room temperature for an hour for achieving thermal stability of the sample. The samples were then washed and cut into cylindrical slices of 10 mm thickness and 20 mm diameter. The dryer was started 30 min before of the experiment for allowing the system reaches the steady state condition. The drying experiments were performed at 60°C temperature. For each drying experiment; six samples were taken. During each experiment, air velocity of 0.7 m/s and the relative humidity range between 60-65% were maintained. The moisture content of the sample at the different stage of drying was measured using X-ray microtomographic images. The details of the moisture content measuring technique can be found in author's previous work <sup>14</sup>.

## 2.2 X-ray microtomography

In this study, X-ray  $\mu$ CT was used to investigate the micro level structural changes. X-ray  $\mu$ CT is able to scan the entire sample to obtain micro-level information such as cell and pore size distribution without the need for serial cuts or chemical treatment. Therefore, the same sample can be used at the next stages of the drying process. To observe the micro level morphological changes, the samples were taken out from the dryer tray after every 30 min during drying. Before placing into the X-ray  $\mu$ CT, the samples were kept in a desiccator to avoid the natural rehydration to the ambient condition of the laboratory. The apple samples were scanned using a Scanco-40  $\mu$ CT high-resolution desktop  $\mu$ -CT system which consists of a resolution of 6  $\mu$ m. The scanning was operated at 55KV, and the images were taken through 0°-180° of rotation. The process is controlled by a built-in a software package which uses the back-projection algorithm. After the scanning, the samples were placed back into the dryer, and the scanning images were collected for the further investigations.

## 2.3 Image processing and data analysis

The grayscale images obtained from the X-ray  $\mu$ CT was transferred to MATLAB image processing environment for further processing. The image processing involved the noise elimination and segmentation. The noise elimination was performed by the intensity thresholding and the filtering process. Segmentation was performed after the noise elimination process to characterize solid materials in the microscopic images. For this purpose, Watershed algorithm was used. The area of the cells and intercellular spaces are obtained from the pixel of the X-ray tomographic images of the food material. At the different stages of drying the images were collected and the area was calculated. The change of shrinkage was estimated from the area ratio (AR) by the following relationship

$$AR = \frac{A_x}{A_0} \quad (1)$$

where,  $A_x$  is the area of the cell/intercellular space at a different stage of drying,  $A_0$  is the area of cell/intercellular space of fresh sample.

The porosity of the samples at different stages of drying was determined from the X-ray  $\mu$ CT data. The porosity was calculated by the following relationship<sup>17</sup>:

$$\text{Porosity} = \frac{V_{Int}}{V_T} \quad (2)$$

where,  $V_{Int}$  is the total volume of the intercellular space and  $V_T$  is the total volume of the sample.

The area distribution of cell and intercellular space in tissue was estimated by probability density function as given below<sup>18</sup>

$$\Pr(a \leq x \leq b) = \int_a^b f(x)dx \quad (3)$$

where,  $x$  is the variable denotes the area of the cell or intercellular spaces.

### 3. Result and discussion

The structural change of food material is the result of collapse and shrinkage of the cells and cell walls during the drying period when significant loss of water takes place<sup>19-20</sup>. There is a significant difference between collapse and shrinkage. Collapse takes place when cellular or tissue level structure breaks down irreversibly; whereas shrinkage refers to a reversible reduction in the size of food material. The shrinkage of the apple tissue was measured from the tomographic image analysis. The tomographic image of the fresh apple and dried apple is presented in Figure 1. In this figure, the high-intensity region of the image represents the cellular area while the low-intensity region of the image represents the intercellular space area. The fresh tissue the cells are intact and filled with water. In the dried tissue, the cellular area shrinks due to the moisture loss. It is interesting to observe that the overall shrinkage of the sample is arbitrary. This kind of shrinkage is known as anisotropic shrinkage.

The apple tissue has the amorphous structure, and during the drying process, it shows the anisotropic shrinkage. Therefore, it is ideal to estimate the shrinkage of apple tissue in terms of area ratio. The evolution of the areal shrinkage as a function of moisture content at 60°C is presented in Figure 2. It is clear from the figure that the apple tissue experiences 35% shrinkage during the drying process. This kind of shrinkage phenomena is commonly known as large deformation. Several factors are responsible for the shrinkage phenomena including the structural heterogeneity and the drying temperature.

Figure 1. X-ray tomographic image of (a) fresh apple tissue and (b) dried at 60°C temperature

Figure 2. Evolution of areal shrinkage of apple as a function of moisture content during drying at 60°C.

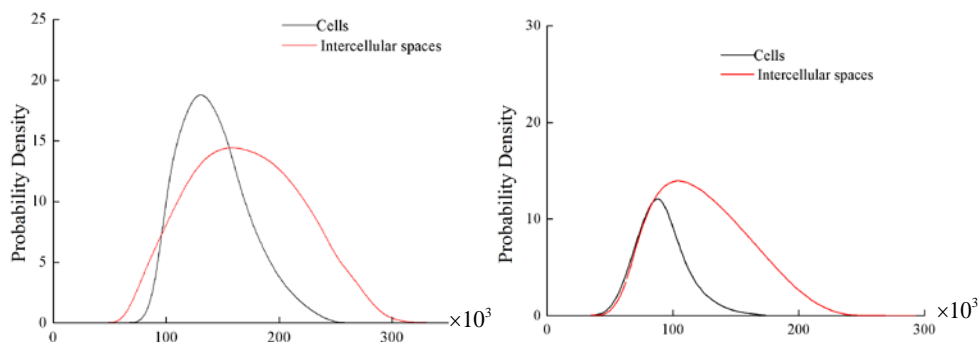

The size of cells and intercellular spaces were obtained from the tomographic image analysis. The size distribution of cells and the intercellular spaces in fresh apple tissue is presented in Figure 3. It can be seen that in fresh sample, the cellular area is distributed in a wide range. It was also observed that the cell size is bigger than the intercellular spaces.

Figure 4 represents the evolution of the area of cells and intercellular spaces during the drying process. After 60 min drying the size of the cellular area is reduced slowly while the area of the intercellular space changes rapidly (Figure 4a). This is because a negative pressure is created inside the cells due to the removal of water during the drying process. The water migration process in this stage is mainly the free water removal. Owing to ongoing moisture migration, the collapse of cells and intercellular spaces is increased at the later stages of drying. After 350 min drying time, it was found that the pore size distribution is greater than the cell size distributions (Figure 4b).

**Figure 3. Areal distribution of cell and intercellular space in fresh apple tissue**

The porosity of the samples was calculated from the images using equation (2). The porosity of the plant-based food materials also shows an interesting relationship with moisture content. Figure 5 shows the changes in porosity of apple sample at 60°C drying temperature against the moisture content. It can be seen that a decreasing trend of porosity has been found just before an inversion starts at moisture ration of 0.7 (Dry basis). This may be due to the shrinkage of initial porosity of apple at the early stage of drying<sup>11</sup>. After that, porosity keeps increasing steadily with moisture content until the end of the drying.

**Figure 4. Areal distribution of cell and intercellular space after (a) 60 min, (b) 350 min of drying**

*Figure 5. Evolution of porosity of apple during drying at 60°C*

#### 4. Conclusion

This paper investigates the evolution of microstructural characteristics of apple samples as a function of moisture content during drying. The applicability of X-ray microtomography along with the image processing technique in the analysis of cell and intercellular space size distribution in fruits and vegetable during drying is established in this study. This technique is nondestructive and requires minimum effort in sample preparation. It has been found that the cell and the pore size distribution of the food material change significantly over the drying period. The cellular area is larger than the intercellular area in the fresh apple tissue. Nevertheless, towards the end of the drying process, a larger amount of intercellular spaces was observed, which is directly related to the porosity of the apple tissue. The quantitative information of this study will facilitate the future researchers to understand the relationship between the moisture content and the evolution of microstructure during the drying process. The findings of this investigation will help the food engineers to develop and validate accurate food drying model which will lead to the design of an efficient food drying process.

### **Abstract**

*The objective of this study was to evaluate the effect of indirect solar drying (ISD) and conventional (CD) (40, 50, 60 °C) on the concentration of phenolic compounds of strawberry slices, coated with opuntia mucilage (Opuntia ficus indica), and measured with the spectrophotometric method. The indirect solar dryer uses solar-thermal and photovoltaic technology with temperatures between 40 and 60 °C. The concentration of anthocyanins was higher in the ISD than in CD. The strawberry coated with the nopal mucilage has a preservation of phenolic compounds in CD and IDS.*

**Keywords:** *strawberry, solar drying, phenolic compounds.*

## **1. Introduction**

The nutraceutical compounds are active biological substances that can be found in foods as natural compounds, they may provide nutritional and health benefits (Amarante et al, 2001), as well as, the prevention of diseases and improvement of the physiological functions of the organism (Garzon, 2008). Strawberry contains nutraceutical compounds as flavonoids, phenolic compounds, and anthocyanins (Giampieri, Tulipani, Alvarez-Suarez, & Quiles, 2012). The study of conditions and pre-treatments for hot-air drying are necessary to minimize the physical and chemical changes during the process. New quality products, attractive to the consumer due to the nutritional value, can be obtained (Adiletta et al 2016).

A pre-treatment as mucilage coatings lead to increased raw strawberry shelf life and improve effects on color, texture, and sensory quality of the fruit (Del Valle et al, 2003). *Opuntia* genus is widely known for its mucilage production (Saenz et al, 2004). Mucilage, a natural polymer with a great capacity to absorb water, is considered as a potential source of industrial hydrocolloid (León et al, 2010). Mucilage contains L-arabinose, D-galactose, L-rhamnose and D-xylose and galacturonic acid (Sepúlveda et al, 2007).

Drying is the most expensive unit operation due to the energy requirements in the drying chamber, as, heating by gas, electricity, or biomass. However, the price of fuel is the main economic factor that affects drying operations; also; the pollution and the environmental consequences of this process (Babu et al, 2018).

Solar energy is harnessed to improve solar heating systems in drying, using equipment for controlling the air flow and the greenhouse effect (Kamruzzaman et al 2017). Solar drying equipment improves the protection of the product against environmental contaminants (Abhay et al 20017). It also improves the protection of the product against environmental contaminants (Sharma et al, 2009).

The solar dryers can be the direct, indirect and mixed type, with or without forced convection (Ramana, 2009). In the indirect solar dryers, the solar collector for air heating and the drying chamber are separated (Mahesh et al 2016). The air is heated in the collector and solar radiation does not affect the food placed into the drying chamber. The drying is faster compared to open sun drying due to their shape and dimensions (Lingayat et al, 2017). Solar dryers design generally needs air ventilation system guarantees adequate moisture removing from inside them, environmentally friendly concept, seeking energy efficiency and using easily accessible materials (Visavale, 2012).

## **2. Materials and Methods**

The strawberry was obtained from the local market in Morelos, México. The fresh strawberries were washed and disinfected with a colloidal silver solution in the concentration indicated by the supplier. They were subsequently rinsed to remove any

remaining residue. The samples were selected manually, and the sepal and wick eliminating.

### 2.1 Color

The color of raw strawberry was measured during drying according to  $L^* a^* b^*$  values. The parameters  $a^*$  and  $b^*$  were used to calculate the Hue angle according to the following equation:

$$Hue = \text{Tan}^{-1} \left( \frac{b^*}{a^*} \right) \quad [1]$$

### 2.2 Moisture

The determination of moisture content of raw strawberry coated with opuntia mucilage (*Opuntia ficus indica*) was measured during drying using the AOAC 972, 1990 method.

### 2.3 Coating (*Opuntia ficus indica*)

The opuntia mucilage extraction was carried out from cladodes of 6 months, harvested in the month of January. A cladode: water (1:2) ratio was used. Cladodes were cut into slices of 1 x 1 cm. The slices were weighed and placed in a stainless-steel container with distilled water. The heat treatment was carried out for 3 minutes at 80 ° C with constant stirring. The mucilage was separated by decantation method and refrigerated (Lopez-Ortiz et al, 2016).

The coating method used for the present project was by immersing and emerging the strawberry in the nopal mucilage for its subsequent placement in the dryer trays.

### 2.3 Conventional drying

Three temperatures (40, 50 and 60 ° C) were tested with an air velocity of 1 m/s.

### 2.4 Indirect solar drying (ISD)

The experimental indirect solar dryer system (ISD) was previously described in (Castillo-Téllez, Pilatowsky-Figueroa, López-Vidaña, Sarracino-Martínez, & Hernández-Galvez, 2017). The indirect solar dryer consists of a horizontal tunnel of rectangular shape with a constant section of flow with forced convection. Five flat plates solar collector for water heating was used. A radiator type heat exchanger was used for air-water heat transfer. Food samples were placed into the indirect solar dryer. For the air flow was an impulse by a fan connected to five photovoltaic solar panels. Temperature and air velocity were registered using a data acquisition system. The air velocity into the dryer was according to the solar irradiance (Gama, 2007).

Fresh strawberry coated with opuntia mucilage were placed in plastic meshes and introduced in the drying chamber. Fresh strawberry coated with cactus mucilage were placed in plastic meshes and introduced in the drying chamber. The air velocity in this dryer was according to the solar irradiance.

**Fig. 1 Indirect solar dryer type tunnel**

## 2.5 Data acquisition

The solar irradiance was obtained from the meteorological and calorimetric station of the UNAM. The geographical location of the Instituto de Energías Renovables - UNAM, in Temixco, Morelos, (18.85° latitude North and -99.2333° longitude East and an altitude of 1219 m above sea level). The solar dryer was instrumented with thermocouple T type temperature sensors, in different points: entrance and exit of solar collectors for water heating, entrance, and exit of the heat exchanger and along to the interior of the tunnel type-drying chamber. Temperature reading time intervals every 30 s. The water flow for heat exchanger was controlled at 10 L/s. The air velocity was measured and recorded with an anemometer at the entrance of the drying chamber.

## 2.6 Determination of anthocyanin

The pH-differential method was used to determine the total anthocyanin content (AC) according to the methodology reported by Giusti and Wroldstad (1996), using two buffer systems: potassium chloride buffer (0.025 M, pH = 1.0) and sodium acetate buffer (0.04 M, pH = 4). The content of anthocyanins was calculated as equivalents of Pelargonidin-3-glucoside (molecular weight (MW) = 449.2 g/mol, molar extinction coefficient ( $\epsilon$ ) = 26,900 L/mol/cm), the dilution factor (FD) of 0, was taken as the value of  $A_{\text{vismax}515}$  and  $A_{700\text{nm}}$  for the sample of the two pH. Quartz cells of 1 cm light passage.

$$A = (A_{\text{vismax}} - A_{700\text{nm}})_{\text{pH}1} - (A_{\text{vismax}} - A_{700\text{nm}})_{\text{pH}4.5} \quad [1]$$

$$\text{AC (mg/L)} = (A \times \text{MW} \times \text{FD} \times 1000) / (\epsilon \times 1) \quad [2]$$

## 3 Results and discussion

### 3.1 Color

The strawberry dried at 60 °C showed a change in color (darkening). The changes in strawberry coloring are due to different enzymes or chemicals, the degradation of the precursor's compound of the red pigmentation in the strawberry is labile to the prolonged

exposure of temperatures. During drying chemical reactions are slowed down as water activity decreases.

Fig. 2 Kinetics of color

Fig. 3 Kinetic of moisture

### 3.2 Kinetic of drying

Drying time for 50, 60 °C and ISD were 5 hours, while at 40° C drying time was 7 hours. The coating does not affect the moisture transfer during the drying process (Lopez-Ortiz et al, 2016). During the first 180 minutes, it had major mass transfer during drying which includes the water transfer from inside of the strawberry to the surface and the water removal from the surface to the environment. Figure 3 shows two drying periods; in the first period, the conditions of the surface of the food reaches an equilibrium with the hot air conditions. The drying kinetics at 60 ° C shows a greater decrease in moisture content in the food reaching values of 9.8% wet bases after 300 minutes. Also, in the drying kinetics of the ISD can be observed that the moisture losses were low during the first 120 min due

to the initial drying temperature (30 °C). After 120 min, the drying kinetic was similar to 50°C in the convective dryer. This behavior was due to the increment in the temperature during the solar day. The second period is when the food already loses most of the water there is a decrease in the rate of drying, which makes it difficult to moisture movement as noted from the 180 minutes until reaching 300 minutes, which represents the end of the dehydrated.

### 3.3 Measurements of solar drying

During the ISD process, the water inlet temperature, the inlet temperature of the tunnel-type solar dryer and the outlet temperature were measured, having a maximum of 62.47 ° C water inlet and after the water leakage 58.46 ° C, having a loss in water temperature due the heat transfer to the air, the maximum temperature difference was 15 °C ± 0.05 obtained at 13:30 hrs.

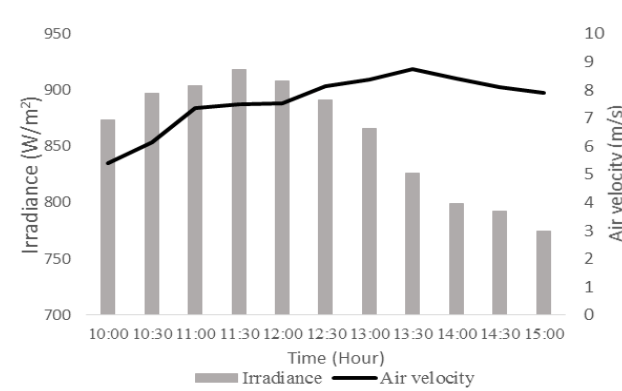

Fig. 4 Irradiance and air velocity during the solar drying process

Fig. 5 Kinetics of anthocyanin content

The initial direct irradiance measured during drying in the solar tunnel-type was 873 W/m<sup>2</sup> at 10:00 am and a final irradiation at the end of the drying of 774.2 W/m<sup>2</sup> at 15:00 pm. The maximum solar irradiance was 918 W/m<sup>2</sup> at 11:30 am, and the average was 858.96 W/m<sup>2</sup>.

### **3.4 Phenolic compound: Anthocyanin**

The anthocyanins were measured by the differential pH method in a double-beam spectrophotometer, of which 1 g of sample was used from its beginning until 60 minutes, after which the amount of sample for analysis had to be reduced to 0.1 g.

The samples were analyzed according to the dehydrated temperature having an initial concentration of  $1.5 \pm .3$  gP3G/g<sub>ds</sub>. For drying at 40 °C, 50 °C and ISD, the concentration of anthocyanin had an increment in until the 120 minutes, after this it had a diminution in its content. The diminution was due the compounds are sensitive to prolonged exposure to temperature, being affected after 150 minutes in the different two temperatures in conventional drier and indirect tunnel-type solar drier. The concentration of anthocyanin was mostly preserved in the tunnel-type solar dryer, considering a final content of 1.07 gP3G/g<sub>ds</sub>, reducing 28.61 % of the initial concentration, unlike the different convection dryer dehydration temperatures (40 -68.92%, 50-42.2%, and 60 °C-71.32%).

## **4. Conclusions**

The coating does not affect the moisture transfer during the drying process. The drying kinetics at 50 °C was similar to drying kinetics in the ISD, besides of the nonconstant conditions in air velocity and temperature. The color in the dehydration at 40 °C in a conventional dryer had a minor darkening of the red color. The drying at 60 °C had a mayor darkening. The concentration of anthocyanin was greater preserved in the tunnel-type solar dryer, considering a final content of 1.07 g gP3G/g of Pelargonidin 3-Glucoside, preserving the compound in 34.70% in relation to the initial concentration.

### Abstract

*The objective of this work is to contribute to the generation of a significant advance of the coconut agroindustry in Colombia, for which the process of spray drying was optimized to obtain coconut powder added with functionally active components (CP+PAC) (calcium and vitamins C, D<sub>3</sub> and E), food that is framed in the context of functional foods. Initially, the behavior of the physicochemical properties of the coconut during storage at a temperature of 25°C was evaluated. Then the base emulsion was designed, determining the influence of the composition of emulsions based on coconut milk, on its physicochemical stability, the answer surface methodology was used with a central composite design, considering the independent variables: water/coconut ratio; xantan gum; coconut fiber; terbutilhidroquinona. Subsequently, it was experimentally optimized according to the operating characteristics of the dryer and the product, using a response surface design based on five independent variables: Maltodextrin, air inlet temperature, air outlet temperature, atomizer disk speed and vacuum pressure in the drying chamber. Finally, the stability of the PC+PAC properties was evaluated, using a factorial design based on the independent variables: storage temperature, storage time and packaging.*

**Keywords:** coconut, colloidal system, deposit formation, yield, vitamins.

---

## 1. Introduction

The coconut is a crop of great importance both economically and subsistence, directly dependent on more than 80 million people in more than 90 countries, in addition to the importance for its nutritional and medicinal values [1]. One of the most used techniques for the production of powders from liquid solutions and suspensions of fruit juices and pulp is spray drying (SD), with powdered food being valuable matrixes in terms of transport, packaging, storage and life useful [2], it is also one of the most effective techniques, which protects, stabilizes, releases the compounds and at the same time allows its solubility in an aqueous medium [3].

The coconut chain is identified as one of the most interesting for the Pacific and Atlantic coasts of Colombia, due to the impact it has on the population, seen from the families that depend on primary production to its commercialization and consumption. For which it is intended to provide the agroindustrial sector, the technological basis for obtaining a variety of dehydrated powders based on coconut and excellent quality attributes, which would represent new alternatives for diversification, in addition to contributing to the reduction of nutritional deficiencies in the population. In this context, this research aims to contribute in the medium to long term to increase the consumption of coconut drinks after reconstitution and to encourage the production of powdered coconut milk (CM) as a raw material for multidominios of the sector of the food industry and national and international markets

The objective of this work is to contribute to the generation of a significant advance of the Colombian agroindustry from the research, which allows the optimization of the process of spray drying (SD) for obtaining coconut powder added with physiologically active components (calcium and vitamins C, D<sub>3</sub> and E) (CP+PAC), food that is part of the context of functional foods.

## 2. Materials and Methods

Cocos (*Cocos nucifera* L.) variety Malayan Dwarf (manila) or Alto Pacifico (typical) from the Colombian Pacific region were used, with a flowering age at harvest of approximately 12 months and a post-harvest time between 15 and 36 days, time in which through preliminary studies was shown to have acceptable quality to be used as raw material for processing. The whole coconuts to be used were initially washed with water and disinfected with a 200 ppm sodium hypochlorite solution, then the coconut water (CW) was removed and blanched for 20 min in boiling water at  $T \approx 96^{\circ}\text{C}$  (local barometric pressure  $\approx 640$  mmHg), subsequently the shell of the coconut pulp (CP) was removed. The selected CP was again subjected to a water washing process and disinfection with hypochlorite, cutting into pieces and grinding (mill TM32 INOX BRAHER 3HP - 16801002).

The characterization of the PC+PAC properties were carried out according to the following methodologies: humidity (%) ( $X_w$ ): official method AOAC 930.15 [4]; Water activity ( $a_w$ ): determined with a dew point hygrometer at  $25^{\circ}\text{C}$  (Aqualab 3TE series, Decagon, Devices,

Pullman, WA, USA) [5]; Solubility (S): method used by Cano-Chauca et al., (2005) modified [6]; Peroxide Index (PI): was performed on the extracted oil, obtained according to the method of Bae and Lee (2008) modified [7], where 4 g of powder was taken. The PI was determined by the spectrophotometric method based on the ability of peroxides to oxidize ferrous ions to ferric ions, which react with various reagents that produce colored complexes [8].

The quantification of vitamins E and D<sub>3</sub> was performed by high performance liquid chromatography (HPLC) (Shimadzu Prominence 20A), using a reverse phase column (C18 - 5  $\mu$ m 4.6 mm x 250 mm), diode array, mobile phase: acetonitrile/methanol/water (45.3/51.2/3.5), flow: 1 mL/min, oven temperature 40°C and wavelengths of 325 and 265 nm, respectively. The quantification of vitamin C was also performed by HPLC, using a column in reverse phase (C18 RP-5  $\mu$ m 4.6 mm x 250 mm), diode array, mobile phase: KH<sub>2</sub>PO<sub>4</sub> 0.02 M pH= 3.00 (Ortho-Phosphoric Acid 85% ), flow: 1 mL/min, furnace temperature of 35°C, wavelength of 244 nm and an injection volume of 5  $\mu$ L. The extraction of vitamin C was carried out according to the methodology adapted by Peña-Correa et al., (2013) [9]; while the extraction of vitamins D<sub>3</sub> and E was carried out according to the methodology proposed by Cortés (2004) modified [10] by inclusion by ultrasound treatment for 20 min to the samples treated with hexane. Calcium quantification was performed by the spectrophotometry method by flame atomic absorption, according to NTC 4807 (2000), supported by ISO 5151 (2003). The CP+PAC fortification criteria were set within the framework of the declaration of nutritional properties established in Resolution 333 of 2011 (Ministry of Social Protection Colombia), for the purpose of declaring the descriptor "Rich in" or "Excellent source of " CFA in a 100 g serving.

The particle sizes were determined as percentiles D<sub>10</sub>, D<sub>50</sub> and D<sub>90</sub>, using the Mastersizer 3000 (Malvern Instrument Ltd., Worcestershire, UK), after dispersing the samples in 500 mL of distilled water until obtaining a darkening value of 10 $\pm$ 1%, considering the size distribution from the theory of Mie and using the refractive index of 1.52 [11]. The color was determined by means of the CIE-La\*b\* coordinates, using an X-Rite spectrophotometer model SP62, illuminant D65, observer of 10° as reference [5]. Additionally, micrographs of the CP+PAC were made using a scanning electron microscope (Jeol 5910LV) at 15 Kv [6], where the samples were deposited on a copper conductive tape and on a sample holder, then they were coated with gold in a vacuum evaporator (Dentom Vacumm, 30 mA, 5 kV, 100 millitorr).

**Preparation of the feed emulsion to the dryer:** Batches of 3000 g of dryer feed emulsion (DFE) were prepared, initially a mixture of CP, CW and drinking water with a ratio ((CW+H<sub>2</sub>O)/CP) was homogenized in an Osterizer 600 Watts blender (position III) for 5 min, then the mixture was filtered on a 500  $\mu$ m mesh screen, separating the fiber from the LC. The fiber was subjected to a drying process at 40°C for 48 hours and then to a dry milling (IKA MF 10.1 mill, USA). The CM was homogenized again in a Silverson series L5

homogenizer using the emulsifying head at 10000 rpm for 10 min, adding the native milled fiber (5-15% w/w) and the rest of the ingredients: milk whey (Instant WPC 80) as surfactant (0.5%), NaCl (9 mMol/L), xanthan gum (0.5-1.0% w/w), terbutylhydroquinone (TBHQ) (100-200 mg/kg) and CFA in the chemical forms of Calcium Citrate powder (6.0 g) (BELL CHEM), Vitamin C (1.0 g) (Ascorbic acid): 99.5% powder, BELL CHEM), Vitamin D<sub>3</sub> (0.5 g) (Colecalciferol): 512900 IU/g powder, BELL CHEM), Vitamin E (1.0 g) (DL- $\alpha$ -Tocopherol Acetate): 50% USP GRADE powder, BELL CHEM). A cooling bath was used during the preparation to control that the temperature of the DFE will not exceed 35°C

**Spray drying process:** A co-current flow pilot spray dryer was used (Vibrasec, model PASLAB 1.5). The evaluation of the spray drying process was carried out using the response surface methodology with a central composite design, considering the independent variables: Maltodextrin (MD) (5-15%), air entry temperature (AET) (150-170°C), air outlet temperature (AOT) (80-90°C), atomizer disk speed (ADS) (24000-28000 rpm) and vacuum pressure in the chamber (VPC) (1.0-1.88 "H<sub>2</sub>O) and the dependent variables: Process performance (R\*) kg solids of the powder obtained/kg solids of the DFE; Deposit formation (DF) kg adhered material/kg DFE; Xw; a<sub>w</sub>; solubility (S); Retention of the PAC (%); Particle size (D<sub>10</sub>, D<sub>50</sub>, D<sub>90</sub>); PI, color (L\*, a\*, b\*).

**Process for assessing the stability of coconut powder during storage:** The product was packed in multicoated bags made by Alico SA, laminated film thickness (PET): 12  $\mu$ m, aluminum foil: 8  $\mu$ m polyethylene sealant layer: 100  $\mu$ m, weight of 136.54 g/m<sup>2</sup>, with water vapor barrier <1 cc/m<sup>2</sup> x 24h x atm) and O<sub>2</sub> <1 cc/m<sup>2</sup> x 24h x atm). The samples were stored in climatic chambers conditioned at a relative humidity of 65%, with the treatments applied: 15-N<sub>2</sub>, 15-Amb, 25-N<sub>2</sub>, 25-Amb, 35-N<sub>2</sub> and 35-Amb, at storage times (tA): 0, 30, 60, 90, 120, 150 and 180 days. The dependent variables evaluated were: Xw, a<sub>w</sub>, S, color (L\*, a\*, b\*), PI, %R-VC, %R-VD<sub>3</sub>, %R-VE, %R-ABTS, %R-DPPH, %R-FT, %R-Ca, particle size (D<sub>10</sub>, D<sub>50</sub>, D<sub>90</sub>) and microstructural analysis.

For both the process of optimization of the emulsion and the drying process, the effect of the independent variables was determined using the multiple regression method for the prediction of the linear, quadratic coefficients and the interaction of the independent variables in the surface models. In response, a polynomial model of order 2 (equation 1) was used:

$$Y = \beta_0 + \beta_A A + \beta_B B + \beta_C C + \beta_D D + \beta_A^2 A^2 + \beta_B^2 B^2 + \beta_C^2 C^2 + \beta_D^2 D^2 + \beta_{AB} AB + \beta_{AC} AC + \beta_{AD} AD + \beta_{BC} BC + \beta_{BD} BD + \beta_{CD} CD \quad (1)$$

Where  $\beta_0$  is a constant,  $\beta_A$ ,  $\beta_B$ ,  $\beta_C$  y  $\beta_D$  is the linear coefficient of each factor;  $\beta_A^2$ ,  $\beta_B^2$ ,  $\beta_C^2$  y  $\beta_D^2$  is the quadratic coefficient of each factor;  $\beta_{AB}$ ,  $\beta_{AC}$ ,  $\beta_{AD}$ ,  $\beta_{BC}$ ,  $\beta_{BD}$  y  $\beta_{CD}$  is the product coefficient of the interactions of the factors. The adequacy of the models was carried out using the lack of fit test and the regression coefficient (R<sup>2</sup>); In addition, the analysis of

variance (ANOVA) was performed with a confidence level of 95%. The matrix of the experimental design, the analysis of the results and the optimization procedure were carried out using the software Statgraphics Centurión XVI.I. From the conditions of optimal operation, three additional experiments were carried out to verify the accuracy of the model with respect to the real response variables, in order to verify the regression models and for stability in the storage a design was applied. with a factorial arrangement of the order  $6^*7$  with two independent variables: treatment and time, where the treatment is defined as the combinations (temperature-packaging) and packaging was carried out in  $N_2$  atmosphere and under environmental conditions.

### 3. Results and discussion

In the 1<sup>st</sup> phase of physicochemical characterization of the raw material (coconut) to identify the ideal conditions and determine the adequate time for its transformation as a raw material, the results showed a general deterioration of the CP and CW after 36 days of storage, mainly due to the increase in acidity, fermented odor, moisture loss ( $X_w$ ), lipid oxidation, softening and discoloration of the CP, among others.

In the 2<sup>nd</sup> phase of design and optimization of the base emulsion, the optimal conditions were: water/coconut ratio ((CW+H<sub>2</sub>O)/CP): 2.0; xanthan gum: 0.5%; Coconut fiber (CF): 5.0%; antioxidant (TBHQ): 200 mg/kg, reaching a potential- $\zeta$ :  $-45.6 \pm 2.5$  mV; viscosity:  $741.7 \pm 25.5$  cP; color ( $L^*$ :  $67.5 \pm 0.7$ ,  $a^*$ :  $3.2 \pm 0.2$  and  $b^*$ :  $8.6 \pm 0.5$ ); Peroxide value (PI):  $0.14 \pm 0.04$  meqH<sub>2</sub>O<sub>2</sub>/kg; particle size ( $D_{10}$ :  $4.3 \pm 0.8$   $\mu$ m,  $D_{50}$ :  $323.7 \pm 43.6$   $\mu$ m and  $D_{90}$ :  $743.0 \pm 65.1$   $\mu$ m) and total solids (TS):  $20.0 \pm 0.3\%$ .

The numerical experimental optimization was carried out in order to obtain optimal values for independent variables, thus determining the desirable response parameters that allow obtaining a final product with the appropriate quality attributes. For this case and according to the statistical results found, the criteria were the following: approximate viscosity of 1000 cP (condition of maximum viscosity allowed by the dryer), higher percentage of TS, higher  $L^*$ , less enzymatic browning and oxidation of the lipids (<IP and <potential  $\zeta$ ). These response variables were significantly influenced by the xanthan gum and %FC, being the variables that tend for a better emulsion behavior, and where the antioxidant becomes a supporting factor that tends to the good performance of the xanthan gum interaction and %FC [12, 13, 14].

In the 3<sup>rd</sup> phase of optimization of the SD process according to the operational characteristics of the dryer and the product, where the results obtained from the dependent variables and the ANOVA performed, were planned taking into account the most important variables of the process, maximizing S,  $L^*$ ,  $R^*$ ,  $D_{90}$  and PAC; minimizing H, Hu, PI and DF, it was also set at an average value of  $X_w$  and  $a_w$ , since its fluctuations were not very large, where the optimal conditions were: air inlet temperature (AIT): 170°C; Air outlet

temperature (AOT): 85.8°C; Atomizer disk speed (ADS): 26.676 rpm; Vacuum pressure in the chamber (VPC): 1.6 "H<sub>2</sub>O; percentage of maltodextrin (%MD): 7.0.

Under these process conditions, the experimental values of the response variables were as follows: humidity: 1.7±0.4%;  $a_w$ : 0.170±0.020; solubility (S): 58.4±2.1%; hygroscopicity (H): 8.4±0.6%; L\*: 79.5±0.9; a\*: 1.5 ± 0.1; b\*: 9.5 ± 0.5; % vitamin C retention (%R-VC): 32.4±6.2; %R-VE: 6.1±1.9; %R-VD<sub>3</sub>: 7.8±1.8; %R-Ca: 41.7±2.9; Wettability (Hu): 263.0±19.8 s; peroxide index (PI): 2.4±1.3 meqH<sub>2</sub>O<sub>2</sub>/kg fat; Deposit formation (DF): 32.4±2.3%; yield (\*R): 44.0±1.0%, and particle size distribution D<sub>10</sub>: 1.7±0.1 µm; D<sub>50</sub>: 8.5±2.1 µm; D<sub>90</sub>: 78.2±24.3 µm; obtaining a product with good quality attributes; Additionally, the proximal composition of PC+PAC was: fat: 30.5±0.9%, protein: 4.1±0.5%, total dietary fiber: 23.9±1.6%, ashes: 2.3±0.0%, highlighting the dietary fiber, which confers benefits on consumer health, in addition to its PAC present [15, 16, 17].

And in the 4<sup>th</sup> phase, it was determined that the best treatment for PC+PAC storage, with respect to all the response variables, was 15°C-N<sub>2</sub>, where the humidity gain and the increase in  $a_w$  were low for this type of products and the percentages of retention of vitamins and antioxidants were the highest, reaching values at 180 days of: X<sub>w</sub>: 2.97±0.09%;  $a_w$ : 0.342±0.009; color: (L\*: 77.96±0.04, a\*: 1.44±0.06 and b\*: 8.59±0.13); S: 51.48±2.30%; IP: 0.225±0.19 meqH<sub>2</sub>O<sub>2</sub>/kg fat; %R-VC: 62.56±5.70; %R-VD<sub>3</sub>: 51.00±0.99; %R-VE: 57.18±3.23; %R-FT: 50.89±4.78; %R-DPPH: 91.88±1.79; %R-ABTS: 42.14±2.18; D<sub>10</sub>: 2.44±0.12 µm; D<sub>50</sub>: 51.49±1.48 µm; D<sub>90</sub>: 153.80±14.0 µm [18, 19] (see figure 1).

Fig. 1. Micrographs of PC+PAC obtained by SA at 100X and 500X.

#### 4. Conclusions

In general, the intermediate levels of the hydrocolloid and fiber added are those that tend for a better emulsion behavior, the ratio ((CW+H<sub>2</sub>O)/CP) although it influences in some

specific cases, it is not very determinant, while the antioxidant becomes in a support factor that tends to the good performance of the hydrocolloid and fiber interaction.

The experimental optimization carried out using statistical tools represents an effective way to define the most appropriate conditions of the SD process, and at the same time represents a significant advance for its subsequent industrial scaling and its potential generation of added value to the coconut agro chain.

According to the behavior of the PC+PAC during the storage this is a hygroscopic product, potentially sensitive to oxidative processes during storage, which could lead to changes in color, flavors or strange odors, so it will require a packing with low permeability to water vapor and O<sub>2</sub>, to minimize these changes.

### **Abstract**

*Proliposomes are dry phospholipid-based particles in which bioactives can be entrapped, and that can produce liposomal suspensions if adequately hydrated. In our study, curcumin and cholecalciferol were incorporated in proliposomes obtained by coating of micronized sucrose. Different mass ratios of Lipoid S40 and Phospholipon 90H were used to produce the proliposomes. The powders were structurally characterized and bioactives content were analyzed over 60 days of storage. Curcumin and cholecalciferol amounts in F100CV formulation were 100 and 98.7% of their initial amount, respectively. Structural characterization showed bioactives were successfully incorporated in concentrations compatible with recommended daily dosages.*

**Keywords:** *proliposomes, curcuminoid, vitamin D<sub>3</sub>, Raman spectroscopy, powder characterization*

## 1. Introduction

Proliposomes are defined as dry, free-flowing powders composed mainly of phospholipids and that can instantly form liposome dispersions upon addition of an aqueous solution under appropriate conditions [1]. Advantages attributed to proliposomes as the convenience for transportation, distribution, and dosing, including the production of capsules/tablets, easier to be industrialized [2].

Curcumin is the major yellow hydrophobic pigment of the rhizomes of *Curcuma longa*. Nowadays, despite its use as food spicy, curcumin has been studied by pharmaceutical and medical researchers because of its antioxidant, anti-inflammatory and anti-carcinogenic actions [3]. However, the main limitation for the application of curcumin in food is its low water solubility and its poor bioavailability [4]. Cholecalciferol (vitamin D<sub>3</sub>) is the naturally occurring form of vitamin D. It plays an important role in regulation of calcium homeostasis and mineralization of bones [5]. Unfortunately, vitamin D<sub>3</sub> carency affects almost 50% of worldwide population due, mostly, to lifestyle habits and environment factors that reduce the exposition to sunlight [6]. Thus, its supplementation is highly necessary as few enriched food are commercially available. However, as curcumin, vitamin D<sub>3</sub> is extremely sensitive to higher temperatures and exposure to light [7]. Hence, encapsulation in lipid delivery system could increase their stability and bioaccessibility [8,9].

In this study, curcumin and cholecalciferol were incorporated in proliposomes obtained by coating of micronized sucrose. The powders were characterized by Raman spectroscopy (RS) and Fourier-transform infrared spectroscopy (FTIR). In addition, proliposomes were analyzed in terms of their morphology, hygroscopicity, solubility, and amount of bioactives retained. Data revealed by this research will help to show the feasibility to produce proliposomes containing both bioactives in concentrations compatible with their recommended daily dosage for further application in food formulations.

## 2. Materials and Methods

### 2.1. Production of proliposomes by coating of micronized sucrose

Proliposomes production was based in the methodology described by Silva et al. (2017) [10]. Different mass percentages of phospholipids were tested: 50% Lipoid S40 + 50% Phospholipon 90H (F50), 70% Lipoid S40 + 30% Phospholipon 90H (F70), and 100% Lipoid S40 (F100).

### 2.2. Spectroscopical characterizatón of the proliposomes

The spectra in the infrared regions were obtained in the 4000-400 cm<sup>-1</sup> region by using a Perkin Elmer FT-IR Spectrometer (Waltham, MA, USA). Raman spectroscopy analyses

were performed with a RAMII (Billerica, MA, USA) in the 4000-400  $\text{cm}^{-1}$  region with Ge detector and a 1064 nm laser.

### 2.3. Morphology of proliposomes by scanning electron microscopy (SEM)

Morphology was studied using a scanning electron microscope (model 3000 TM; Hitachi, Japan) equipped with TM3000 software.

### 2.4. Hygroscopicity and solubility

The proliposomes were characterised in terms of hygroscopicity according to the procedure described by Cai and Corke (2000) [11]. The solubility of the proliposomes was determined according to the method of Eastman & Moore (1984) [12].

### 2.5. Quantification of bioactives in proliposomes

Curcumin quantification was carried out according to Silva et al. (2017) [10]. Concentrations were obtained by absorbance readings at 425 nm in a spectrophotometer (Libra S22; Biochrom, Cambridge, UK). Regarding cholecalciferol retained in proliposomes, these values were obtained by high-performance liquid chromatography (Shmadzu; Kyoto, Japan) according to Staffas and Nyman (2003) [13].

## 3. Results and Discussion

### 3.1. Visual aspect and morphology of proliposomes

The visual aspect of blank and curcumin-cholecalciferol-loaded proliposomes are shown in Figure 1. The powders containing curcumin presented an intense and characteristic yellow color. The formulation prepared with only Lipoid S40 (F100) seemed to be more agglomerated than the produced with Phospholipon 90H. This may be due because Lipoid S40 is a non-hydrogenated phospholipid, with a strong tendency to absorb moisture from the environment.

**Figure 1.** Visual aspects of blank (superior line) and curcumin-cholecalciferol-entrapped (inferior line) proliposomes produced with (A, D) 50% Lipoid S40; (B, E) 70% Lipoid S40; (C, F) 100% Lipoid S40

The coating of micronized sucrose by phospholipids produced flake powders whose morphological characteristics are shown in the scanning electron micrographies illustrated in Fig. 2. In the SEM micrographies, it is possible to distinguish a layer of phospholipid coating the micronized sucrose granules. The coated material presented very irregular and different shapes, with many agglomerates in the visual fields.

**Figure 2.** Micrographies obtained by scanning electronic spectroscopy for the blank (superior line) and curcumin-cholecalciferol-entrapped (inferior line) proliposomes produced with (A, D) 50% Lipoid S40; (B, E) 70% Lipoid S40; (C, F) 100% Lipoid S40. Scale: 2µm. Magnitude: 50x

### 3.2. Fourier-transform infrared spectroscopy (FTIR)

The characteristic absorption peaks for blank and loaded proliposomes obtained by FTIR are shown in Figure 3. No major changes were detected in the spectra of empty and loaded proliposomes. Intense vibration peaks were observed at 2854 and 2920  $\text{cm}^{-1}$  in all spectra. These peaks are related to  $\nu(\text{CH}_2)$ , and the higher their intensity, the more ordered are the acyl chains of the phospholipids. Therefore, as shown in Figs. 3E and 3F, higher amounts of Lipoid S40 in the proliposomes led to a reduction in the peak intensities. Such reduction was mainly due to the high content of unsaturated phospholipids in Lipoid S40, which helps to decrease the acyl chains ordering [10]. On the other hand, asymmetrical stretching mode of a P=O group is identified by a peak in the range 1200-160  $\text{cm}^{-1}$  according to Lewis and McElhane (1996) [14]. In this case, proliposomes showed this peak as the located in the wavenumber near 1043  $\text{cm}^{-1}$ . Popova and Hinch (2003) [15] stated this peak increased its position with hydrogen bonding. Regarding these peaks in Figs 3E and 3F, it can be verified a slight decrease, an indication that part of sucrose interacted with the polar heads of phospholipids, in a behavior that resembles that in which sucrose is used as cryoprotector during the production of lyophilized liposomes [16]. These interactions caused also a decrease in C=O stretching, which was located at 1741  $\text{cm}^{-1}$ . Summarily, it can be stated that part of sucrose interacted with some polar heads of the phospholipids presented in Lipoid S40, hindering the coating process [10].

**Figure 3.** FTIR spectra obtained for formulations F50 (A); F50CV (B); F70 (C); F70CV (D); F100 (E) and F100CV (F).

### 3.3. Raman spectroscopy

Figure 4 shows the FT-Raman spectra obtained for blank and loaded proliposomes. The bands at 1596 and 1632  $\text{cm}^{-1}$ , are attributed to  $\nu(\text{C}=\text{C})$  motions of the inter-ring chain of curcumin and to  $\nu(\text{C}=\text{O})/\nu(\text{C}=\text{C})$  vibrations in the side aromatic rings of both curcumin and cholecalciferol. As can be seen, these peaks appeared only on formulations F50CV and F70CV. Therefore, it can be stated that in formulation F100CV both bioactives remained entrapped in the phospholipid matrix in their amorphous form. Changes in the broadening of the 1596 and 1632  $\text{cm}^{-1}$  bands seen between F50CV and F70CV are due to conformational modifications on the side aromatic rings that can cause a variation of the electronic conjugation degree along the entire molecule [17]. Other Raman peak assignments for curcumin were obtained by Mohan et al. (2012) [18] and appeared in F50CV and F70CV spectras, as it follows: 1125  $\text{cm}^{-1}$  ( $\delta(\text{CCH})$  of aromatic rings and  $\delta(\text{C}-\text{OH})$  of the enolic group coupled to  $\delta(\text{C}=\text{CH})$  in the inter-ring chain), 1241  $\text{cm}^{-1}$  ( $\delta(\text{CH})$  of the aromatic rings, combined to  $\nu(\text{C}-\text{O})$  of the ether groups linked to these rings), 1295  $\text{cm}^{-1}$  ( $\delta(\text{CCH})$  of the inter-ring chain ( $\text{C}^{10}$  and  $\text{C}^{11}$ ), and 1439  $\text{cm}^{-1}$  ( $\delta(\text{CCC})$ ,  $\delta(\text{CCH})$  and  $\delta(\text{C}-\text{OH})$  of aromatic rings). Cholecalciferol peak at 1650  $\text{cm}^{-1}$  was possibly covered by peak at 1655  $\text{cm}^{-1}$  commonly found in polyunsaturated lipids [19]. In addition, the low

concentration of cholecalciferol added in proliposomes may have remained within the surrounding matrix, which explained the absence of its related peak.

Figure 4. FT-Raman spectra obtained for formulations F50 (black); F50CV (red); F70 (blue); F70CV (green); F100 (purple) and F100CV (orange).

### 3.4. Hygroscopicity, solubility and amount of bioactives retained

Physicochemical parameters obtained for proliposomes over 60 days of storage are in Table 1. Higher hygroscopicities were obtained for proliposomes with higher contents of Lipoid S40. These values can be considered low, which is a highly desirable characteristic for powders. The incorporation of the hydrophobic actives in proliposomes did not lead to a decrease in solubility values. This result corroborates what was mentioned before, that both molecules remained entrapped in phospholipid matrix. However, the values obtained were quite lower than those obtained by Silva et al. (2017) [10] which also produced proliposomes containing curcumin by coating of micronized method. Additionally, it is important to mention that Silva et al. (2017) [10] produced proliposomes using only Phospholipon 90H, which contains a higher number of hydrogenated phospholipids, which are easier to be dispersed in aqueous medium.

The amount of bioactives retained in proliposomes after 60 days of storage are presented in Table 1. Considering that curcumin and cholecalciferol are highly sensitive to degradation, the results obtained can be considered promising, as 100% of curcumin and more than 85% of the cholecalciferol initially present in the powder were preserved.

**Table 1. Physicochemical parameters obtained for blank and loaded proliposomes**

	Solubility (%)	Hygroscopicity (%)	Preserved bioactives (after 60 days) (%)	
			Curcumin	Cholecalciferol
F50	36.4 <sup>C</sup> ± 2.02	7.24 <sup>B</sup> ± 0.23	-	-
F50CV	42.4 <sup>B</sup> ± 0.64	5.90 <sup>C</sup> ± 0.23	100 ± 1.18	92.3 ± 3.50
F70	44.5 <sup>A</sup> ± 0.93	6.49 <sup>C</sup> ± 0.31	-	-
F70CV	44.8 <sup>A</sup> ± 1.38	7.50 <sup>BC</sup> ± 1.47	100 ± 0.91	85.1 ± 0.10
F100	37.9 <sup>C</sup> ± 1.36	11.1 <sup>A</sup> ± 2.66	-	-
F100CV	42.5 <sup>AB</sup> ± 1.49	8.62 <sup>AB</sup> ± 1.54	100 ± 1.04	98.7 ± 0.37

#### 4. Conclusions

The experimental data indicate it is possible to produce proliposomes containing curcumin and cholecalciferol by coating of micronized sucrose. The process of coating with phospholipid was effective as illustrated by SEM images. Proliposomes presented low hygroscopicity and moderate solubility, which not hinders the production of liposome dispersions, as mechanical energy can be applied during their preparation. The amount of cholecalciferol added to the formulations was low, which hindered its determination by spectroscopies. The results showed the feasibility of producing proliposomes incorporating both bioactives in concentrations compatible with their recommended daily dosage for further application in food formulations.

### **Abstract**

*The physical properties of 12 commercially available infant milk formula (IMF) and follow-on (FO) powders were assessed. Polarised light micrographs of powders revealed that two types of powders existed: Type I - homogenous mixtures of milk powder particles and Type II – heterogeneous mixtures of milk powder particles and tomahawk-shaped  $\alpha$ -lactose monohydrate crystals. Conventionally employed correlations between particle size, flowability and compressibility were found to be highly dependent on the presence of crystalline lactose in powders. Overall, results showed the importance of micro-structural evaluation during analysis of physical properties of dairy powders and, in particular, IMF/FO powders.*

**Keywords:** *max. Infant formula; microstructure; physical properties.*

---

## **1. Introduction**

Infant milk formula (IMF) powders are dehydrated emulsions consisting of the protein, fat carbohydrate, vitamins and minerals necessary to nourish infants in the absence of breast milk. Composition of powders changes as infants grow and IMF is classified into “stages” based on the age of the infants i.e. from birth, 6 months +, 1 year, follow on (FO), etc.. The U.S. Food and Drug Administration (2003) classify IMF manufacturing processes into three categories: 1) wet processing, 2) dry processing or 3) a combination of wet and dry-blending. In wet processing, ingredients are hydrated in water to the desired composition and are subsequently spray dried [1]. Dry processing involves mixing of dried ingredients and is often employed in combination with spray dried base powder [2].

The manufacturing process has a large effect on the physical quality of dairy powders [1, 3-6]. Powder particle size can be controlled by viscosity of feed concentrate and agglomeration during spray drying [7, 8]. Large powder particle sizes generally increase flowability due to a reduction in the area of contact between particles during flow [9]. However, other factors can affect flowability, which in some cases can lead to a weak relationship between particle size and flowability. The surface composition of powder particles is especially important in dehydrated emulsions and high quantities of non-emulsified fat at the powder surface can reduce flowability [10]. Shape of particles can also affect flowability of powders with more spherical powders having greater flowability [11].  $\alpha$ -lactose monohydrate crystals are generally pyramidal or tomahawk shaped [12] and thus may reduce sphericity, and possibly, flowability of powders if present.

In recent years there has been an increase in the publications dealing with IMF manufacture [1, 5, 6, 13, 14]. Hanley et al. [13] provided some information regarding the physical properties of a limited number of commercial IMF samples, whereas the others did not equate data obtained to standard commercial products. This aim of this study were to determine differences in physical quality of commercial IMF related to composition of powders, microstructure and/or processes employed by manufacturers.

## **2. Materials and Methods**

### **2.1 Commercial infant milk formula**

A total of 12 IMF and FO powders were studied. 9 samples were purchased from an Irish supermarket and 3 samples of non-Irish IMF powders were donated by Biostime Inc. (Guangzhou, P.R. China). Crystalline structure of the powders was determined using polarised light microscopy (Olympus Corporation, Tokyo, Japan) and powders were subdivided into two categories; I – a homogenous mix of milk powder particles (n=6) and II – a heterogeneous mix of milk powder particles and crystalline particles (n=6).

## 2.2 Powder properties

Particle size distribution was measured by a Mastersizer 3000 (Malvern Instruments Ltd., UK) as described elsewhere [14]. Sauter mean diameter,  $D[3,2]$ , which gives the diameter of a sphere with the same volume to surface area ratio of the whole distribution was used as a measure of particle size.  $D(v,0.1)$ , which gives the diameter below which 10 % of the distribution (by volume) lies, was used to quantify the amount of fine particles in the distribution.

Particle shape was measured by Morphologi G3 (Malvern Instruments Ltd., UK). Powders were dispersed on to a microscope plate, using pressurised air. The air pressure used was 4 bar, which was applied to the sample dispersion for 10 milliseconds; a settling time of 1 minute was then allowed for powder particles to disperse on the microscope plate.

Bulk density and surface free fats were determined as per GEA Niro Standard [15]. The difference between poured and tapped (100 times) bulk densities gave the compressibility of the powder. Particle densities were measured by a helium gas pycnometer, AccuPyc II 1340 (Micromeritics, GA, USA).

## 2.3 Flowability

Flowability was measured by two methods: 1 – the time taken for a defined volume of powder to leave a rotating drum [15] and 2 – flow function measured using a Powder Flow Tester (Brookfield Engineering Laboratories Inc., MA, USA). For the drum flowability method it was noticed some powder would always adhere to the walls of the drum and would not exit. Therefore, the flowability from this method was defined as a flow-rate given by:  $F_d = (g_{p1} - g_{p2})/\text{time}$ , where  $F_d$  is the drum flowability (g/s);  $g_{p1}$  and  $g_{p2}$  represent the amount of powder (g) in the drum at the start and finish of the test, respectively. Flow function was determined as described by Crowley et al. [16]. Five uniaxial normal stresses (0.3 to 2.4 kPa) were applied to each powder, in combination with three over-consolidation stresses at each normal stress. The Jenike flow index ( $i$ ), was used to characterise the flow of the powders (Table 1; [11]).

*Table 1. Jenike flow index (i) classification*

Flowability	Hardened	Very cohesive	Cohesive	Easy-flow	Free-flowing
$i$	<1	<2	<4	<10	>10

## 2.4 Statistical analysis

A t-test was used to compare Type I and II powders.. Pearson's  $r$  was used to determine the degree of correlation between the two sample sets. This was calculated using the CORREL function of Microft Excel

### 3. Results and Discussion

#### 3.1 Powder properties

Polarised light microscopy revealed that standard IMF powders (made from intact bovine proteins) could be classified into two groups; I – homogenous powders and, II – heterogeneous mixtures of non-crystalline particles and distinct crystalline particles (Figure 1). Type I powders showed small degrees of crystallinity indicated by bright areas within particles. This may be a result of partial lactose crystallisation which could occur, for example, if powder is not cooled sufficiently after spray drying or absorbs moisture locally during storage. The crystalline particles observed in Type II powders were very likely  $\alpha$ -lactose monohydrate due to their pyramidal or tomahawk shape [12]. The presence of crystalline lactose in Type II powders could indicate a manufacturing process where a base powder containing protein and fat ingredients was manufactured by spray drying, after which  $\alpha$ -lactose monohydrate crystals were added by dry-blending [2].

**Figure 1.** Polarised light images of Type I (powder 1) and II (powder 10) powders. Scale bar is 200  $\mu\text{m}$ .

There were significant ( $P < 0.05$ ) differences in powder particle size and shape between Type I and II powders (Table 2). Type I powders had less fine particles ( $D(v,0.1)$ ), and as a result Sauter Mean Diameter,  $D[3,2]$ , was significantly larger ( $P < 0.05$ ).  $D[3,2]$  gives the diameter of a sphere with the same volume to surface area ratio as the whole powder distribution [5]. The significantly larger  $D[3,2]$  of Type I powders, compared to Type II powders, indicated that the specific surface area of Type I powders was lower. Type I powders were less elongated than Type II; measured elongation means were  $0.18 \pm 0.02$  and  $0.25 \pm 0.03$ , respectively. The presence of crystalline lactose tomahawks/pyramids in Type II powders (Figure 1) likely contributed to the greater elongation observed. Surface free fat content did not vary significantly ( $P > 0.05$ ) between Type I ( $0.96 \pm 0.30$  g free fat  $100 \text{ g}^{-1}$  powder) and Type II ( $0.81 \pm 0.22$  g free fat  $100 \text{ g}^{-1}$  powder) powders.

**Table 2. Powder particle size and surface free fat for individual powders (mean of two replicates). Average values presented below were calculated based on powder type  $\pm$  standard deviation**

Powder Type	Powder No.	D [3,2] ( $\mu\text{m}$ )	D(v,0.1) ( $\mu\text{m}$ )	Span of particles	Surface free fat (% w/w of powder)

<b>Average II</b>		<b>142.9 <math>\pm</math> 18.2</b>	<b>82.2 <math>\pm</math> 14.8</b>	<b>1.7 <math>\pm</math> 0.1</b>	<b>0.8 <math>\pm</math> 0.2</b>

### 3.2 Flowability

Flowability of powders was measured by two means; a – Jenike flow index and b – the rate at which powder exited from a rotating drum. Table 3 summarises the flowability data. All powders measured had a flow index (i) of greater than 4 and, thus, were deemed to be easy flowing powders over the range of consolidating stresses applied [9]. There was no significant difference in flow index or drum flowability behaviour between Type I and II powders. Flow index and drum flowability were highly correlated for Type I powders ( $r = 0.95$ ) and somewhat correlated for Type II powders ( $r = 0.69$ ).

Type II powders had lower particle size ( $P < 0.05$ ), were less spherical ( $P < 0.05$ ) and were more elongated ( $P < 0.05$ ) compared to Type I powders. Taking this into account, it is perhaps surprising that average flowability of Type I and II powders was not significantly different (Table 3;  $P \gg 0.05$  for both flow index and drum flowability). Large particle size is generally desirable for good powder flowability [17]. Large powder particles reduce specific surface compared to smaller particles which reduces cohesive inter-particle interactions. In addition, increased sphericity of particles has been found to positively affect flowability [11]. However, particle size can often be weakly correlated with flowability [9] possibly due to the effect of surface composition, which also plays an important role in flowability [10]. Presence of crystalline lactose in Type II powders likely resulted in different overall surface composition compared to Type I powders. This difference could explain the good flow behaviour of Type II powders. Similarly,

Yazdanpanah and Langrish [18] found that skim milk powder particles with crystalline surfaces and amorphous cores had better flowability than fully amorphous particles.

**Table 3. Flowability of powders (mean of two replicates  $\pm$  standard deviation). Average values presented below were calculated based on powder type  $\pm$  standard deviation**

Powder Type	Powder No.	Flow index (i)	Drum flow (g min <sup>-1</sup> )
I	1	6.5 $\pm$ 0.3	32.9 $\pm$ 1.0
I	2	4.6 $\pm$ 0.3	11.2 $\pm$ 0.2
I	3	4.7 $\pm$ 0.2	17.4 $\pm$ 1.7
I	4	7.7 $\pm$ 0.8	38.5 $\pm$ 1.2
I	5	7.7 $\pm$ 0.1	38.5 $\pm$ 1.5
I	6	8.7 $\pm$ 0.5	38.2 $\pm$ 1.2
<b>Average I</b>		<b>6.6 <math>\pm</math> 1.6</b>	<b>29.4 <math>\pm</math> 11.6</b>
II	7	8.7 $\pm$ 3.4	39.0 $\pm$ 0.3
II	8	8.3 $\pm$ 0.1	29.0 $\pm$ 1.3
II	9	4.4 $\pm$ 0.3	24.8 $\pm$ 0.1
II	10	6.9 $\pm$ 0.3	35.1 $\pm$ 0.1
II	11	5.6 $\pm$ 0.4	34.6 $\pm$ 1.0
II	12	4.7 $\pm$ 0.2	20.2 $\pm$ 0.4
<b>Average II</b>		<b>6.4 <math>\pm</math> 2.1</b>	<b>30.5 <math>\pm</math> 6.8</b>

### 3.3 Compressibility

Compressibility was measured by two means a – difference in powder volume before and after tapping 100 times b – difference in volume before and after flow index analysis. No significant ( $P < 0.05$ ) difference in compressibility was observed between Type I and II powders. Compressibility measured during flow index testing was always higher than compressibility measured by tapping, indicating higher compressive force in the former measurement. Correlation between the two tests was high for Type I powders ( $r = 0.99$ ) but for Type II powders no correlation was observed ( $r = 0.16$ ). The exact reason why there was strong correlation for Type I powders and no correlation for Type II powders is unclear, but may be related to the presence of lactose crystals in Type II powders.

High compressibility of powders is often reported to be related to poor flowability [11, 16, 19]. Table 4 shows correlations, for Type I and II powders, between all flowability and compressibility measurements. For Type I powders, compressibility was well correlated with flowability;  $r$  was between -0.9 and -1 in each case. The negative sign of  $r$  indicated that as compressibility increased, flowability decreased. For Type II powders, compressibility obtained by tapping was not correlated to flowability. Correlation of compressibility to flowability in Type II powders was higher when compressibility obtained from flow index was used. It is possible that, at the lower compression associated with the tapping test, lactose crystals present in Type II powders may have affected the established relationship between compressibility and flowability. It is clear from Table 5 that different methods which supposedly measure the same parameter i.e. compressibility, can be

influenced by powder structure. Researchers must take into account powder structure when drawing conclusions from compressibility and flowability data.

**Table 4. Correlation (Pearson's *r*) between compressibility and flowability measurements for Type I and II powders (*n* = 6 for each correlation)**

	Type I		Type II	
	Drum flowability	Flow index	Drum flowability	Flow index
Compressibility by tapping	-0.94	-0.90	0.35	0.33
Compressibility by flow index	-0.98	-0.93	-0.88	-0.75

#### 4. Conclusions

Quick structural analysis of IMF powders using polarised light microscopy gave an indication of the process used for powder manufacture. The presence of large lactose tomahawk crystals in some IMF powders indicated a manufacturing process where at least some degree of dry blending of lactose was utilised. The presence of lactose crystals resulted in markedly different powder behaviour compared to similar powders containing no crystalline lactose. This highlights the importance of powder microstructural analysis to compliment more commonly used measurements of particle size, compressibility and flowability during analysis of powder behaviour.

### Abstract

*Unfired tile mechanical properties are very important in the ceramic tile manufacturing process. Inadequate mechanical properties lead to rejects (both in unfired and fired tiles). Unfired tile mechanical strength changes significantly after the tiles exit the industrial dryer. This behaviour can be explained by assuming that the fast-drying process generates stresses in the tile, which subsequently relax. A kinetic model has been derived, based on Maxwell's viscoelastic elements, which explains the development of dried tile mechanical strength. This increases asymptotically when the dried tiles are stored in dry conditions. However, if tiles adsorb humidity (upon exiting the dryer), tile mechanical strength rises and then decreases. This is the result of two opposing phenomena: stress relaxation raises mechanical strength while the concurrent rise in moisture content lowers mechanical strength. The developed model successfully describes this joint mechanical behaviour.*

**Keywords:** *ceramic tiles, fast drying, stress relaxation, kinetic model.*

---

## **1. Introduction**

Simultaneous heat and mass transport during fast drying (20min) of ceramic tiles produces temperature and, in particular, moisture content gradients in the tiles [1]. Such differential drying would also lead to differential drying shrinkage of the layers if they were not joined together. However, as each individual layer cannot shrink freely, mechanical stresses develop among the layers. Indeed, faster drying of the tile faces generates a moisture content gradient inside the tile, causing the tile faces to be subjected to tensile stresses while the inner tile is under compression. These stresses are not eliminated immediately, so that tile mechanical strength will vary after the tile has been dried and has exited the dryer, as the residual stresses generated during fast drying relax.

This study was undertaken to develop a kinetic model that describes the development of unfired tile mechanical strength after tile drying, both during tile storage in a completely dry and in a humid environment (70% relative humidity).

## **2. Materials and Methods**

Floor tiles measuring 31x31x1cm, made by industrial pressing of a standard spray-dried powder, were used. Fast drying (20min) was performed in a horizontal industrial dryer. Moisture content and mechanical strength were determined in all test pieces. Mechanical strength was determined by three-point bend testing [2]. Ten tiles were used for each test condition.

## **3. Results and discussion**

### **3.1 Stress relaxation in dried tiles placed in bags to keep the tiles dry**

Unfired tile mechanical strength,  $\sigma_B$ , rises considerably during dried tile storage time in bags owing to relaxation of the stresses generated in the tile during drying (Fig. 1). The proposed model that describes these results is based on the following assumptions:

- i) The unfired tile is assumed to consist of a series of uniform layers of infinitesimal thickness, each of which is subject to different uniform residual stress.
- ii) The viscoelastic behaviour of each layer can be described by a Maxwell element [3].
- iii) Total strain is independent of time and position.

Fig. 1. Variation of the mechanical strength,  $\sigma_B$ , of dried tiles placed in bags with storage time. Fit of the experimental data to the developed model, Eq. 3.

These assumptions yield the Maxwell model stress relaxation, which describes the evolution of the residual stress,  $\sigma$ , for a layer:

$$\sigma = \sigma_i \exp\left(-\frac{t}{\tau_0}\right) \tag{Eq. 1}$$

where  $\sigma_i$  is the initial residual stress (at the dryer exit) (MPa) and  $\tau_0$  is the relaxation time of the dried material (h).

- iv) In a bending test, tile mechanical strength,  $\sigma_B$  (MPa), is the maximum tensile strength that the bottom layer can withstand. Consequently, during the relaxation process,  $\sigma_B$  is the difference between the mechanical strength of the already relaxed layer,  $\sigma_{B\infty}$  (MPa), and the residual stress,  $\sigma$ , acting upon this layer:

$$\sigma_B = \sigma_{B\infty} - \sigma \tag{Eq. 2}$$

Introducing Eq. 1 in Eq. 2 yields:

$$\sigma_B = \sigma_{B\infty} \left[ 1 - \gamma \exp\left(-\frac{t}{\tau_0}\right) \right] \quad \text{Eq. 3}$$

where:

$$\gamma = \frac{\sigma_{B\infty} - \sigma_{Bi}}{\sigma_{B\infty}} \quad \text{Eq. 4}$$

where  $\sigma_{Bi}$  is dried tile mechanical strength at the dryer exit.

This equation describes the evolution, with relaxation time, of the mechanical strength of dried tiles stored in bags to keep the tiles dry (tile moisture content:  $X=0$  kg water/dry solid).

The solid line in Fig. 1 is the plot of Eq. 3. Excellent fit was found.

### 3.2 Relationship of relaxed unfired tile mechanical strength, $\sigma_{BR}$ , to moisture content, $X$

Fig. 2 shows the mechanical strength of stress-free (relaxed) unfired tiles,  $\sigma_{BR}$ , versus moisture content,  $X$ , for different experiment series: by moisture adsorption in dried tiles and on drying as-pressed tiles to different moisture contents.

The following equation relates  $\sigma_{BR}$  to moisture content,  $X$ , [4] [5]:

$$\sigma_{BR} = \sigma_{BR0} \exp(-\beta X) \quad \text{Eq. 5}$$

where  $\sigma_{BR0}$  is the mechanical strength of stress-free dry tiles (MPa) and  $\beta$  is a fit parameter.

The solid line in Fig. 2 is the plot of Eq. 5. Excellent fit was found.

Fig. 2. Effect of moisture content,  $X$ , on stress-free unfired tile mechanical strength,  $\sigma_{BR}$ . Fit of the experimental data to Eq. 5.

### 3.3 Development of dried tile mechanical strength on storage in ambient air

When a tile emerging from the dryer is stored in ambient air ( $T=20^{\circ}\text{C}$  and relative humidity=70%), it will simultaneously be subject to moisture adsorption and stress relaxation. The sum of the opposing effects that each of these phenomena has on unfired tile mechanical strength causes the variation of this property with time to exhibit a maximum value (Fig. 3).

Fig. 3. Variation of dried tile mechanical strength,  $\sigma_B$ , and moisture content,  $X$ , with storage time in ambient air ( $T=20^\circ\text{C}$  and relative humidity=70%).

To derive the model the following modifications must be performed in Eq. 3:

- i) As moisture content increases, stress relaxation becomes faster, so that  $\tau$  decreases according to the following expression:

$$\tau^{-1} = \tau_0^{-1} + \alpha X \tag{Eq. 6}$$

where  $\alpha$  is a fit parameter. Consequently, in Eq. 3,  $\tau_0$  must be replaced with Eq. 6.

- ii)  $\sigma_{B\infty}$  must be replaced with Eq. 5.
- iii)  $\gamma$  does not depend on moisture content,  $X$ . This parameter is the same as the  $\gamma$  calculated in the previous fit to Eq. 3.

Taking into account the aforementioned assumptions, the final equation becomes:

$$\sigma_B = \sigma_{BR0} \exp(-\beta X) \left[ 1 - \gamma \exp\left(-\left(\frac{1}{\tau_0} + \alpha X\right) t\right) \right] \tag{Eq. 7}$$

For this particular case, substituting the fit parameter values into Eq. 7 yields:

$$\sigma_{B=}=2.20\exp(-0.33X) \left[ 1-0.4\exp\left(-\left(\frac{1}{4.69}+100X\right)t\right)\right] \quad \text{Eq. 8}$$

The agreement between Eq. 8 and the experimental data is good (Fig. 3). The equation reproduces the peak strength attained after a certain time.

#### 4. Conclusions

Unfired ceramic tile mechanical strength changes significantly after the tiles exit the industrial dryer. Dried tile mechanical strength increases asymptotically when the tiles are stored in dry conditions. When these tiles adsorb humidity, tile mechanical strength exhibits a peak.

A model has been developed, based on Maxwell's viscoelastic element, which successfully describes this mechanical behaviour.

The relationship between the mechanical strength of stress-free unfired tiles and tile moisture content was found to be independent of whether the process involved modifying tile moisture content by drying or by moisture adsorption.

### **Abstract**

*Structural properties of packed-beds of non-spherical biological materials were investigated. The particles tested were oats, lentil, barley and soy, with sphericity ranging from 0.4 to 0.8. Porous alumina particles with sphericity of 0.98 were also included. The particles dimensions and sphericity were measured under moisture content ranging from the equilibrium up to 24% (dry basis). Mean voidage, bulk density, permeability and tortuosity of the packed-beds were obtained in the whole moisture range. The data were used as input into a correlation to predict Sherwood numbers under constant air velocity and the results were compared to evaluate the influence of packing characteristics on convective mass transfer.*

**Keywords:** *Sphericity; Permeability, Tortuosity, Fixed-Bed Dryers.*

---

## 1. Introduction

It is well-known that variables such as particle shape, size, surface roughness, among others, influence the gas-particle interaction in fixed-bed drying because the packed bed permeability, tortuosity, interparticle contact and residence time are greatly affected by them. For particles of irregular shape and wide size distribution, a great number of packing arrangements can be achieved, leading to changes in the local porosity and contact area that affect the heat and mass transfer rates. Drying is a preservation method widely used for grains, a class of materials that exhibits a widespread variety of shape and sizes. Besides, the dimensions and shape of grains often change throughout drying due to the shrinkage, making the design of drying equipment a challenging task [1]. The influence of the particle properties on fixed-bed drying is useful information for a fundamental analysis of drying processes of grains and seeds.

As a preliminary stage of a study aimed at investigating how the packed-bed characteristics may affect convective fixed-bed drying, a characterization of the packed-bed's structural properties was performed for different biological materials. Particles' characteristic dimensions, volume, equivalent diameter, surface area, sphericity and density were obtained as a function of the moisture content. The bulk density, mean voidage, permeability and tortuosity were obtained for the different packed-beds. The experimental data were used as input to an empirical correlation based on the packed-bed properties to evaluate the mass transfer coefficients and compare the mass transfer potential of each bed.

## 2. Materials and Methods

### 2.1. Particulate materials

The biological materials were selected to cover a wide range of characteristics: soy (*Glycine max* L.), green lentils (*Lens culinaris*), barley (*Hordeum vulgare* L.) and oats (*Avena sativa*). Nearly spherical porous alumina particles with a diameter of 2.5 mm were included to serve as a standard material for comparison. The dehydrated materials were purchased from a local market and either humidified or dried to reach specified moisture content ( $X$ ) (% d.b.), which were set to 24%, 16%, 9% and the equilibrium moisture ( $X_{eq}$ ). Humidification was done by placing 150 g samples in polyethylene plastic packages, adding the necessary amount of deionized water and storing the sealed packages at 4°C for 48 h. The drying was performed in a hot-air drying oven (TE-394/1, Tecnal®) at 50°C.

## 2.2. Physicochemical characterization

Particles were assumed to have a triaxial spheroid shape. The length ( $L_p$ ), width ( $W_p$ ) and mean diameter ( $D_m$ ) of 60 particles were measured by the image analysis technique using the software Image-Pro Plus® 6.0. The thickness ( $T_p$ ) was measured using a digital caliper. The volume ( $V_s$ ) and sphericity ( $\varphi$ ) were calculated according to [2]. The packed-beds' bulk density ( $\rho_b$ ) was obtained by measuring the weight and volume of the samples, using a digital scale (AS 1000, Marte®) and a glass measuring cylinder with diameter of  $5.0 \times 10^{-2}$  m. Small portions of particles were discharged from a constant height through a funnel into a graduated glass vessel. The vessel was tapped over a flat surface until a constant volume. The apparent density ( $\rho_a$ ) was estimated by liquid pycnometry with toluene (99.5%, Dinâmica®). The mean voidage ( $\varepsilon_b$ ) was evaluated from the values of  $\rho_a$  and  $\rho_b$  [2]. The measurements were performed in triplicate.

## 2.3. Determination of the permeability and tortuosity

The packed-bed static pressure drops were measured in a cylindrical vessel with diameter ( $D$ ) of  $5.0 \times 10^{-2}$  m and height of  $29.5 \times 10^{-2}$  m (the ratio  $D/D_m$  varied from 7.0-16.0). The pressure taps were distributed along the vessel height at each 5 cm. The particles were randomly packed according to the same procedure described in section 2.2. The pressures ( $P$ ) were measured under different air flow rates and at a constant air temperature (27°C). The air velocity ( $U$ ) ranged between 0.05-0.58 m.s<sup>-1</sup>. The permeability ( $\kappa$ ) was obtained from a linear regression of Eq. (1), with experimental values of  $\Delta P$  and  $U$ . The tortuosity ( $\tau$ ) was estimated based on the capillary model, using Eq. (2) [3].

$$\frac{\Delta P}{Uz} = \frac{\mu}{\kappa} + \frac{c}{\sqrt{\kappa}} \rho U \quad (1)$$

$$\tau = \frac{\varepsilon_b^3 D_m^2 \varphi^2}{72 \kappa (1 - \varepsilon_b)^2} \quad (2)$$

## 2.4. Mass transfer coefficients

To evaluate how the packed-bed structure affect the mass transfer in a hypothetical drying limited by the external resistance, the mass transfer coefficients were estimated from a generalized semi-empirical correlation developed for porous media. As described in [4], the equation assumes that packed-bed structure can be described by a capillary geometry and defines a wall energetic criterion ( $Xe_w$ ). The correlation is given by:

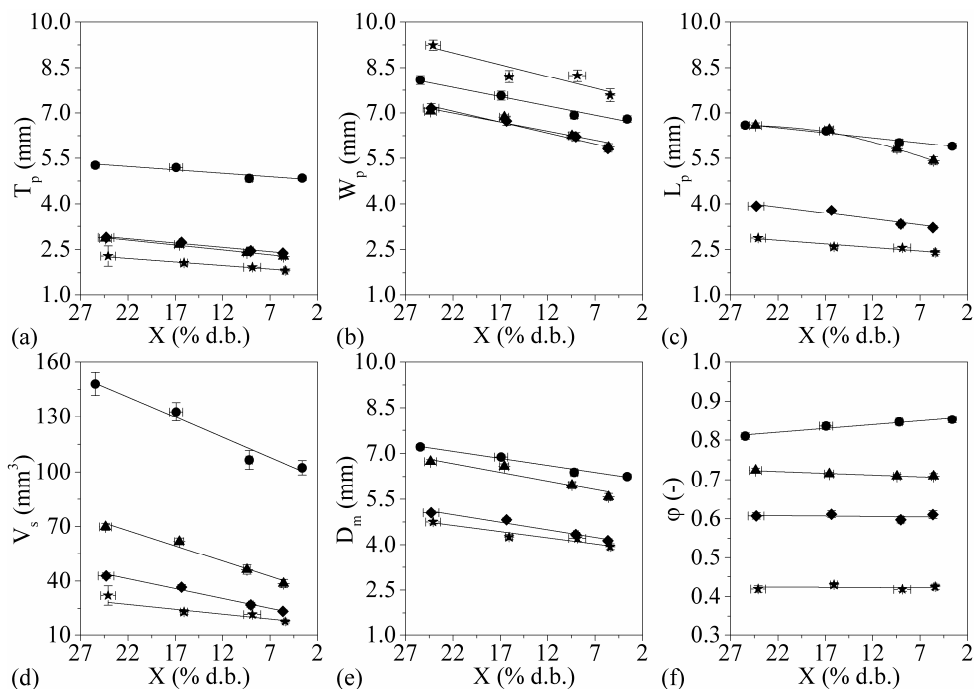

$$Sh = 3.66 + 0.101 \left[ 1 + \frac{\pi}{4} \frac{1 - \varepsilon_b}{\varepsilon_b} (\tau - 1) \left( 1 + \frac{\varepsilon_b}{\tau^2} Sc^{\frac{1}{3}} e^{-\frac{11 - \varepsilon_b}{3} \sqrt{\tau Y X e_w^{\frac{1}{3}}}} \right) \right] X e_w^{\frac{11}{48}} Sc^{\frac{1}{3}} \quad (3)$$

The dimensionless groups  $Xe_w$ ,  $Sh$ ,  $Re$  and  $Sc$  were estimated according to [4]. The diffusivity of moisture in the air ( $D_A$ ) was obtained from [5]. Air physical properties and  $D_A$  were estimated at ambient temperature (30°C). The aspect ratio ( $Y$ ) was obtained from the ratio of particle thickness over particle width,  $T_p/W_p$  [4].

### 3. Results and Discussion

#### 3.1. Particles characteristics

The particles' linear dimensions, ( $L_p$ ,  $W_p$ ,  $T_p$ ), mean diameter ( $D_m$ ), volume ( $V_s$ ) and sphericity ( $\phi$ ) are shown in Figs. 1(a) to 1(f).

**Fig. 1** Particles' dimensions and sphericity as a function of the moisture content;  $T_p$  (a),  $W_p$  (b),  $L_p$  (c),  $V_s$  (d),  $D_m$  (e) and  $\phi$  (f). Legend: soy (●), lentil (▲), barley (◆) and oats (★).

A reduction in  $X$  resulted in a linear decrease in the particles' dimensions, owing to the shrinkage phenomenon that appears as a result from an unbalance between the material's inner pressure and the external pressure [6]. Shrinkage is usually observed in food materials with a solid matrix in the rubbery state [6,7]. The particles characteristics of alumina are not shown because its dimensions do not change with moisture variation. The results and

qualitative behavior of variables in Fig. 1 are consistent with those reported in the literature [8-11]. Although the linear dimensions change,  $\varphi$  is not significantly affected by the moisture reduction, as can be observed in Fig. 1(f).

### 3.2. Packed-beds structural properties

The particles' sphericity are, in a decreasing order, 0.98 (alumina), 0.8 (soy), 0.7 (green lentils), 0.6 (barley) and 0.4 (oats). It is worth noting that the particles differ also in size, shape, apparent density and surface roughness. All these variables may affect the packing structure, however the differences cannot be avoided when working with biological particles. The variation of  $\rho_b$  and  $\varepsilon_b$  as a function of  $\varphi$  are shown in Fig. 2 for  $X$  equal to 24% and for dry particles (equilibrium moisture). The results obtained at 16% and 9% stayed between the upper and lower limits and for the sake of concision are not shown in the graphs.

Fig. 2 Bulk properties as a function of  $\varphi$ :  $\varepsilon_b$  (a) and  $\rho_b$  (b) for alumina (■), soy (●), lentil (▲), barley (◆) and oats (★). Legend: moistures contents of 24% (—) and  $X_{eq}$  (.....).

Fig. 2 (a) shows that at a constant  $X$ ,  $\varepsilon_b$  did not vary significantly as  $\varphi$  was reduced from 0.98 to 0.60. Only at  $\varphi=0.40$  a slight increase was observed, suggesting that packed-beds of oats tend to produce large pores. However, it is not clear why  $\varepsilon_b$  was not affected by the moisture content in this particular case. The variation of  $\rho_b$  with  $\varphi$  is complex and does not show a clear trend, as can be seen in Fig. 2(b). At a constant  $X$ ,  $\varepsilon_b$  and  $\rho_b$  depend not only on  $\varphi$ , but also on additional factors, such as the particles' dimensions and  $\rho_a$ . Additionally, the variation of  $D_m$  and  $\rho_a$  with moisture content is different for each particle. Even the particles' surface roughness can be affected by moisture and it is quite difficult identifying the different contributions of each variable in the packed-bed structure. The apparent density of alumina, for instance, decreases as  $X$  is reduced, as its volume does not change. On the other hand, the grains shrink and an opposite behavior is observed. Therefore,

several combined effects are responsible for the patterns observed in Figs. 2(a) and 2(b). The qualitative dependence of  $\rho_b$  and  $\varepsilon_b$  on  $X$  were similar to those reported by [8-11] for lentil, barley, soy and oats, respectively. A reduction of  $X$  caused an increase in  $\rho_b$  (Fig. 2 (b)) and a decrease in  $\varepsilon_b$  (Fig. 2 (a)), which is probably associated to the decrease in  $D_m$  observed as the moisture content is reduced (Fig. 1(e)). For random packing of non-spherical particles, smaller values of  $D_m$  generate smaller intraparticle void spaces, thus increasing  $\rho_b$  and decreasing  $\varepsilon_b$  [12]. Alumina presented an atypical behavior, because  $D_m$  does not change with  $X$  for this particle.

The influence of  $X$  on  $\kappa$  and  $\tau$  is displayed in Fig. 3 as a function of  $\varphi$ . A decrease in  $X$  resulted in lower values of  $\kappa$  and higher values of  $\tau$ . This can be attributed again to the reduction of  $D_m$  with  $X$  due to the shrinkage of grains, and is consistent with the patterns described in Figure 2.

Fig. 3 Packed-bed parameters as a function of  $\varphi$  for alumina (■), soy (●), lentil (▲), barley (◆) and oats (★);  $\kappa$  (a) and  $\tau$  (b). Legend: moistures contents of 24% (—) and  $X_{eq}$  (.....).

It is also observed in Fig. 3 that, at a constant  $X$ ,  $\kappa$  tends to decrease with the decrease in  $\varphi$  and  $\tau$  tends to increase. According to the literature [5], deviations from the spherical shape may contribute to reducing the pore diameter. However, for the particles considered here, not only the particle shape but other variables, such as the size and apparent density can affect the packed-beds' structural properties. It can also be observed that the influence of  $\varphi$  on  $\kappa$  and  $\tau$  is much more evident at a high  $X$ , which is probably related to the dependence of the grains' dimensions on  $X$ . Once more, an atypical behavior is observed for alumina for the aforementioned reasons.

### 3.3. Mass transfer coefficients

The values of  $Re$  and  $Sh$  were estimated for the different packed-beds at  $U=0.58 \text{ m}\cdot\text{s}^{-1}$  and are shown in Fig. 4 as a function of  $\phi$ , for values of  $X$  equal to 24%, 16%, 9% and  $X_{eq}$ .  $Re$  was calculated based on the estimated capillary diameters.

At  $X=24\%$ , it can be observed in Fig.4(a) that  $Re$  is practically constant for the packed-beds of different particles, regardless of the value of  $\phi$ . Only for alumina a significant increase in  $Re$  was observed, which is attributed to the smaller size of this particle. At a low moisture content ( $X=9\%$ ), a slight decrease in  $Re$  is observed as  $\phi$  increases from 0.4 to 0.7 and it increases again as  $\phi$  is further increased. These quite different patterns are justified by the influence of the moisture content on the particles' dimensions. The dependence of  $Sh$  on  $\phi$  in Fig. 4(b) shows quite similar patterns to those observed in Fig. 4(a), as the convective mass transfer is directly correlated to  $Re$ . High values of  $Re$  favor fluid turbulence, flow eddies and mixing and contribute to increasing mass transfer, as the boundary layer thickness and mass transfer resistance are reduced [13]. Therefore, higher values of  $Sh$  are observed under higher values of  $Re$ . Among the biological particles tested, and at a constant  $X$ , higher  $Sh$  were observed in the packed-beds of oats, which is the particle of lower sphericity.

Fig. 4. Estimated values of  $Re$  (a) and  $Sh$  (b) as a function of  $\phi$  for alumina (■), soy (●), lentil (▲), barley (◆) and oats (★) at  $0.58 \text{ m}\cdot\text{s}^{-1}$ . Legend: moisture of 24% (—), 16% (---), 9% (-·-·-) and  $X_{eq}$  (·····).

### 4. Conclusions

Based on the experimental data, it was verified that the permeability and tortuosity of packed-beds of soy, oat, lentil and barley were significantly affected by the particles shape and size and by the moisture content. The results suggest that the packed-bed structure may change significantly throughout drying depending on the particle characteristics, as the particles dimensions vary with their moisture content, while their shape practically do not

change. Because each particle was differently affected by the moisture content and have distinct shape and sizes, no consistent correlation between the structural properties such as mean voidage, bulk density, permeability and tortuosity to the particle characteristics could be identified.

### **Abstract**

*This study aimed to evaluate the effects of ozone pretreatment on drying of green apple carried out in a fluidized bed dryer to determine drying kinetics and identify operating parameters for improved product quality. Results reveal that drying temperature in different levels affected water diffusivity and retention of bioactive compounds. The ozone pretreatment showed unexpected results since the pretreatment reduced the water diffusivity and promoted an increase in the enzyme activity. The treatment time strongly affected the final polyphenoloxidase and peroxidase activities. On the other hand, the ozone treatment resulted in lower color changes compared to non-ozone treated dried apples.*

**Keywords:** *diffusivity; polyphenoloxidase; enzymatic browning; ozone.*

## **1. Introduction**

Foods with high moisture like fruits and vegetables are dried to increase shelf storage and to reduce the storage and transportation costs. However, the drying methods used for food should be not only efficient and economical but also produce high quality, tasty and nutritious products with good uniformity, appearance, and texture. The main challenge in drying food is to maintain the quality of the product<sup>1,2</sup>.

The drying process is related to the simultaneous application of heat and removal of food moisture. The main parameters that control the drying rate of fruits are the air temperature, relative air humidity and air velocity as processing conditions variables. These parameters are chosen based on the nature of the food and the particular design of the dryer<sup>3,4</sup>. Fluidized bed drying is a method for controlled and mild drying of wet solids. A proper bed flow control provides a homogeneous drying, with greater drying efficiency without the application of excessive heat and mass transfer when compared to other conventional drying systems. However, the efficiency of a conventional fluidized bed system is usually low. It is, therefore, desirable to improve the efficiency of the drying process.

Pretreatment with ozone in fruits and vegetables is usually carried out to prolong its shelf life. One of the applications of ozone as a preservative treatment in fresh fruits and vegetables is due to the effective increase of the antioxidant defense system by increasing the activity of superoxidase dismutase (SOD), peroxidase (POD) and catalase (CAT)<sup>5</sup>.

Polyphenoloxidases are enzymes responsible for the enzymatic browning in fruits and vegetables. These enzymes also cause degradation of polyphenols, leading to discoloration and loss of antioxidant activity<sup>2</sup>.

Thus, this study aimed to evaluate the application of ozone pretreatment before drying of green apple carried out in a mini vibrated fluidized bed dryer to determine drying kinetics and identify the main operating parameters for improved product quality.

## **2. Materials and Methods**

### **2.1 Preliminary drying tests**

The apples (Granny Smith variety) were cut in cubes (0.5 cm) and dried at 40, 45 or 50 ° C in a mini fluidized bed dryer and evaluated in different temperature and air flow parameters (Table 1). The final moisture obtained was 10 % (dry base), and the processing effects on color parameters, phenolic compounds, antioxidant capacity (DPPH) <sup>6</sup> and the polyphenol oxidase (PPO) and peroxidase (POD) activities<sup>2</sup> were evaluated. The optimum drying temperature was selected based on the effective water diffusivity of apple cubes calculated using Fick's law.

**Table 1. Drying parameters**

Temperature (°C)	Airflow (m <sup>3</sup> /min)	Final Airflow (m <sup>3</sup> /min)	Drying time (h)
40	75	40	2
45	75	40	2
50	75	40	2

## 2.2 Ozone pretreatment

To evaluate the blanching effects of ozone pretreatment on dried apples, the cubes were inserted into a glass column reactor with a sintered glass porous plate (4.5 cm in diameter and 30 cm high), coupled to a Model O & L1.5 Portable Ozone Generator, (OzoneLife, São José Dos Campos, São Paulo, Brazil).

For ozone pretreatment, samples with 65 g of green apple cubes were exposed to different processing times: 10, 20 or 30 minutes. The oxygen flow was 250 mL/min and the ozone production was 40.9 mg / L.

For drying, 55 g of ozone pretreated green apple cubes were dried in a fluidized bed dryer (Labmaq do Brasil, Ribeirão Preto, São Paulo, Brazil). The ozone pretreated apples were dried at 50 °C because this temperature resulted in the highest diffusivity of drying.

## 2.3 Quality parameters of the dried apples

The sample's moisture was determined using a moisture balance (Marconi, Piracicaba-Brazil). The water activity was determined at 25°C with a water activity meter (AquaLab, Decagon CX-2, Pullman, Washington, USA). The drying kinetics the thermal diffusivity apples were calculated according to the Fick's law.

The instrumental color was determined using a Minolta CR300 colorimeter (Tokyo, Japan) and the color parameters were expressed as L\* (whiteness/darkness), a\* (redness/greenness), b\* (yellowness/blueness), C\* (saturation index) and °h (hue angle). The readings were done in quintuplicate and the total color difference ( $\Delta E$ ), was calculated according to the following equation:

$$\Delta E = \sqrt{(\Delta L)^2 + (\Delta a)^2 + (\Delta b)^2} \quad (1)$$

Total phenolic compounds were determined by the Folin-Ciocalteu method<sup>2</sup>.

### 3. Results and Discussion

#### 3.1 Effects of fluidized bed drying on bioactive compounds and drying kinetics

According to the results presented in Table 2, fluidized bed drying has influenced the activity of the spoiling enzymes reaching almost 80% of inactivation for PPO and POD at 50°C after 2 hours of drying. Yemenicioglu et al. (1997)<sup>6</sup> reported that the time required for 50% reduction of initial PPO activity of Granny Smith apples at 68°C and 78°C was 35 and 3 min, respectively, showing the effect of temperature on PPO. Antioxidant capacity (DPPH) also decreased due to the drying processes. However, at 40°C it was observed an increase of 200% for total phenolic compounds (TPC), which agrees to the highest antioxidant value found at 40 °C. Possibly, drying promoted the release of insoluble phenolics increasing both the phenolic content and the antioxidant activity. Water activity reached values below 0.4, after 2 h (50°C), 2.4h (45°C) or 3h (40°C) of drying, which is appropriate to prevent bacterial and fungi growth. The results suggest that fluidized drying is a viable technology for drying apples.

*Table 2. Residual concentrations of total phenolic compounds, polyphenol oxidase (PPO), peroxidase (POD) and total antioxidant activity (DPPH) of fluidized bed dried green apple*

Temp.	Residual Concentrations (%)				Diffusivity (10 <sup>9</sup> m <sup>2</sup> /min)
	TPC	PPO	POD	DPPH	
40°C	301.47±22.78	30.46±1.07	31.61±0.89	101.44±0.32	8.50 ± 1.02
45°C	88.11±2.92	31.42±1.00	39.53±1.51	36.82±2.78	11.50 ± 0.85
50°C	78.25±1.14	21.36±2.54	15.30±0.43	27.82±0.79	16.50 ± 3.20

#### 3.2 Ozone pretreatment

The ozone pretreatment reduced the water diffusivity as showed in Table 3, which leads to a reduced drying efficiency. The negative effect on the water diffusivity was proportional to the ozone application time. After 30 min of ozone pretreatment, the diffusivity was reduced by 43%. This might be occurred probably due to structural changes after increasing time exposure to ozone.

*Table 3. Diffusivity values of ozone pretreated apples at 50 °C*

Time (min)	Diffusivity (10 <sup>9</sup> m <sup>2</sup> /min)
0	16.50 ± 3.20
10	15.80
20	12.90
30	9.39

The results of the color analysis are presented in Table 4. The color difference ( $\Delta E$ ) was calculated against the control sample (non-dried apple). For all pretreated samples, the drying process increased the total color difference, but this variation was lower when the drying was combined with the ozone pretreatment. Thus, it is possible to state that the application of ozone before drying reduced the color changes during drying. The mechanism involved are object of future studies.

FB 50°C	68.73	17.09	76.08	4.11	16.59	21.3

Control: non-processed apple; OZ – sample submitted to ozone treatment; OZ+FB – sample submitted to ozone treatment followed by fluidized bed drying.

Table 5 shows the residual activity of PPO and POD after ozone pretreatment and fluidized bed drying.

**Table 5. Residual activities (%) of ozone pre-treated and fluidized bed dried green apple**

	<b>POD</b>	<b>PPO</b>
OZ 10	442.96 ± 5.90	162.28 ± 13.94
OZ 10 + FB	243.80 ± 13.22	30.54 ± 13.25
OZ 20	85.71 ± 2.96	102.42 ± 4.84
OZ 20 + FB	182.56 ± 8.84	48.68 ± 8.50
OZ 30	76.24 ± 0.0	121.10 ± 3.06
OZ 30 + FB	54.92 ± 3.06	49.55 ± 6.04

The maximum reduction (23.76%) was achieved after 30 minutes of ozone exposure. An inhibitory effect of ozone on POD occurred probably due to the high oxidation potential of ozone<sup>7</sup>. For PPO the activity increased up to 62% after short time ozone processing (10 min) and then it was reduced. After drying, PPO activity decreased probably due to the temperature effect (Table 2). The highest enzymes inactivation was achieved in the samples treated with ozone by 30 minutes. However, the POD and PPO residual activity were higher than the found in the samples dried without the ozone pretreatment.

## Conclusions

Our results suggest that fluidized bed drying is a viable technology for drying apples. The ozone pretreatment resulted in unexpected results since the pretreatment reduced the water diffusivity and promoted an increase in the enzyme activity. The treatment time strongly affected the final PPO and POD activity. On the other hand, the ozone treatment resulted in lower color changes when compared to non-ozone treated dried apples.

To our knowledge this the first study applying ozone as pretreatment for fruit drying. The results strongly suggest a behavior similar to the ultrasound pre-treatment where some parameters can increase or decrease depending on the intensity and processing time. Thus, more studies on the effect of ozone as pretreatment for drying fruits are necessary to understand the mechanism of the effects reported in the present study.

### **Abstract**

*By combining vacuum freeze drying combined with high-frequency dielectric and/or infrared heating, the drying time for frozen gels containing 1% agar with sucrose or sodium chloride was successfully shorten, and the drying time was influenced by the heating methods and by the additive component to the sample. Additionally, it was experimentally confirmed that the power consumption for freeze drying combined with electromagnetic wave heating could be reduced because of the shortened drying time. Consequently, this study could be a very important step for designing a vacuum freeze drying process optimally combining electromagnetic wave heating for each sample component.*

**Keywords:** *freeze drying, electromagnetic wave heating, food model, sucrose, sodium chloride*

---

## **1. Introduction**

Vacuum freeze drying (FD) is less physical and with less chemical changes in the sample qualities; in recent years the application fields have been expanded. Vacuum FD is commonly and widely utilized for high quality preservative foods [1]. However, the drying time for conventional FD is very long (for example; several tens of hours). Therefore, freeze drying is actively studied for the purpose of shortening the drying time. Wang et al. performed FD of sliced potatoes by combining microwave heating, and established the drying time could be shortened by 37% [2, 3]. Microwave, combined FD is not enough uniform heating under the high vacuum. Additionally, Pan et al. tried to shorten the FD process of sliced bananas in consideration of the influence of infrared irradiation [4]. Furthermore, Schössler et al. studied an ultrasound assisted freeze drying of red bell pepper pieces cut into 1-cm squares, but noted only a minimal effect [5].

We then focused our attention on high-frequency dielectric (HF) heating to directly heat frozen foods for the purpose of the reduction of the time of the vacuum FD. The combined vacuum FD and HF heating has the potential of a multi-stage operation without a heating medium, and a large number of samples could be vacuum freeze-dried at one time. As the results, drying time could be shortened by using HF heating [6]. However, on the first half of the drying, the combination effect was very slight. This study aims to further shortening the drying time by combining vacuum FD combined with HF and/or infrared (IR) heating since infrared rays could be significantly absorbed by all phases of water. As the food model, a cylindrical frozen agar gel was selected because of easy formability and adjustments to its components. We then study the effects of the assistance of HF and/or IR heating on the FD characteristics and the influences of the additive of sucrose or sodium chloride (NaCl) to the food model on them.

## **2. Materials and Methods**

### **2.1. Materials**

Frozen agar gels containing 1 wt% agar were used as the food model samples. We also made the frozen agars including sucrose of 20 wt% or NaCl of 7.5 wt% as the drying samples. The outline of the sample preparation procedure is shown in Figure 1. The agar, sucrose and NaCl were of special grade and obtained from Wako Pure Chemical Industries (Osaka, Japan). The initial water content of the agar was precisely controlled by

suppressing the moisture evaporation. The formed sample was stored in a freezer which was set to 253 K.

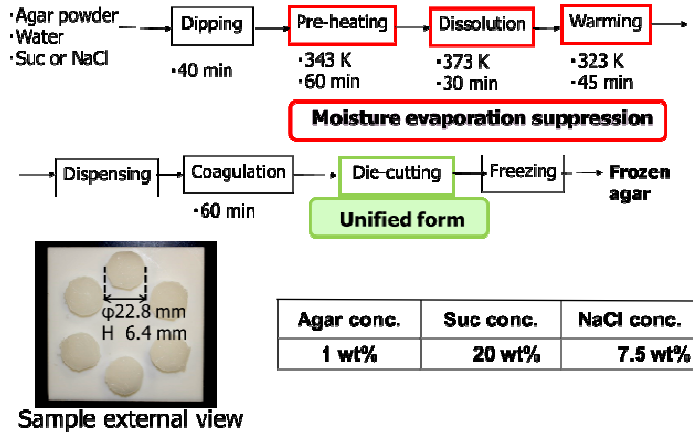

Fig. 1 Outline of sample preparation procedure.

## 2.2. Experimental apparatus

Drying experiments were performed in a Lab-scale vacuum chamber (Espec Co., Ltd., Osaka, Japan) equipped with the high frequency dielectric and infrared radiative heating

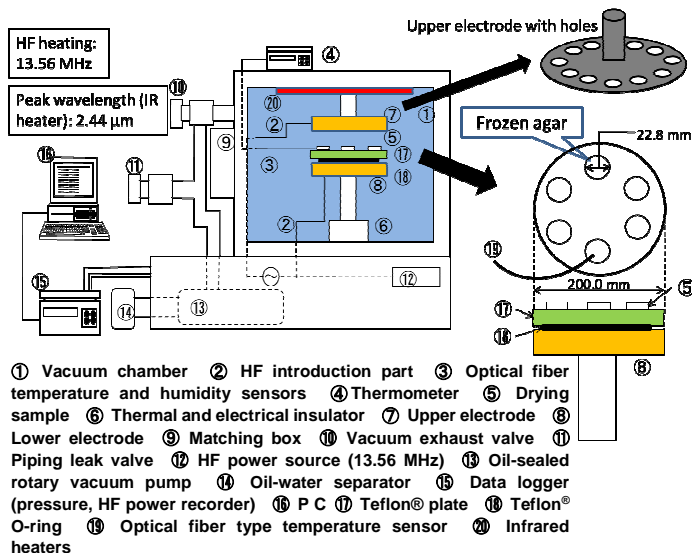

Fig. 2 Schematic diagram of high frequency dielectric heating with freeze-dryer.

systems. A scheme of the drying equipment is presented in Figure 2. The output power of the high frequency dielectric heating is automatically adjusted to a set point by the matching box (9) during freeze-drying. The upper electrode (7) has the holes on the circumference for transmitting the infrared rays from the infrared heaters (20) equipped on the top plate inside the vacuum chamber (1). The infrared radiative power is controlled by adjusting the energization time to the infrared heaters. A vacuum pump was used for maintaining the vacuum in the chamber. The data of the pressure, high frequency traveling wave power and high frequency reflection wave power are recorded using the data logger (15).

### 2.3. Drying experiments

Six frozen agar samples are put on the Teflon® plate (82× 82× 10.5 mm) and are kept in a freezer set at 253 K overnight. The samples and the plate were put on the lower electrode. To avoid the heat transfer from the lower electrode to the sample, a Teflon® O-ring (φ3, 60 mm inside diameter) (18) was put on the lower electrode (8), and the samples (5) on the plate (17) were put on the O-ring. The distance from the sample to the upper electrode (GND) was set at 15 mm based on the preparatory experiment results.

In case of the assistance of HF heating, after the pressure in the vacuum chamber reached around 100 Pa, HF power was supplied to the frozen samples and the drying experiment was started. During drying, the sample temperature and the pressure in the chamber were continuously monitored. At the specified drying time, one agar was sampled from the chamber after the inner pressure was returned to atmospheric pressure. Drying of the remaining agar samples were then started again. To determine the moisture content of the sample, the sample after vacuum freeze drying was dried in an oven set at 378 K for 24-72 hours. The dry weight of the sample was gravimetrically measured.

## 3. Results and Discussion

### 3.1. Drying characteristics

The influences of the HF power on the combined vacuum freeze drying characteristics of the frozen agar gel were experimentally studied, and Figure 3 shows the influences on the time courses of the normalized water content ( $w/w_0$ ) relative to the initial one ( $w_0$ ) for the frozen agar gel (no additive) and of the sample temperatures. As shown in Figure 3, the drying rate was accelerated by combining electromagnetic wave heating. The drying time was shortest when HF and IR heating were simultaneously used (HF+IR). However, the

sample temperature rose and the part became burned. We then performed the other combination of HF and IR heating with FD (HF+IR→HF). Drying with HF+IR was carried out in the initial stage, and infrared irradiation was cut off when the sample temperature began to rise. As the result, the temperature rise of the sample was suppressed, and it was possible to shorten the drying time almost the same as HF+IR drying.

Drying of frozen agar supplemented with sucrose or NaCl was performed by combining electromagnetic wave heating, and Figure 4 shows the relationship between the drying time  $t_d$  and the final temperature of the samples. We then performed the preliminary approach to quantitatively confirm the differences of the drying characteristics of each sample. For the additive free sample under the FD process without the assistance of HF and/or IR heating, the time course of the normalized water content was fitted using the following simple

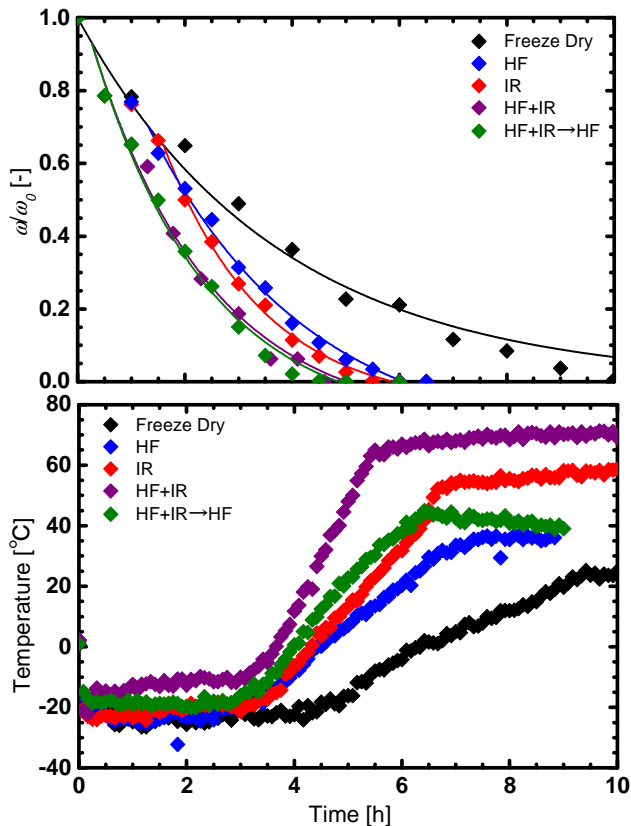

Fig. 3 Time courses of normalized water contents and temperatures of frozen agar gel (no additive).

exponential equation.

$$\omega/\omega_0 = \exp(-kt) \quad (1)$$

Here,  $t$  and  $k$  are the drying time and the drying rate constant, respectively.

For the other samples, the curve fitting for the time courses of the normalized water content was carried out using the following equation which modified Eq. (1) from the middle of the drying process [6].

$$\omega/\omega_0 = \left\{ \left( \omega/\omega_0 \right)_s - 1 \right\} + \exp\{-k_1(t - t_s)\} \quad (2)$$

Here,  $t_s$  and  $(\omega/\omega_0)_s$  are the start point of the exponential curves for parallel translation of Eq. (1). An intersection of both curves expressed by Eq. (1) and (2) means the critical point of the drying characteristic.  $k_1$  is the drying rate constant for the latter exponential curve. We could then calculate the drying time  $t_d$  based on Eq.(2).

As indicated in Figure 4, for the samples added sucrose as an organic substance, the effect of shortening the drying time was more pronounced for IR heating assistance than for HF heating assistance. In addition, for the samples added NaCl as an electrolyte substance, no significant difference was observed in the time reduction effect by HF and IR heating assistance, but the dry sample temperature was lower for HF heating assistance than in for IR heating assistance.

Fig. 4 Relationship between dried sample temperature and drying time.

### 3.2. Electric power consumption during drying process

We also measured the electric power consumption during each drying process. Figure 5 illustrates the relationship between the electric power consumption and the drying time. It was confirmed that the power consumption could be reduced by shortening the drying time with the assistance of electromagnetic wave heating. In addition, based on the near-infrared spectroscopic imaging results of the dried samples (data not shown), it was experimentally confirmed that the component changes of the dried samples except for those dried under the HF+IR drying conditions could be negligible. Consequently, from the experimental results indicated in Figure 3, 4 and 5, the effectiveness of the assistance of electromagnetic heating to vacuum FD of the food model was experimentally found.

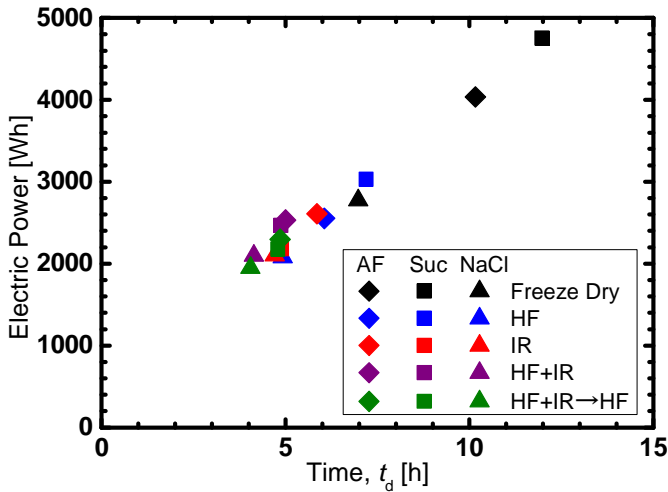

Fig. 5 Relationship between electric power consumption and drying time.

## 4. Conclusions

By controlling the combined use conditions of HF and/or IR heating for each sample component, drying time could be shortened. Additionally, a vacuum freeze drying process could be optimally designed by combining electromagnetic wave heating with the reduction of electric power consumption and without the quality change of the dried sample.

### **Abstract**

*Flavor release from powders depends on the glass transition temperature ( $T_g$ ) and water absorption. This study reports a simple method to estimate the apparent  $T_g$  by aroma sensing upon flavor release from spray-dried powders. Four different wall materials (maltodextrin (MD), MD blends with fructose at 20 and 40wt%, and yeast cells) were used to encapsulate flavors by spray-drying. The apparent  $T_g$  values of MD and MD with 20 and 40wt% fructose were determined as 130, 110, and 75 °C, respectively, similar to those calculated by the Gordon–Taylor equation. The slow flavor release from dried-yeast powder afforded the highest  $T_g$ .*

**Keywords:** yeast; flavor; encapsulation; spray drying; aroma sensor.

---

## 1. Introduction

Spray drying is a unique technique to encapsulate active compounds. The rapid drying rate, availability of the instrumentation, and continuous operation processing make spray drying a widely useable technique in the encapsulation field. Additionally, good quality powders and high flavor-retention powders can be obtained by spray drying. Encapsulation is the entrapment of an active material inside a wall material. The encapsulation of flavors in solid powders has great benefits as it can reduce the volatility losses, protect from adverse environments, and increase their shelf-life and stability. The encapsulation efficiency differs vastly among different wall and core materials. The glass transition temperature ( $T_g$ ) is a key property that affects the release of flavors from encapsulated powders.[1] Chirife and Karel[2] and Roos and Karel[3] have described how flavor retention or release from amorphous matrices may be due to the transformation of said amorphous matrices from a glassy to a rubbery phase. They highlighted two causes for this transition: an increase in the moisture content and an elevated temperature. At the  $T_g$ , the molecular movement in the powder increases and the amorphous material changes from a glassy to a rubbery state, with consequences of stickiness and collapse of the powder.[4] Furthermore, the stickiness of the powder observed at the  $T_g$  results in poor quality and low yields during drying, and handling and storage problems.[5] Therefore, the determination of the  $T_g$  of wall materials is very important for application in encapsulating powders. Usually, the glass transition temperature is measured by differential scanning calorimetry (DSC). However, the determination of  $T_g$  values by DSC is very difficult due to the small changes in the heat capacity near the  $T_g$ .

In this study, a method for the measurement of the  $T_g$  of flavor-encapsulated spray-dried emulsified powders and yeast powders is proposed using a simple instrument named aroma sensor. The rapid increment in flavor release from the encapsulating powders was monitored using a ramping method (linear programmed temperature gradient).

## 2. Materials and Methods

### 2.1. Materials

Drum-dried yeast cells, *Saccharomyces cerevisiae* cells (partially  $\beta$ -glucan extracted), were obtained from Fuji Foods Corp. (Yokohama, Japan). Maltodextrin (MD, DE = 19) and fructose (Fr) were kindly donated by Matsutani Chemical Industries, Ltd. (Itami, Japan). Sodium caseinate, the emulsifier, was received from Mitsubishi-Chemical Foods Corp. (Tokyo, Japan). The flavors, i.e., the core materials, hexanol, *d*-limonene, and ethyl hexanoate were purchased from Wako Pure Chemical Industries, Ltd. (Osaka, Japan). All

other chemicals were of analytical grade and obtained from Wako Pure Chemical Industries, Ltd. (Osaka, Japan).

## 2.2. Methods

### 2.2.1. Preparation of *d*-limonene and ethyl hexanoate-encapsulated yeast powders

*d*-Limonene and ethyl hexanoate were encapsulated in yeast cells following the method described by Sultana et al.[6]

### 2.2.2. Preparation of hexanol-encapsulated emulsified powders

Three different powders were prepared by changing the MD-to-Fr ratio in the feed solution. Powders of MD (100%) and blends of MD and Fr at ratios of 4:1 and 3:2 were prepared using a pilot spray dryer Ohkawara-L8 (Ohkawara Kakouki Co., Ltd., Yokohama, Japan) equipped with a centrifugal atomizer. Feed solutions were prepared by dissolution of MD or its blends with Fr (38.5 wt%) together with sodium caseinate (1.5 wt%) and hexanol in medium chain triglyceride (MCT) oil (10 wt%) in distilled water (50 wt%). The solid content was maintained at 50 wt%. Hexanol was diluted in MCT oil at a ratio of 1:4 (% wt). The mixture was homogenized using a mechanical homogenizer, a polytron homogenizer (PT-10, Kinematica GA, Littau, Switzerland), at 8000 rpm for 3 min. Finally, the carrier solution was spray-dried at an inlet air temperature of 160 °C, atomizer speed of 10,000 rpm, and feed flow of 20 mL/min. The outlet temperature was monitored at 83–106 °C.

### 2.2.3. Analysis of the *d*-limonene and ethyl hexanoate extracted from yeast powder

The encapsulated *d*-limonene and ethyl hexanoate were extracted from yeast cells and analyzed by gas chromatography following the procedure described by Sultana et al.[7]

### 2.2.4. Analysis of hexanol from flavor-encapsulated powders

The flavor-encapsulated powder (0.1 g) was completely dissolved in 5 mL of distilled water in a glass bottle. Diethyl ether with cyclohexanone (5 mL of 1000 ppm) was added as the internal standard and the mixture was vortexed for 20 min at 20 °C in a high speed shaker (CM-1000, Tokyo Rikakikai Co., Ltd., Tokyo, Japan). After centrifugation, a small amount of anhydrous sodium sulfate was added to the upper phase and 1 µL was injected in a gas chromatograph-mass spectrometer (GC-MS, Shimadzu Corp., Kyoto, Japan). The GC-MS

## Estimation of the apparent glass transition temperature of spray-dried emulsified powders and yeast powders by their flavor release behavior under temperature ramping conditions

was equipped with a fused silica capillary column (30 m × 0.25 mm × 0.25 μm; DB-1, Agilent Technologies Japan Ltd., Tokyo, Japan). The column temperature was programmed from 80 to 260 °C at a rate of 3 °C/min and from 260 to 300 °C at 20 °C/min, where the temperature was maintained constant for 28 min.

### 2.2.5. Measurement of the apparent $T_g$ of flavor-encapsulated powders with aroma sensor

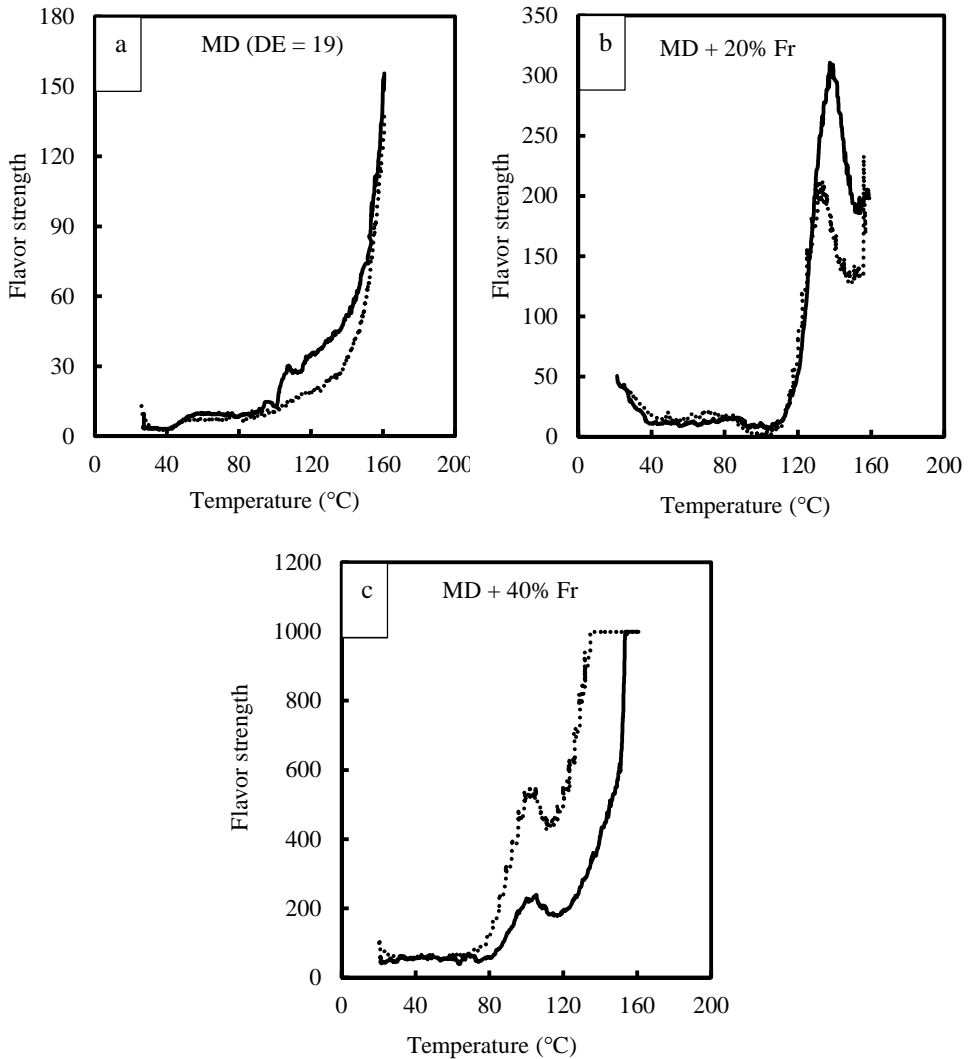

The flavor-encapsulated powder (1 g) was placed in a glass vessel (24<sup>d</sup>×45<sup>h</sup> mm) and covered with a rubber cap. The cap of the glass vessel had holes for two needles, one for nitrogen supply and the other one for air sampling. The air sampling port was connected to a handheld odor meter (KANOMAX, OMX-SRM model, Kobe, Japan) through a polyurethane tube (PISCO, Okayama, Japan). The released flavors were detected by the aroma sensor. A nitrogen flow rate of 30–50 mL/min was maintained depending on the aroma strength of the sample. To determine the aroma strength of the encapsulated yeast powder, a Tee connector was connected to the tube from the sampling vessel to the sensor to dilute the flavor concentration. The vessel was placed in an aluminum block on a digital plate heater, which was used to control the temperature of the powder at two different ramp rates (0.5 and 1 °C/min). The powder temperature was recorded with a data logger. The data filing software OMX-SRM was installed in the computer to collect the released flavor data during the whole process. The apparent  $T_g$  was the intercept temperature of the tangent line in the flavor release plot.

## 3. Results and Discussion

### 3.1. Measurement of the apparent $T_g$ of emulsified flavor powders

The moisture content of the emulsified flavor powders was below 2%, whereas the retention of encapsulated hexanol in the MD (DE = 19) and MD with 20 or 40 wt% Fr samples was about 100%, 70%, and 65%, respectively. Figure 1 shows the hexanol release behavior of the emulsified powders with the increasing temperature at rates of 1 and 0.5 °C/min. The flavor strength gradually increased with the temperature, even though the flavor strength was very low near 20 °C. However, the strength of the flavor sharply increased at a certain temperature, indicating the glass transition temperature of the wall material. The apparent glass transition temperature is the intercept point of the tangent line for the hexanol release rate (flavor strength detected by the aroma sensor). The apparent glass transition temperature of the MD (DE = 19) and MD with 20 and 40 wt% Fr containing powders were determined to be around 130, 110, and 75 °C, respectively.

**Fig. 1** Hexanol release behavior of emulsified powders: (a) maltodextrin (DE = 19), (b) MD with 20 wt% Fr, and (c) MD with 40 wt% Fr (solid lines: 1 °C/min; dotted lines: 0.5 °C/min).

It can be seen that the addition of Fr to MD reduces its glass transition temperature. The low  $T_g$  of pure Fr, which was reported by Roos[8] to be 5 °C, reduces the apparent  $T_g$  of the wall material. It must be noted that the  $T_g$  values for the above mentioned powders calculated using the Gordon–Taylor equation are very similar to the experimental values shown in the graphs.

### 3.2. Measurement of the apparent $T_g$ of flavor-encapsulated yeast powders

**Fig. 2** Release behavior of (a) ethyl hexanoate and (b) *d*-limonene from yeast powders (solid lines: flavor strength; dotted lines: retention of flavor).

Figure 2 illustrates the release behavior of ethyl hexanoate and *d*-limonene from yeast cells with the increasing temperature at 1 °C/min. The initial high flavor strength possibly corresponds to the surface flavor of the yeast powder. After that, the flavor strength decreases to finally increase again at very high temperatures (180–190 °C). The complex structure of yeast, i.e., the presence of different sugars, proteins, and others species, hampers the accurate monitoring of the flavor release. To confirm the apparent  $T_g$  of the flavor-encapsulated yeast powders, *d*-limonene and ethyl hexanoate were extracted from yeast cells under ramping temperature conditions (at 1 °C/min) and analyzed by GC-FID. The retention of the encapsulated flavor was calculated following the method by Sultana et al.[6] The obtained intercept point was very similar to the apparent  $T_g$  value found using the aroma sensor. The presence of trehalose, sucrose, and other sugars in yeast cells may be the reason behind the high apparent  $T_g$  of yeast cells.

## 4. Conclusions

The apparent glass transition temperatures of flavor encapsulated spray-dried powders were successfully determined using an aroma sensor. The apparent  $T_g$  of powders composed of MD (DE = 19) and MD with 20 and 40 wt% Fr were approximately 130, 110, and 75 °C, respectively. The increasing temperature rate did not significantly affect the  $T_g$  of the encapsulating powders. In contrast, yeast cells exhibited a slower release of flavors and higher  $T_g$  value.

### **Abstract**

*In this paper, hot air drying (HAD) was applied when moisture content of apple slices range from 50% to 86%, and then vacuum-filling nitrogen drying (VFND) was used till moisture content reaching 7%. Results showed that, the drying rate of apple slice during VFND period increased with temperature increment and decreased with increment of slice thickness; compared to freezing dried samples, samples dried in this research were owned lower Vc and higher flavonoid; when HAD (70°C, 3.0m/s)+VFND(relative pressure 0.08MPa, 50°C) and thickness of 6.0mm, nutrients reached better levels: retentions of Vc, total phenolics and flavonoid were 1.63mg/100g, 4.07mg/100g and 2.10mg/100g, respectively.*

**Keywords:** *apple slices, hot air drying, vacuum-filling nitrogen drying, drying rate, nutrients*

## **1. Introduction**

Apple is a main fruit in many countries. As the results from Wang and others, till 2013, the annual production of fresh apple fruit in China is about 39.7 million t, accounting for 49% of the global production<sup>[1]</sup>. Fresh apple fruits are usually graded for higher economic benefit. Fresh apples with the better quality would just be fresh consumed while the apples with the poor quality are generally used to produce juice, jam, and dried products for examples apple chips or nature apple powder and so on. Drying process of apple is a better way to prolong storage. And the main drying techniques used to dehydrate apple slices include FD, HAD, VD, HAD combined VD, and so on. HAD apple slices is the conventional technology studied widely in the past two decades<sup>[2-4]</sup>, however, browning and oxidation even hardening happened during HAD<sup>[5-7]</sup>, which induced undesirable quality. Freeze drying can produce perfect quality dried fruits and vegetables<sup>[8,9]</sup>, but it also high energy consumption. So, various combine drying methods applied to dry fruit and vegetable appear in recent years. Hazervazifeh et al. studied combined microwave-hot air and other drying methods dehydration of apple slices and found that, microwave power 2000W at 70°C with the air velocity of 2.0m/s can induce the minimum drying time<sup>[10]</sup>. However, fruit and vegetable dried by microwave combined hot air does not always maintain the better quality, for example low rehydration<sup>[11]</sup>. Huang and others investigated effects of combined drying methods on composition, aroma, eating quality of apple slices<sup>[12]</sup>; in their studies, freeze-drying, freeze-drying + microwave vacuum drying and microwave vacuum drying + freeze-drying were used to dry apple slices; and the results showed that, microwave had significant effects on aroma, total phenols and pectin, and longer drying time high temperature at desorption drying stage and short time higher temperature at microwave vacuum drying period during freeze-drying + microwave vacuum drying induced lower retention of both aroma and reducing sugar. It was proved that vacuum drying can afford a low oxygen environment and the retention of various nutrients in vegetables and fruits could be better. Nitrogen is an inert gas and if it was filled with vacuum drying circumstance, it may be induce dried products with better quality.

The aim of this work is to study the drying characteristics of HAD + VFND dried apple slices and the quality of apples slice including retention of vitamin C, total phenolics and flavonoid. For this purpose, experiments of apple slices dried after HAD and then dried in VFND under different conditions were conducted and nutrients were also determined.

## **2. Materials and methods**

### **2.1. Samples preparation**

Fresh apples *malus pumila* mill were obtained from local market and stored at 3-4°C in a refrigerator and were used within 14 days. The initial moisture contents of fresh apples were within 85 to 87% (wet basis), which were determined by hot air oven method at 103-105°C until the constant mass. Samples were sliced to the thicknesses of 2.0-8.0mm after peeling and then immersed into 0.2% ascorbic acid solution for 2minutes to restrain browning.

## 2.2. Hot air drying

Apple slices were dried with hot air at 70°C with the velocity of 3.0m/s after immersed into 0.2% ascorbic acid solution for 2 minutes and the moisture contents were declined from about 86% to 50% w.b. During hot air drying, the weights of samples were obtained by electronic balance with an accuracy of 0.001g every 10 minutes.

## 2.3. Vacuum-filling nitrogen drying

The half dried apple slice samples were dried in vacuum-filling nitrogen drying oven until the moisture contents were about 7% w.b. In vacuum-filling nitrogen drying method, materials were put into vacuum oven, and then vacuuming(10kPa)→filling with nitrogen (near 0.1MPa)→vacuuming(10kPa)→filling with nitrogen (near 0.1MPa)→vacuuming (10kPa). Temperatures were range from 50 to 80°C during VFND. While during vacuum-filling nitrogen drying, the weights of samples were obtained every 20 minutes.

## 2.4. Nutrients assay

Dried apple slices were crushed by a pulverizer, and nutrients in nature apple powder were determined.

In this research, vitamin C was determined by Philin's reagent colorimetry according to the methods of Benassi & Antunes<sup>[13]</sup>and Marfil, Santos & Telis<sup>[14]</sup> with some modifications. Apples powder of 0.500g was homogenized with the extraction solution (2 g oxalic acid/100g solution) and diluted to 50ml with the extraction solution in a volumetric flask, and then vacuum filtered after 30 minutes' standing. Filtrate of 10ml was taken for titration with 2,6-dichlorophenolindophenol solution (50mg 2,6-dichlorophenolindophenol/250ml pure water). When the pink color of filtrate did not disappear in 15s, the titration end point was determined. All analyses were performed in triplicate.

The flavonoid content of apple powder was analyzed according the method described by Jia et al<sup>[15]</sup> with slight amendments. 1.000g apple powder was homogenized with 50ml of ethanol (7:10) for 60 minutes and then vacuum filtrated. 1.0ml of the filtrate was placed in a 25ml volumetric flask, 10ml of ethanol (7:10) and 1ml of NaNO<sub>2</sub>(1:20) were added and shaken well, 10ml of 1 mole per litre NaOH was added after 6 minutes, and the total volume was made up to 25ml with ethanol (7:10). After 15 minutes' standing, this sample was placed in colorimetric tube and the absorbance was measured at 510nm.

Total phenolics content of natural apple powder were determined by the Folin-Ciocalteu method<sup>[16]</sup>. Apple powder of 1.000 grams were added to the ethanol solution with the content of 75% and diluted to 50ml. 5ml of sample was taken into volumetric flask, 50ml of pure water and 4ml of Folin-Ciocalteu reagent were also added. After 3-4minutes' standing, 8ml of 10% sodium carbonate was put into the volumetric flask. And the final volume was made up to 100ml with pure water. After 120 minutes of reaction at 25°C, absorbance at 765nm was measured and used to calculate the phenolic contents using a standard curve prepared with gallic acid. All measurements were conducted in triplicate.

### 3. Results and discussion

#### 3.1. Hot air drying characteristic of apple slice

In this paper, drying rate was expressed as follow:

$$DR = \frac{MC_{t-\Delta t} - MC_t}{\Delta t} \quad (1)$$

Where  $MC_{t-\Delta t}$  and  $MC_t$  represented moisture content at the time of  $t-\Delta t$  and  $t$ , separately, dry basis, %;  $t$  was drying time, min; and  $\Delta t$  was time interval, min.

During HAD apple slices, there existed significant falling rate period, and the constant rate period was obvious for apple slices with the thickness of 2.0mm, while it was not evident for the apple slices with the thicknesses of 4.0-8.0mm, such as figure 1. Because, there exists longer path and greater resistance in the thicker slices for water molecules migrating. Moisture content of apple slices declined more slowly as the increase of the slice thickness.

Fig. 1 Curves of dehydration rate of apple slices with different thicknesses during HAD(70 °C, 3.0m/s)

#### 3.2. Vacuum-filling nitrogen drying characteristics of apple slice

After HAD, apple slices were dried with VFND until the moisture content lower than 7.0%w.b. And there is only falling rate period for apple slices during VFND, showed in figures 2 and 3, owing to bound water in apple slices in this period.

During VFND, dehydration rate of apple slices declined as the decrease of temperatures and the increase of the slices thickness. As the analyzed above, there are the longer path and greater resistance for moisture to transfer to surface in the thicker apples slices. And when the thickness was 2.0mm, the greatest dehydration rate appeared which is approximate twice of that with the thicknesses of 6.0, 8.0mm. The higher temperature, the greater drying rate is for apple slices dried in vacuum-filling nitrogen condition, and it was the same as the results from apple slices vacuum drying<sup>[17]</sup>.

Fig. 2 Drying rate curves of apple slices during VFND with different thicknesses (60°C)

Fig. 3 Drying rate curves of apple slices during VFND at different temperatures (4.0mm)

### 3.3. Nutrients of apple slice dried with combined drying methods

Nature apple powder was made by the dried apple slices dried with different drying methods. And the nutrients of Vc, total phenolics, flavonoid in apple powder were expressed as mg/100g of initial fresh samples, showed in table 1. From table 1, it was found that, retentions of Vc in samples dried with HAD+VFND were lower than that of samples dried with FD, while the retentions of total phenolics of both samples dried with HAD+VFND and FD were at the same levels, and flavonoid retentions of samples dried with combined drying were almost higher to that of FD. Results reviewed that the combined method of HAD+VFND could be an available method for maintain flavonoid and total phenolics of apples; although vitamin C in samples dried with HAD+VFND was lose seriously, just only about 30% to 52% of that in fresh apples. And when HAD at 70°C, 3.0m/s combined with VFND at temperature 50°C, relative pressure -0.08MPa and slice thickness of 6.0mm, nutrients in dried sample were better: the vitamin C content of 1.63mg/100g, total phenolics content of 4.07mg/100g and the flavonoid content of 2.12mg/100g. In generally, it is available for HAD combined VFND to dehydrate apple slice.

Effects of temperatures during VFND period on vitamin C retention of apple slices dried with HAD+VFND showed in table1. It was clearly found that, when the temperature was set 50 °C during VFND period, vitamin C content of samples dried with combined method was higher than others. Because, vitamin C is heat sensitive material and is decomposed seriously as the increase of the drying temperature<sup>[18]</sup>. However, the difference of vitamin C among all samples was not obvious when apples were sliced with different thicknesses.

Total phenolics in apple slice slightly declined with the increase of slice thickness. As thickness of apple slice became greater, drying time was longer that mean samples were exposed to high temperature condition for longer time, and it would induce lower retention of total phenolics.

Retention of flavonoid in samples was decreased firstly and then increased with the increase of slice thickness, showed in table1. When slice thickness was 2.0mm, flavonoid retention in

apples slice was decreased with the increase of temperature, while the result was on the contrary when slice thickness was 8.0mm. The main reasons were that, it took short drying time to reach moisture content safe level when slice thickness was 2.0mm at different drying temperatures during VFND period, and lower temperature can keep flavonoid at better level; however, the drying time became longer when slice thickness was 8.0mm at all temperatures, especially at lower temperature, that means samples were exposed in the high temperature condition for long time.

#### 4. Conclusion

In combined drying method of HAD+VFND, the drying rate of apples slice in VFND period was significantly affected by thickness and temperature. Retention of total phenolics and flavonoid in both samples dried with HAD+VFND and FD were at same levels although vitamin c was lower in samples dried with combined method. VFND might be an available drying technique for resisting oxidation reaction during drying process of fruits and vegetables.

### **Abstract**

*An alternative as to offer higher stable and easy handling than fresh fruit is in powdered form, as long as the process used to obtain it ensures a high quality product. The objective of this study was to compare the bioavailability of the vitamin C of a juice prepared from powdered grapefruit obtained by freeze-drying and by spray-drying. A trial was conducted with 11 healthy volunteers. A relative increase of 1,4 – 25,8 % of blood serum vitamin C concentration was quantified after juices intake, with no significant differences ( $p>0.05$ ) due to the process used to obtain the powder.*

**Keywords:** *vitamin C; bioavailability in humans; grapefruit powder; freeze-drying; spray-drying.*

---

## **1. Introduction**

Consumer attention is currently focused on healthy eating habits. Fruit juices can be clearly included in a healthy diet as they contain different health-promoting bioactive compounds, mainly vitamin C and phenolic. Nevertheless, consumer also looks for high quality, stable and ease to handle foods. In this sense, fruit powder may be an interesting alternative to offer a juice after being rehydrated. Different techniques can be used to obtain food powder, freeze-drying and spray-drying being the most commonly used as they offer very high quality products. A lot of studies, too much to be cited in the context of this manuscript, have been carried out to evaluate the impact of different food processes on the product quality. In fact, many processes have been optimized taking into account these quality aspects. Nevertheless, the studied quality attributes are related to the composition, physical, chemical or biochemical properties or sensory aspects, among others. Nonetheless, we have not found any study investigating the impact of the processes on the bioavailability of the bioactive compounds potentially responsible for the functional value of foods.

The biological functions of vitamin C depend upon its ability to act as an electron donor. Among these it acts as cofactor for a variety of enzymes with critical functions throughout the body, functions as a highly effective water-soluble antioxidant and it is suggested that is involved in the regeneration of vitamin E *in vivo*<sup>[1,2]</sup>. Reported beneficial effects of this vitamin include increased baroreflex sensitivity, improved endothelial vascular function, augmented inotropic and thermogenic response to beta-adrenergic stimulation, decreased systemic inflammation and reduced fluid requirements during recovery from thermal injury, improved fatigue resistance, increased iron bioavailability and decreased risk of cardiovascular diseases<sup>[3,4,5]</sup>. Severe vitamin C deficiency produces scurvy. Despite humans are unable to synthesize their own vitamin C, it must be easily obtained from the diet, principally through a adequate fruit and vegetable consumption<sup>[1]</sup>.

The research on which this study is part, started with the comparison of freeze drying (FD) and spray drying (SD) as two drying technologies with which to obtain grapefruit powder with the lowest water content, hygroscopicity, luminosity, color change and the highest content of total phenolic, total carotenoids, vitamin C and antioxidant capacity, despite the highest powder yield<sup>[6]</sup>. In that study, response surface methodology (RSM) was used to evaluate the effect of three process variables on the different mentioned properties. The considered process variables were the amount of gum Arabic and bamboo fiber added to prevent the powder stickiness, also as the feed inlet water content or the inlet air temperature in the case of FD and SD processes, respectively. The conclusion of that study was that FD might be proposed as a better technology than SD with which to obtain grapefruit powder with a higher vitamin C and total carotenoids content. Taking these

results into account, the aim of the present study was to investigate if there was a different impact of the previously optimized FD and SD processes on the bioavailability of the vitamin C.

## 2. Materials and Methods

### 2.1 Tested grapefruit products

The volunteers who participated in the trial consumed two grapefruit juices. They were obtained by rehydration of the grapefruit powder obtained by freeze-drying (FDJ) and by spray-drying (SDJ) of a previously formulated grapefruit mix. The same grapefruit (*Citrus paradise* var. Star Ruby) batch, purchased in a local supermarket (Valencia, Spain), was used to obtain both powdered products which were processed taking into account the optimum conditions proposed in the previously mentioned study<sup>[6]</sup>. Briefly, peeled and grounded grapefruit was mixed with 4.2 g GA + 0.6 g BF/100 grapefruit pulp to obtain FDJ or with 4.3 g GA + 2.1 g BF/100 liquidized grapefruit to obtain SDJ. No shelf temperature was applied during FD and inlet air temperature for SD was 120 °C. FD cake was crushed to obtain a powder which was vacuum packed and freezing stored until used. SD powder was stored in the same conditions. The vitamin C content of the grapefruit batch used in the study, analyzed as described below, was 41.8 mg /100g pulp.

Each powder was rehydrated in the day of the trial, two hours before being given to the participants. The amount of water to be added to the powder was calculated in order to ensure a juice which offers the same amount of grapefruit own's solutes present in the grapefruit batch used for the study. The corresponding mass balance was applied to this end, taking into account the water mass fraction of the grapefruit, the amount of GA and BF added to the prepared mix and the water mass fraction of the obtained powders.

### 2.2 Research participants

Ethical approval for the trial was obtained from the Ethics Committee of the Universitat Politècnica de València (Valencia, Spain). The trial was conducted with a total of 11 healthy volunteers from different countries of South America and Europe, who met the inclusion and exclusion criteria established for the study. Inclusion criteria included age within the range of 18–40 years, with a normal body mass index (BMI between 19 and 29 kg/m<sup>2</sup>). Exclusion criteria included smokers and people with special dietary habits (vegetarians, vegans, macrobiotics, etc.), allergic to any food, pregnant or with intention to be in the trial period, medicated (includes dietary supplements: vitamin, protein, etc.),

suffering infectious diseases by blood (positive serology for hepatitis B virus and C or human immunodeficiency virus), presenting some picture of intestinal malabsorption, suffering metabolic diseases (diabetes, dyslipidemia, thyroid disorders, etc.) and suffering cardiovascular or kidney diseases (high blood pressure, renal insufficiency, etc.). All the 11 selected participants signed the corresponding informed consent after being explained about the nature, purpose and risks of the study.

### **2.3 Experimental design and blood sample collection**

A crossover design was considered for the clinical trial. With this design, each research participant consumed both juices, obtained from FD and SD rehydrated powders, in different time periods separated by 15 days. One of the advantages of crossover designs in contrast to parallel ones is that the former could yield the same level of statistical power or precision with a lower sample size, as each subject serves as his/her own matched control, thus blocking the variability due to the subjects.

All the participants in the study were cited on two different days, one for FDJ consumption and another one for SDJ. Each day, each subject underwent a first overnight fasting blood test and another one 4 h after having drunk 400 g of the corresponding juice which was given with no meal. They were not allowed to eat anything in the 4 h between extractions. Two blood samples from each participant were collected into BDVacutainer SSTII Advance Tubes (REF 367953), that were allowed to coagulate for 30 min and after centrifuged at 20 °C and 1500 x g for 10 min to separate the serum which was analyzed in its vitamin C content. Serum concentration of ascorbic and dehydroascorbic acids, as related to grapefruit juice vitamin C bioavailability, was analyzed by means of HPLC as described below. The mean value (and standard deviation) of the two tubes of each subject was considered as the corresponding result.

### **2.4 Vitamin C analysis**

The total vitamin C content of the grapefruit batch used for the study was analyzed as described by Igual et al.<sup>[7]</sup> and Xu et al.<sup>[8]</sup>. The same methodology slightly modified was used to quantify the total vitamin C content present in serum. Briefly 0.5 mL serum was mixed with 1 mL of a 20 g/L DL-dithiothreitol solution for 2 h at room temperature and in darkness. Afterwards, 1 mL of this mixture was extracted with 2.25 mL 0.1% oxalic acid for 3 min and immediately filtered through a 0.45 mm membrane filter before injection. The HPLC conditions were: Ultrabase-C18, 5 mm (4.6 x 250 mm) column (Análisis Vínicos, Spain); mobile phase 0.1 % oxalic acid, volume injection 20 mL, flow rate 1 mL/min, detection at 243 nm and at 25 °C. A standard solution (Panreac, Spain) was prepared.

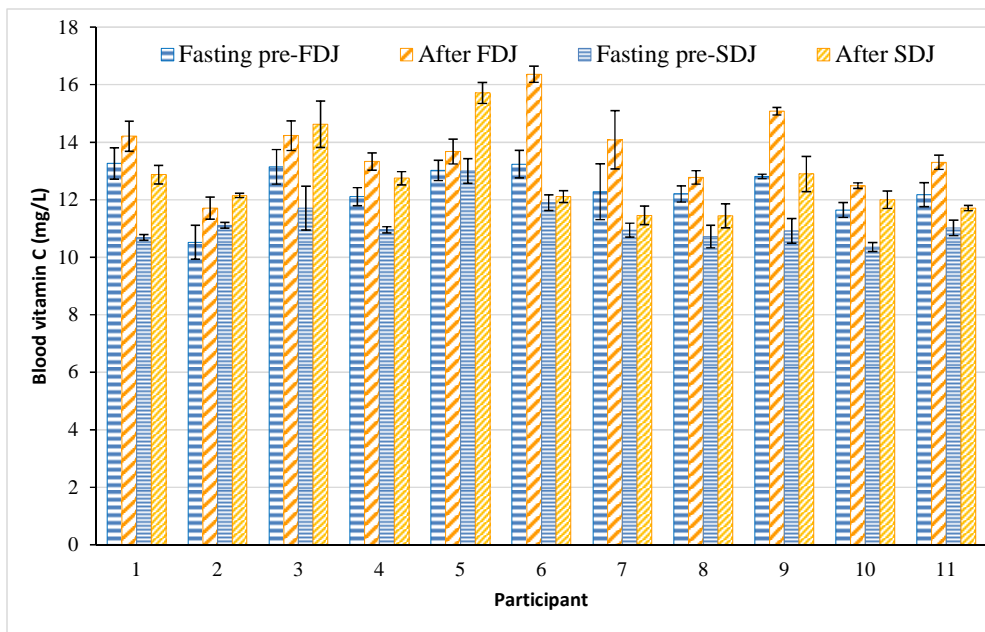

## 2.5 Statistical analysis

The difference in serum vitamin C concentration before and after the juices intake was considered as the response variable, taken as a measurement of the juice vitamin C bioavailability. A multifactor analysis of variance was performed for this response variable taking into account the factors individual and juice, with a total of 11 individuals and 2 juices tested. Statgraphics Centurion XVI.II for Windows was used for the statistical analysis.

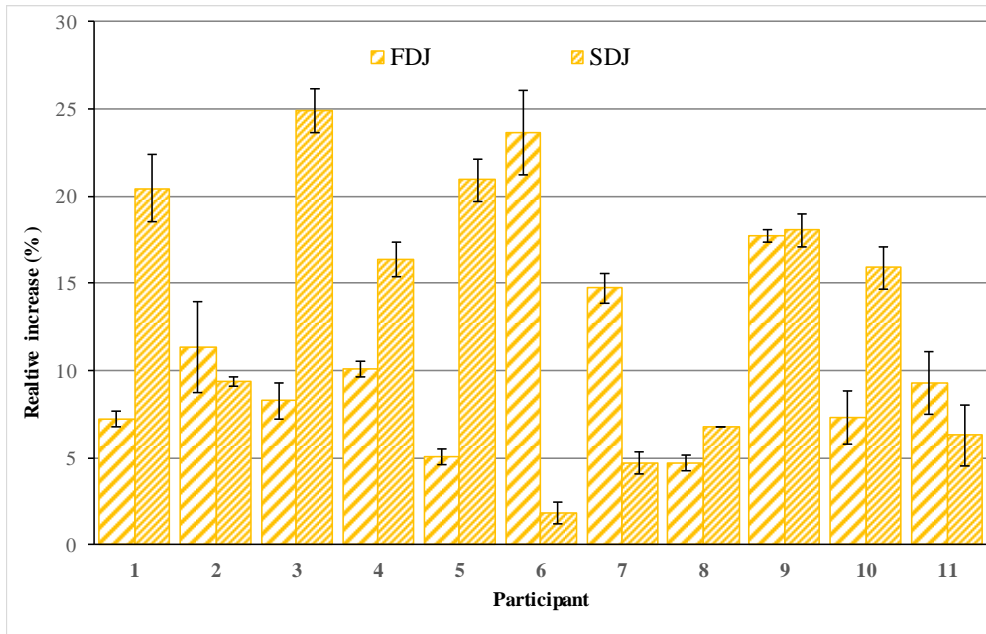

## 3. Results and discussion

Figure 1 shows the vitamin C concentration found in blood serum. The fasting serum vitamin C values of the participants in the trial varied between 10.1 and 13.6 mg/L. As expected from the country of habitual residence of the participants, all of them were above the adequate level of plasma vitamin C (i.e.  $50 \mu\text{mol/L}^1 = 8.80 \text{ mg/L}$ ), with any hypovitaminosis case detected.

**Fig. 1.** Mean value and standard deviation of serum blood vitamin C concentration analyzed in the participants the days of consuming reconstituted freeze-dried (FDJ) and spray-dried (SDJ) juices, both fasting and 4 h after the intake of each juice.

The level of vitamin C in the blood serum of all the participants in the trial increased after the ingestion of each juice, the level reached varying between 11.1 and 16.6 mg/L (Fig. 1). This increase, compared to the basal fasting level, evidenced the absorption of vitamin C from juices. When comparing the circulating concentration of vitamin C fasting with the one 4 h following the ingestion of the juices, an increase between 0.17 and 3.27 mg/L was observed. The increase related to the fasting level, for each participant, is shown in Figure 2, this relative increase being in the range 1.4 – 25.8 %.

**Fig. 2. Mean value and standard deviation of the relative increase of serum blood vitamin C concentration suffered by the participants due the intake of reconstituted freeze-dried (FDJ) and spray-dried (SDJ) juices.**

Taking into account the average values of the 22 relative increase values considered, for each of the 11 people on the day of the intake of each of the juices, only three times the relative increase in the concentration of vitamin C in blood compared to fasting baseline was below 5%. In eight cases this increase was between 5 and 10%, in three between 10 and 15%, in four between 15 and 20% and in four between 20 and 25%. In order to compare the blood vitamin C increase caused in each participant by FDJ and SDJ ingestion, an ANOVA was carried out with the factors juice and individual. No significant differences ( $p>0.05$ ) were observed in any case. In this way, the mean 10.85 % relative increase of blood circulating vitamin C in the participants in the trial caused by FDJ ingestion was not

significant different ( $p>0.05$ ) to the mean 13.23 % detected after SDJ ingestion (standard error 2.5). As far as the individuals is concerned, the mean relative increase caused by the two juices tested was not significant different ( $p>0.05$ ) in any of them, the lowest relative increase being 5.7 % and the highest 17.9 % (standard error 0.06). In this way a relative increase of vitamin C in blood due to juices intake of 12% can be assumed as a grand mean of the 22 average values considered.

#### **4. Conclusions**

Vitamin C present in juices prepared by rehydration of grapefruit powder obtained by freeze-drying and by spray-drying is absorbed by the human body, without differences in its bioavailability due to the different process applied to obtain the powder.

### **Abstract**

*Fruit is a highly valuable food whose consumption should be encouraged. In addition, it would be desirable to design processes and products to channel the surplus and take advantage of the post-harvest losses that limit its fresh marketing. Freeze-drying is a known industrial process that permits the obtaining of high quality products, despite having always been labeled as very expensive. In this study, the economic feasibility of freeze-drying to obtain powdered fruit has been proven, as it yields a product more than twice as cheap as when obtained by spray-drying, recognized for its low cost.*

**Keywords:** *freeze-drying; spray-drying; economic profitability; production costs*

---

## **1. Introduction**

The influence of climatic conditions on fruit production makes seasonal surpluses an inherent characteristic of the sector. In addition, they are highly perishable foods that in the phases of post-harvest, storage and transport lose a part of their properties, which limits their fresh consumption. Last but not least, a great deal of fruit is lost both in wholesale and household waste. In this sense, preventing the waste of fruit becomes a challenge for society. For this reason, it seems appropriate to propose viable new processed fruit products, so that their surpluses are used and the consumption of this food is promoted. Freeze-drying is a dehydration technique that allows high quality products to be obtained, ones which are highly stable and very easy to handle, in terms of their greater ease of transport and storage. However, this process has always been labeled as a very expensive one. Spray-drying also allows high quality powder to be obtained from food. An important difference between the two processes is that freeze-drying may take advantage of all the edible part of the fruit in the form of a puree, whereas the liquidized fruit is required for the spray-drying, with the consequent generation of a greater quantity of by-products. In both cases, the obtained powdered product will be of great microbiological, chemical and biochemical stability. However, it could present important physical problems related to the glass transition of its amorphous matrix. In the rubbery state, the structural collapse of the amorphous matrix occurs. In the case of powdered products this leads to phenomena such as stickiness development<sup>[1]</sup>. To avoid this problem, the incorporation of high molecular weight biopolymers as stabilizers is suggested<sup>[2]</sup>. In this context, the research team involved in this study has worked towards obtaining powdered fruit by freeze-drying and spray-drying. In this sense, the amount of biopolymers to be added has been optimized in order to obtain a powdered grapefruit with a high product yield and also of high physical, nutritional and functional quality<sup>[3]</sup>. The obtained results allow freeze-drying to be put forward the propose as a better technique than spray-drying for the purposes of obtaining high quality fruit products. However, from the perspective of the commercial viability of new products, it is essential to consider the final consumer cost, dependent on both the initial investment and the cost associated with its production. Thus, it seems necessary to perform an economic analysis by comparing both processes, which was the objective of the present study.

## **2. Materials and Methods**

The industrial processes considered in this study were freeze-drying and spray-drying. The raw material needed to carry out both of them were grapefruit (*Citrus paradisi*, var. Star Ruby), gum Arabic (GA, Scharlab) and bamboo fiber (BF, Vitacel® BAF 200). Water was also needed in the case of spray-drying.

## **2.1. Quantification of the initial investment**

To quantify the initial investment, the machinery necessary to implement both processes was considered. To select the different equipment needed in each case, the estimated product production volume was considered, as were its technical characteristics and price. In order to propose the necessary amount of powder product, it was assumed that its final use was to be rehydrated for the purposes of obtaining a fruit juice. In order to fix the fruit juice to be obtained, the average annual production of refrigerated juice by a company located in the Valencian Community between 2009 and 2014, 87 t, was selected as a reference value. The amount of raw material to be processed by each process was calculated taking into account the amount of powdered product needed to obtain the 87 t of rehydrated juices<sup>[4]</sup>. The most appropriate and economical machinery was selected from what was proposed by the different manufacturing companies and consequently dimensioned.

## **2.2. Production cost analysis**

Variable and fixed production costs were calculated. Variable costs depend on the quantity of product produced and include raw material, personnel costs, electrical costs and the management of by-products (grapefruit peel, pulp and water removed from fruit). The fixed costs are independent of the quantity produced and include maintenance and amortization, calculated according to the straight-line method, which consists of dividing the machinery acquisition value by the useful life according to the technical information.

## **2.3. Investment analysis**

To calculate the minimum cost of the product, a static analysis was carried out, comparing income and expenses and equalling the profit to zero. On the other hand, to calculate the price that provides a minimum profitability, a dynamic analysis was carried out. A discount rate calculated as the sum of a risk-free rate plus a risk premium was used. As a risk-free rate, the average of the 10-year bond yield on the primary market, issued by the Spanish government in 2016, was taken, this being 1.6%. As a risk premium, 5.5% was considered. These data were obtained from a study carried out in 2015 on 41 countries<sup>[5]</sup>. Therefore, the assumed discount rate was 7.1%.

### **3. Results and discussion**

#### **3.1. Selected machinery**

To prepare the sample for freeze-drying, an industrial automatic-feeding knife peeler (1000 - 1100 grapefruit/h). was selected. The selected crusher was a hammer mill with vertical axis (1500 kg/h). The grinding process does not generate waste because the hammers of the mill disintegrate the particles until they reach the right size. For the sample to be spray-dried, a high-performance centrifugal liquidizer was chosen. This machine guarantees a quick process so that product oxidation is minimized. In this case, obtaining the liquidized product generates a by-product in the form of grapefruit pulp. According to the technical characteristics of the selected equipment, for each kilo of fruit that enters the liquidizer, 0.383 k of pulp and 0.617 k of liquidized fruit are obtained. The obtained by-product has been supposed to be commercialized. For both processes, a horizontal shaft vane mixer was selected to incorporate the biopolymers and the water into the puree or the liquidized fruit, thus achieving a better product homogenization.

Due to the characteristics of the sample and the estimated production volume, two freeze-dryers based on conduction heat transfer and a centrifugal spray-dryer were chosen. In the case of freeze-drying, this process was estimated to require 24 hours of operation to sublimate the water correctly<sup>[3]</sup>. For this reason, two freeze-dryers have been considered working in parallel so that they can operate continuously every day. In the case of the spray-dryer, as the one that most suited the required volume of powder production actually has a higher production capacity, the corresponding operational costs were refitted to the latter in order not to discriminate by oversizing it.

For the packaging of the obtained powdered products, an opaque material of very low water vapour permeability was selected, so as to prevent the humidification and destruction of photosensitive compounds, such as vitamin C. The selected packaging machine allows different formats to be used. A mono-dose (44.5 g of powder) and another one for the HORECA channel (379 g of powder) were chosen. These quantities respond to the powder needed to obtain a glass of juice of 125 cm<sup>3</sup> and 1100 cm<sup>3</sup>, respectively.

#### **3.2. Production costs**

To obtain the 87 t of juice assumed as the reference value, 26,551 kg of powder obtained either by freeze-drying or by spray-drying need to be rehydrated. The corresponding raw material required (grapefruit, GA, FB and water) and its cost was calculated by taking into account the yield of each selected machine and our own preliminary experiences<sup>[4]</sup> (Table

1). Assuming the price of the raw materials, according to commercial data (0.73 €/kg grapefruit, 78.9 €/kg GA, 2.5 €/kg FB and 0.0025 €/kg water), the total annual costs were 771,309.27 and 2,704,407.92 € for freeze-drying and spray-drying, respectively. As can be observed in Table 1, the total cost of the raw material needed for the spray-drying process is 3.5 times higher than for freeze-drying. The former has a much lower powder yield than the latter, especially due to the powder loss that occurs in the spray-dryer itself. A significant part of the powder remains adhered to the walls and nozzle of the equipment. For this reason, the fruit cost of spray-drying is 6 times that of freeze-drying.

**Table 1. Daily needs (Dn) and annual cost (Ac) of raw materials for freeze-drying (FD) and spray-drying (SD) processes**

	<b>Grapefruit</b>	<b>GA</b>	<b>BF</b>	<b>Water</b>
Dn FD (kg/day)	654,1	20,60	2,94	147
Dn SD (kg/day)	3885	57,03	28,52	1425,8
Ac FD (€)	174.281,76	593.207,37	2.685,85	134,29
Ac SD (€)	1.035.088,26	1.641.998,13	26.020,51	1.301,03

The total cost in machinery for each technology is presented in Table 2. The initial investment in machinery is 1.4 times higher for the spray-drying than for the freeze-drying process, even though a freezer is used for freeze-drying and two freeze-dryers are required working in parallel. The spray-dryer and the 2 freeze-dryers account for 96% and 94% of the total machinery investment in each process.

**Table 2. Variable and fixed production costs and product price in monodose and HORECA format**

	<b>Freeze-drying</b>	<b>Spray-drying</b>
Electric costs (€)	354.861,65	41.955,41
Raw material costs (€)	770.309,27	2.704.407,92
By-products costs (€)	-658,98	-17.777,56
Personnel expenses (€)	150.970,26	368.494,39
Amortization (€)	55.266,67	73.355,56
Maintenance (€)	97.500,00	130.800,00
Investment in machinery (€)	955.000	1.288.000
Total cost (€)	1.428.248,86	3.301.235,72
Static price mono dose (€/ud)	2,39	5,53
Static price HORECA (€/ud)	17,94	41,47

The electrical cost is usually one of the highest in this type of industry. To calculate the total electrical cost, it is necessary to calculate the energy cost due to electricity

consumption and the contracted power cost that is necessary for the machines to operate. To calculate the electrical cost, the consumption of each selected machine, the number of machines needed in each stage, the working hours per machine and the power were considered (Table 2). For these calculations, an electricity tariff was selected which considers different prices of the kWh depending on whether it is a weekday or weekend and also on the operating hours of the day. When comparing the electrical costs of both processes, it can be affirmed that freeze-drying has an annual consumption that is 8.5 times higher than spray-drying.

Amortization is an economic term referring to the distribution over time of a durable value, with a maximum linear coefficient, or a maximum percentage regulated in the accounting that is allowed to amortize annually, of 12%. The annual amortization has been calculated based on the quotient between the price of the machinery and its useful life. The useful life was considered to be what was specified in the technical characteristics of each machine, except in the case of the freeze-dryer and the spray-dryer. As there were no data available for these equipment, the accounting useful life was considered, this being 18 years according to the provisions of Law 27/2014, of November 27. The amortization of the spray-dryer was 1.3 times higher than that of the freeze-dryer (Table 2). This is due to the fact that the machinery used in the spray-drying technique has a higher cost than what was used for freeze-drying. Again, the freeze-dryer and the spray-dryer are the machines with the highest cost in amortization, due to the much higher acquisition cost of these equipment.

As regards by-products, there are two that could be exploited by other companies: the grapefruit peel after both processes and the pulp that is separated when liquidizing in the case of spray-drying. In these cases, it has been considered that the peel and pulp can be sold at 0.015 and 0.025 €/kg, respectively, according to the average price provided by various companies in the sector. Taking into account the volume of the generated by-products, their sale would provide the income that is observed in Table 2. Thus, the only thing that would cause a real cost would be the discharge of water. Therefore, there is really no a net cost in the management of by-products, but an income that, in the case of spray-drying, is 26 times higher than the income obtained from the management of by-products generated with the freeze-drying.

### **3.3. Minimum price of the product: static analysis**

The total annual cost of the spray-drying technique is 2.3 times higher than that of freeze-drying (Table 2). Figure 1 shows the percentage represented by each item over the total cost. The maintenance and amortization expenses in the case of spray-drying are 1.34 and 1.32 times, respectively, those of freeze-drying. This is because of the greater initial

investment in machinery. In addition, the personnel cost needed to obtain the spray-dried powder is 2.4 times that of the freeze-dried, while the electrical cost for the spray-drying process is 8.5 times lower than for freeze-drying. Such a great difference is due to the need for a vacuum in the case of freeze-drying and the operating time per kg of the fresh product. The highest cost in both processes is that of the raw material, which is 54% and 82% for freeze-drying and spray-drying, respectively. This difference is due to the low yield of the latter when working with fruit.

The static price, or the final product cost, in the case of the spray-dried powder is 2.31 times higher than that of the freeze-dried (Table 2). It was calculated for the two formats with which the powder product was considered to be packaged.

*Fig. 1 Percentage of the cost represented by each of the items considered, calculated as related to the total cost of the freeze-drying and spray-drying processes.*

### 3.4. Price of the product that provides a minimum profitability: dynamic analysis

To calculate this price, the internal rate of return (IRR) and the net present value (NPV) were calculated for both the freeze-drying and spray-drying processes. To this end, it is necessary to know the different cash flows that are calculated, in turn, from the extraordinary payments (renovations in machinery originally planned and that are taken as 5% of the value of the machine when new) and ordinary charges (capital inflows from the sale of the product). In this case, we have considered the NPV null hypothesis in order to calculate the price that will result in IRR being 7, which is the same as looking for the price that will obtain a 7% profitability. Thus, for freeze-dried powder, the price is 2.84 and

21.25€ per unit in the mono-dose and HORECA formats, respectively. The corresponding prices for the spray-dried powder is 6.13€ and 45.95€ per unit.

#### **4. Conclusions**

This economic study shows that the application of freeze-drying to obtain powdered fruit provides a product at a cost that is less than half that of spray-drying, a process known for its low cost. The lower cost of freeze-drying is mainly due to the poor yield of spray-drying in the case of fruit processing. Thus, although the electrical costs are 8.5 times higher in the case of freeze-drying, both the cost in raw material and the initial investment in machinery, personnel costs, maintenance and amortization are higher in the case of spray-drying. So much so that the estimated price for a dose of grapefruit powder equivalent to a piece of fruit, for example, would be 2.84 versus 6.13 euros depending on whether it was obtained by freeze-drying or by spray-drying, respectively.

### **Abstract**

*Freeze-drying may be a good alternative to get less perishable fruit products. The objective of the present study was to evaluate the impact of freeze-drying conditions of an orange puree on some flow related and rehydration properties of the obtained powders. The results showed that the application of heat during freeze-drying does not affect the parameters studied. However, the partial dehydration of the initial sample results in a lesser porosity and wettability values.*

**Keywords:** *freeze-drying; porosity; wettability; angle of repose; particle size distribution.*

## **1. Introduction**

Fruits are basic foods and of great interest in human nutrition. The benefit of fruit consumption in health seems to be related to the presence of various compounds that belong to the group of phytochemical or bioactive substances. The daily consumption of fruits, in sufficient quantity and in a well-balanced diet, helps to avoid serious diseases, such as heart disease, cardiovascular accidents, diabetes and cancer, as well as deficiencies of important micronutrients and vitamins<sup>[1]</sup>. However, the consumption of fruit has declined gradually in recent years, since they have changed the eating habits of society. Despite the great benefits of fruit consumption, two major problems limit its availability, its seasonality and its short shelf life.

The orange is the fruit of the sweet orange tree that belongs to the genus *Citrus* of the Rosacea's family. Its nutritional composition highlights its low energy value, thanks to its high water content and its high content of vitamin C, folic acid and minerals such as potassium, magnesium and calcium. It contains appreciable amounts of beta-carotene, responsible for its typical color and known for its antioxidant properties, in addition to malic, oxalic, tartaric and citric acids, which enhance the action of vitamin C. The amount of fiber is appreciable and this is found mainly in the white part between the pulp and the bark, so that its consumption favors the intestinal transit. The orange has been selected as the object of this study because it is one of the most typical products of the country. Due to the great production that exists, Spain has become one of the largest producers of orange in the world and an asset for export. For this reason the orange represents a product of great importance in the economy of the country.

Currently, new alternatives for the development of less perishable products are being proposed. Powdered products represent a good option as healthy foods, lengthening the useful life of the product and facilitating its transport. Freeze-drying is a technology that consists of dehydrating the freeze product at low pressure. The process does not require the application of high temperatures, however its high cost has limited its use in the food industry. Therefore, the main interest is to find alternatives to minimize energy consumption, in order to decrease the process cost preserving the quality of the product. In this study, two options are proposed for this purpose, as they are the partial dehydration of the feed food and the application of heat during the process. However, this may affect the characteristics of the obtained powder in terms of the size and density of the particles, their porosity and surface properties, among others. In turn, these characteristics will determine the characteristic flow and / or rehydration behavior of a powder. Taking into account all of the above, the objective of this work was to know the impact of a pre-dehydration treatment and of the application of shelf temperature while the freeze-drying of a formulated orange puree on the properties of the obtained powder.

## 2. Materials and Methods

### 2.1. Raw material and formulation

Orange (*Citrus x sinensis* var. Navelina) always acquired in the same chain of supermarkets in Valencia was used for the study. To obtain the orange puree, the fruit was washed, peeled, cut and crushed in a food processor (Thermomix TM 21, Vorwek, Spain). Gum Arabic and bamboo fiber (5 and 1 g, Shauriau-Vitacel, respectively) were added to 100 g puree and homogenized with the same food processor. The °Brix of the mixture were measured (Refractometer Mettler Toledo 30Px), this being 17 °B. A part of this orange formulation, named O, was reserved. The rest of the sample was partially dehydrated (Moulinex Ultimys Duocombi, 600W) by heating in short period times until the sample reached 22 °B. This partially dehydrated orange formulation was named OD.

### 2.2. Freeze-drying

Each formulation was placed in aluminium plates, 1 cm thickness, and freeze in a LIEBHERR MEDLINE equipment at -45 ° C for 48 hours. The freeze-drying step was carried out in a Telstar Lyo Quest 55 equipment operating at -50 °C in the condenser and at 0.063 mbar, for 48 hours. Samples O and OD were freeze-dried with the shelves at room temperature and sample O was also freeze-dried at 40 °C in the shelf (sample O40).

### 2.3. Obtaining powder

The cakes obtained from the freeze dryer were crushed in a food processor (Thermomix TM 21, Vorwek, Spain), at speed 5 for 20 s to obtain a powder. Batches of about 40 g of the powder were sieved through 800 µm mesh, with the corresponding top and bottom placed, to select the particles lower than this size which were characterized in the properties described below. A vibrating drum (AMP0.40, CISA, Barcelona, Spain), 50 Hz, for 5 minutes was used to this end.

### 2.4. Particle size distribution

A batch of about 40 g of the obtained powder lower than 800 µm was again sieved in the same vibrating drum and conditions. The mesh of the sieves used in this case were 500, 300, 200, 150 and 100 µm, with a top and a bottom placed in the column of sieves. The powder collected in each sieve and in the bottom was weighed.

### 2.5. Angle of repose

This is the angle formed between the slope of the product when dropped down from 5 cm height from the horizontal surface. The test consists of pouring 15 g of powdered product in a funnel (top diameter= 80 mm, stem = 11 mm diameter, 29 mm length; Overall height = 85

mm) and measuring the diameter and height of the formed product cone, applying equation (1).

$$\alpha^\circ = \arctan * \left( \frac{2h}{d} \right) \quad (1)$$

where h = height from the top of the formed product cone (cm); d = maximum cone product diameter (cm), taken as an average of at least 6 values.

## 2.6. Wettability

A modified UNE<sup>[2]</sup> standard method for milk powder was used. Briefly 10 g of powder were weighed and dropped progressively (in 25 s) into 250 g of water, measuring the time (s) from when the powder falls until all the particles in the sample have been wetted.

## 2.7. Bulk flow properties

The porosity ( $\epsilon$ ) was calculated from the true and bulk densities by using equation (2). The true density ( $\rho$ ) of the sample was calculated from its individual components. In this case, water and carbohydrates, both own and added, were considered to be the main components of the samples (equation 3). The apparent density ( $\rho_a$ ) was calculated by dropping the sample in a graduated tube until approximately 10 mL, with the help of a funnel; the weight and volume of the exact sample was recorded. Finally the previous sample was compacted using a vortex (1200 rpm, t = 10 s) and the volume of the sample was recorded again to calculate the value of bulk density ( $\rho_b$ ). Based on these data it was possible to calculate the Hausner Index and the Carr Index by using equations (4) and (5).

$$\epsilon = \frac{\rho - \rho_b}{\rho} \quad (2)$$

$$\frac{1}{\rho} = \frac{x_w}{\rho_w} + \frac{x_{CH}}{\rho_{CH}} \quad (3)$$

$$I_H = \frac{\rho_b}{\rho_a} \quad (4)$$

$$I_C = \frac{\rho_b - \rho_a}{\rho_b} \quad (5)$$

where  $\epsilon$  is the porosity;  $\rho$ ,  $\rho_b$  and  $\rho_a$  (g/cc) are the true, bulk and apparent densities of the powder, respectively; x (w/w),  $\rho_w$  (g/cc) and  $\rho_{CH}$  (g/cc) are the mass fraction and density (20 °C) of water (0.9976 g/cc<sup>[3]</sup>) and carbohydrates (1.4246 g/cc<sup>[3]</sup>), respectively.

### 3. Results and Discussion

The particle size distribution is represented in figure 1. All the samples had the greater proportion of particles with a size lesser than 100  $\mu\text{m}$ . In these range, OD sample stands out above the other two samples.

**Figure 1.** Relative powder particle size distribution ( $\mu\text{m}$ ) obtained from the formulated puree orange freeze-dried at room temperature (O), formulated and pre-dehydrated puree orange freeze-dried at room temperature (OD) and formulated puree orange freeze-dried at 40 °C (O40).

The pondered average size particle of each sample was calculated from powder particle size distribution (table 1). Significant differences ( $p < 0.05$ ) were observed among all the samples, sample OD40 being the one with the greatest average particle size and sample OD the one with the smallest average particle size. Particle size may be related with the fracture resistance of the cake when crushed, the greater the resistance the greater the particle size. The increase in the solutes concentration of the microwave pre-dehydrated sample will lead to a decrease in the freezing rate. In this case, greater ice crystals are expected to be formed. This will suppose to obtain a cake with greater porous size and more fragile. On the other hand, when 40 °C shelf temperature is applied during freeze-drying, the drying of the sample is accelerated. In this case, smaller pores size are formed and a more resistant cake is obtained (data not published).

Measured properties related to powders flowability are presented in table 1. Samples doesn't show significant differences ( $p > 0.05$ ) regarding the angle of repose. The values ranged from 40,35° to 42,51°, which are included among acceptable flow properties<sup>[4]</sup>.

**Table 1. Mean values ( $\pm$  standard deviation) of the properties measured to the powder obtained from the formulated puree orange freeze-dried at room temperature (O), formulated and pre-dehydrated puree orange freeze-dried at room temperature (OD) and formulated puree orange freeze-dried at 40 °C (O40).**

Property	Sample		
	O40	O	OD
Average size particle (mm)	0.210 <sup>a</sup> $\pm$ 0.008	0.1703 <sup>b</sup> $\pm$ 0.0006	0.117 <sup>c</sup> $\pm$ 0.004
Angle of repose (°)	43 <sup>a</sup> $\pm$ 2	40.3 <sup>a</sup> $\pm$ 0.5	41.7 <sup>a</sup> $\pm$ 0.5
Wettability (s)	571 <sup>b</sup> $\pm$ 54	467 <sup>b</sup> $\pm$ 18	1924 <sup>a</sup> $\pm$ 400
Porosity (%)	77.1 <sup>a</sup> $\pm$ 0.6	80.1 <sup>a</sup> $\pm$ 1.4	69 <sup>b</sup> $\pm$ 3
Hausner index	1.124 <sup>a</sup> $\pm$ 0.018	1.11 <sup>a</sup> $\pm$ 0.06	1.20 <sup>a</sup> $\pm$ 0.08
Carr index (%)	11.0 <sup>a</sup> $\pm$ 1.4	10 <sup>a</sup> $\pm$ 5	17 <sup>a</sup> $\pm$ 6

The same lowercase letter within rows indicates homogeneous groups established by ANOVA ( $p < 0.05$ ).

The wetting time is inversely related to wettability, the higher the wetting time the worse the wettability. In this way, the microwave pre-dehydrated sample before freeze-drying (OD, table 1) showed the worst degree of wetting. This probably may be related with the smaller average particle size of this sample<sup>[5]</sup>. The lesser particle size induces the particles aggregation and the lump formation.

It is well recognized that dehydrated products obtained from freeze-drying are highly porous<sup>[6]</sup>. However, it is observed that OD sample, which was microwave pre-dehydrated before freeze-drying, shows a value of porosity much lower than the other two samples (table 1). This may also be related to the smaller average particle size of this sample. It has been observed that porosity decreased with decreasing the particle size, because of the decrease in the inter-particle voids with smaller sized particles<sup>[6]</sup>.

Hausner and Carr indexes indicate the level of interaction between particles and therefore the flow properties. There was no significant differences ( $p < 0.05$ ) between the values of both indexes for the samples. According to the classification of Farmacopea<sup>[4]</sup>, all the samples show an excellent to acceptable flowability.

#### 4. Conclusions

The different freeze-drying conditions used in this study doesn't affect the flowability of the freeze-dried orange powder. Nevertheless, pre-dehydration of the formulated orange puree decreases the mechanical resistance of the obtained cake so that a powder with a smaller average particle size may be obtained. This affects the rehydration capacity of the freeze-dried powder, with increased wetting time. In this sense, 40 °C shelf temperature during

freeze-drying may be recommended in order to short the process time and to get a product with both a good flow behavior and good wettability.

### **Abstract**

*The freeze-drying kinetics and the superficial porosity development of grapefruit puree. The impact of biopolymers addition (gum Arabic and bamboo fiber) and to apply (40 °C) or not shelf temperature (room temperature) was considered. To increase the shelves temperature during freeze-drying allowed to an important drying time reduction and doesn't supposed a lower porosity related to the collapse development of the structure. Biopolymers do not affect the drying kinetics. From this results, biopolymers addition and to heat at least up to 40 °C during grapefruit freeze-drying should be recommended.*

**Keywords:** *freeze-drying; shelf temperature; drying kinetics; image analysis; pore size distribution.*

## **1. Introduction**

The growing consumer demand for expanding the diversity of food products has resulted in a rapid development of the food ingredients market. Most of these food products are supplied in powdered form and the technologies involved in their production are increasingly important, since their quality and functionality strictly correspond to the efficiency of the production processes<sup>[1,2]</sup>. Today, the growing awareness of consumer health is forcing food producers to add natural ingredients to food products. Fruit ingredients in powdered form can be applied in many food and pharmaceutical products to improve their color and taste and, at the same time, to provide the human body with an additional constituent for health promoting<sup>[1]</sup>. The quality of a fruit powder depends to a large extent on the drying / grinding conditions, as well as on the composition and physical properties<sup>[2,3]</sup>. Within this context, freeze-drying emerges as a gentle dehydration technique that represents the ideal process for the production of high value dry products. This technique is known for its ability to maintain the quality of the product (color, shape, aroma and nutritional value) greater than many other drying methods, due both to its low processing temperature as to the virtual absence of oxygen during processing, which minimizes degradation reactions<sup>[4]</sup>. Other prominent factors include the structural rigidity exhibited by the previous freezing of the food, as well as the limited mobility of frozen water, that prevents collapses and contractions of the solid matrix when drying<sup>[5,6]</sup>. The freeze-drying process consists mainly of two stages in which the product is frozen first and then a controlled amount of heat is applied under vacuum (vacuum freeze drying) or at atmospheric pressure (atmospheric freeze drying) to promote an initial stage where the sublimation of ice crystals occurs and a secondary stage where the desorption of the remaining non-frozen water occurs<sup>[2,4-6]</sup>. To improve the control of any dehydration process giving high quality dried products, it is important to have models to simulate drying curves in different conditions<sup>[7]</sup>. It is important to note that the composition of the fruit (for example, pectin, dietary fiber, oligosaccharides, polyphenols) influences the degree to which the fruit can be transformed into a powder. In this sense it is necessary to point for the low glass transition temperature ( $T_g$ ) exhibited by the dried fruit products<sup>[8]</sup>. To exceed the  $T_g$  involves the change of the amorphous matrix from a highly stable glassy state to a more unstable rubbery one. In the glassy state structural collapse of powdered products occurs. As in the case of powdered fruit the  $T_g$  is in the range of the room temperature, to add high molecular weight biopolymers is suggested<sup>[8]</sup>. High quality freeze-dried materials are characterized by a low bulk density and high porosity in addition to a minimal shrinkage and negligible collapse. However, it is important to mention that the fraction of the food collapsed during freeze-drying can increase with the heating temperature of the shelf. In fact, many authors have related the most intense contraction exhibited when freeze-drying is carried out at higher temperatures<sup>[9]</sup> and the greater porosity of freeze-dried materials with the lower freeze-drying temperatures<sup>[2]</sup>. The aim of this study was to determine the impact of both to

add gum Arabic and bamboo fiber and to increase the shelf temperature to 40 °C during the freeze-drying of grapefruit puree. The effect on the drying kinetics and the porosity of the obtained product have been studied.

## 2. Materials and Methods

The citrus grapefruit (*Citrus paradise* var. Star Ruby) was purchased in a local market (Valencia, Spain). The fruits were selected according to their size, firmness and absence of physical damage. Biopolymers used to stabilize the powdered product: gum Arabic (GA) Scharlab and Bamboo Fiber (FB) Vitacel® BAF 200.

### 2.1. Sample preparation and process conditions

The peel, albedo and central axis were detached manually from the grapefruit before being crushed (Thermomix Vorwerk TM-21). The obtained product was characterized in its water and soluble solid content (vacuum oven JP Selecta, 60 ± 1°C and pressure <100 mm Hg; Mettler Toledo 30PX refractometer). Two samples of grapefruit puree were prepared, one without the addition of biopolymers (G) and another one with the addition of 4.2% GA and 0.58% FB (GB) (Thermomix Vorwerk TM-21 working at speed 2 for 300 s)<sup>[10]</sup>. Both samples were also characterized in the water and soluble solid content. Samples G and GB were placed in aluminum trays (1 cm thickness, ≈27 g), a pair per sample and after they were frozen (Liebherr LGT 2325) at -45 °C for 6h. The frozen samples were freeze-dried for different times from 1.5 to 21 h in a Telstar Lyo Quest-55 freeze-dryer. The pressure of the chamber (0.09 mbar) was maintained and the temperature of the shelves was varied: without applying heat to the shelves (samples RT, room temperature) and applying 40 °C to the shelves (samples 40). In this way, four samples were processed: G(RT), G(40), GB(RT) and GB (40). Each freeze-drying process was carried out twice. Samples obtained at the different freeze-drying times were weighed (accuracy 0.0001 g). Two images by sample were taken using a Canon EOS 350D digital camera placed in a Kaiser RS2XA, at 23 cm from the sample, and illuminated with a standard white light (6500K). The images were acquired with a focal aperture of 55 mm (Lens EFS 18-55) and in automatic mode.

### 2.2. Modeling of drying kinetics

The drying kinetics was studied on the basis of the mass loss by the samples. The residual water content present in the obtained samples was calculated based on Eq. (1) and used to obtain the moisture ratio (MR) evolution (Eq. 2).

$$X_{wt} = \frac{m_o * X_{wo} - (m_o - m_t)}{m_o * (1 - X_{wo})} \quad (1)$$

$$MR = \frac{X_{wt} - X_{we}}{X_{wo} - X_{we}} \approx \frac{X_{wt}}{X_{wo}} \quad (2)$$

Where  $X_{wt}$ ,  $m_t$ ,  $X_{wo}$ ,  $m_o$  and  $X_{we}$  indicate the water content (g water / g sample, db) and the mass (g) of the freeze-dried sample at time  $t$ , of the sample that enters to the freeze-drier, and of the sample freeze-dried at equilibrium, respectively. The equilibrium water content values are usually very low, and the Eq. 2 is often simplified assuming  $X_{we}=0$  without a significant change in the MR value [11].

Preliminary tests conducted in this study proved that the best fit to our data was obtained with the modified Page model (Eq. 3) [1, 11]. The Matlab R2015b software was used to fit the drying model. For each sample, the MR (Eq. 2) calculated for each freeze-drying experiment was fitted to the model and the mean value of the model constants was considered as the corresponding result.

$$MR = a * e^{-k*t^n} \quad (3)$$

Where  $k$ ,  $n$  and  $a$  are the constants of the model and  $t$  the freeze-drying time (h).

### 2.3. Number and pore size distribution

The pore size distribution was based on the area of the superficial pores formed in the samples. The area of the pores at each freeze-drying time in every sample was analyzed from the images (section 2.1) analyzed by means of the software image J, 1.51g [12,13]. The frequency or number of pores formed of each size was established based on a geometric distribution of the areas containing the minimum and the maximum values found in the image analysis and considering 30 area range. From this data, the mean area of the pores ( $\bar{A}$  mm<sup>2</sup>) at each freeze-drying time was also calculated (Eq. 4).

$$\bar{A} = \frac{\sum_i (A_i * F_i)}{\sum_i F_i} \quad (4)$$

Where  $i$  is each area range,  $A$  is the greatest range area (mm<sup>2</sup>),  $F$  is the pore frequency.

## 3. Results and Discussions

### 3.1 Drying kinetics

The water and soluble solute content of the grapefruit puree used in the study were  $0.876 \pm 0.004$ g water / g sample and  $11.47 \pm 0.12$  °Brix. They changed to  $0.830 \pm 0.001$  g water / g of sample and  $15.23 \pm 0.06$  °Brix after biopolymers addition. For each sample, these water contents were those considered as the corresponding ( $X_{wo}$ ). The change of MR during the

freeze-drying of the different processed samples is presented in Figure 1. As it can be observed, the drying time was greatly reduced when 40 °C shelf temperature was applied.

**Fig.1** Experimental and predicted (modified Page’s model) moisture ratio evolution throughout the freeze-drying of grapefruit samples with (samples GB) and without (samples G) biopolymers added and applying (samples 40) or not (samples RT) heat to the shelves.

Kinetic data were fitted to the modified Page model (Table 1). The  $k$  and  $a$  parameters were lower ( $p < 0.05$ ) when the freeze-drier shelves were not heated, with no significant differences ( $p > 0.05$ ) between the samples with and without biopolymers added. This behavior is related with the enhanced heat transfer promoted when heating the shelves, which is linked to an increased drying rate of the process and a decreased drying time [14,15]. Table 1 shows the drying time needed to achieve a target water content of 0.04 g water/g dry sample (db), this assumed as a normal water content for this kind of products. To heat the shelves just to 40 °C during the freeze-drying considerably reduces the process time up to 52 - 60 %.

**Table 1.** Mean values and standard deviation in brackets of the constants of the modified Page’s model ( $k$ ,  $n$  and  $a$ ). Time needed to reach 0.04 g water/g sample (db):  $t^{0.04}$ . Freeze-dried samples: grapefruit with (samples GB) and without (samples G) biopolymers added and applying (samples 40) or not (samples RT) heat to the shelves.

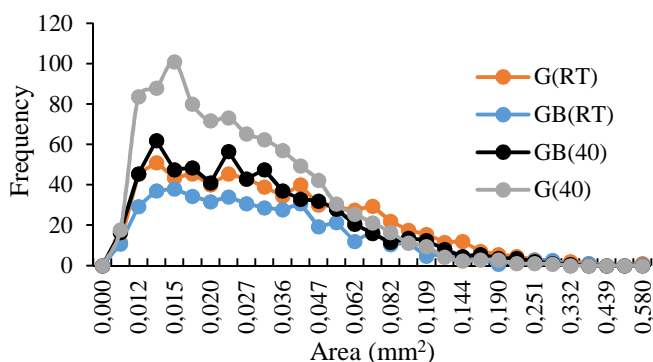

Sample	$k$	$n$	$a$	$R^2$	RSME	$t^{0.04}$ (h)
G(RT)	0.041±0.009a	1.57±0.11b	0.934±0.009a	0.978	0.040	21.8±1.6b
GB(RT)	0.056±0.011a	1.41±0.08ab	0.941±0.009a	0.964	0.046	23.6±1.0b
G(40)	0.25±0.04b	1.31±0.10a	0.993±0.003b	0.993	0.018	10.4±1.6a
GB(40)	0.20±0.01b	1.42±0.10ab	0.996±0.002b	0.994	0.016	9.5±1.5a

(\*) Adjusted regression coefficient ( $R^2$ ), root mean square error (RMSE; Different (a, b) letters in columns indicate non-homogeneous groups established by the ANOVA ( $p < 0.05$ ).

### 3.2 Number and pore size distribution

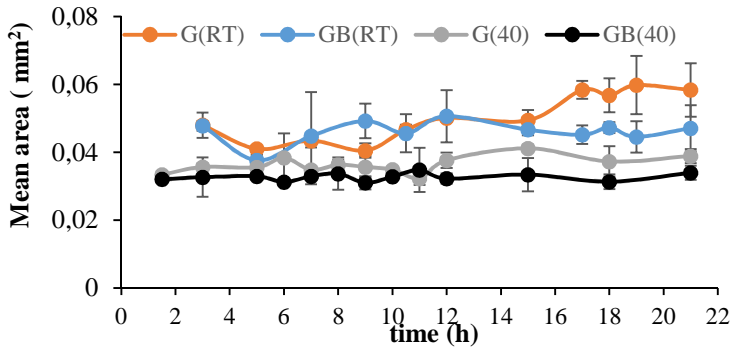

Figure 2 shows, as an example, the number of pores of each areas range considered that was formed in samples G(RT) and GB(RT) freeze-dried for 22 h and in samples G(40) and GB(40) freeze-dried for 10 h. These were approximately the times needed to reach a sample with 0.04 g water/ g sample (db) (Table 1). A similar pore number distribution was observed at each studied freeze-drying time (data not shown) which was used to calculate the pore mean area (Fig. 4). As it can be observed in Fig. 3, at each temperature, more pores were formed in samples without biopolymers added. This could be related with a certain cryoprotector effect of the biopolymers, these decreasing the amount of ice formed<sup>[8]</sup>. On the other hand, in samples G or GB, the higher the temperature, the greater the pore number related to the faster drying rate. Taking into account what it was observed visually in freeze-dried samples, the number of pores formed may be related with the firmness of the structure. In this sense the interaction of the added biopolymers with the own's fruit solutes seems to promote a more compact and firmer structure and a higher drying rate to a weaker one.

For each sample and freeze-drying time, a mean pore size was calculated (Figure 3). As it can be observed, the samples freeze-dried at room temperature showed a greater mean pore size than when heated at 40 °C and, at each temperature, it was greater when no biopolymers were added. In this case, both the biopolymers presence and to increase the drying temperature contribute to decrease the pore size.

**Fig. 2. Distribution of the number of pores (frequency) formed of each area range. Samples: grapefruit with (samples GB) and without (samples G) biopolymers added and heating (samples 40) or not (samples RT) the shelves.**

*Fig. 3 Mean area of the pores formed throughout the freeze-drying time. Samples: GB and G: grapefruit with (samples) and without (samples G) biopolymers added and heating (samples 40) or not (samples RT) the shelves.*

#### 4. Conclusions

To increase the shelves temperature to 40 °C during freeze-drying decreases in more than 50 % the drying time and allows to obtain a sample with more pores formed although these being smallest. The gum Arabic and bamboo fiber added to stabilize the dried product doesn't affect the drying rate although it shows less and smallest pores. As no collapse of any of the obtained samples was observed, to add the biopolymers to grapefruit puree and to heat the shelves to 40 °C during freeze-drying should be recommended.

### **Abstract**

*The effects of saccharide additives on the dehydration and drying properties as well as the quality properties of dried kiwi fruit products were investigated. Sliced kiwi fruits were soaked and dehydrated in citric acid, glucose, sucrose and the pH-adjusted sugar solutions, individually. Osmotic dehydration and drying kinetic parameters were calculated using exponential models. Drying rate constants and water activities of dried kiwi fruits with osmotic dehydration were superior to those without osmotic dehydration. Soaking solutions with a lower pH led to a decrease in lightness. However, soaking solution pH had no significant effect on the water activity or drying kinetics.*

**Keywords:** drying; kinetics; kiwi fruit; osmotic dehydration

---

## **1. Introduction**

Kiwi fruit (*Actinidia deliciosa*) is a popular fruit due to its taste, cost, cooking affinity, nutrition and functional properties. Kiwi fruit is low in fat and sodium, and it is high in organic acids, vitamin C, vitamin E, folic acid, dietary fibre, potassium and polyphenols. Vitamin C, vitamin E and polyphenols show strong antioxidant activities. Additionally, many components in kiwi fruit have a positive effect on human health. Therefore, the consumption of kiwi fruit in Japan has approximately doubled in the last 10 years.

Dried fruit is known to have a long shelf life and has specific texture, taste and functional properties [1-3]. The manufacturing process of dried fruits requires a certain amount of sugar; however, consumers pay attention to their health, and dried fruits with less sugar or without sugar are more desirable. Thus, food companies in Japan have been developing new dried fruit products, such as those with lower calories.

The manufacturing process of dried fruit products involves two main procedures, osmotic dehydration and a drying process. Osmotic dehydration draws water from the fruit and adds a sweet taste by soaking the fruit in a sugar solution [4]. Osmotic dehydration also prevents colour degradation and hardening. Sugar-soaked fruits are then dried in a hot air drying oven or by sun drying. While osmotic dehydration and drying characteristics of fruits are well established [1-4], the addition of pH-adjusted saccharides has rarely been reported in osmotic dehydration and drying processes.

The objectives of this study were to investigate the effect of pH in osmotic dehydration solutions on dehydration and drying properties and to investigate the quality properties of dried kiwi fruit products.

## **2. Materials and Methods**

### **2.1. Osmotic dehydration of fresh kiwi fruit**

Saccharides, such as glucose, sucrose, maltose, citric acid (Wako Pure Chemical Industry, Osaka, Japan), sorbitol, erythritol (B Food Science Co., Ltd., Tokyo, Japan) and trehalose (Hayashibara, Okayama, Japan), glucose and sucrose adjusted to pH 2.0 were selected as soaking solutions for osmotic dehydration.

Fresh kiwi fruits (Zespri, New Zealand) were purchased from a local supermarket. Kiwi fruits were cut into 10-mm-wide slices and weighed. Sliced kiwi fruits were soaked in 60% (w/w) soaking solutions at 60°C for 80 min at 50 rpm in a shaking water bath (Taitec, Saitama, Japan). During soaking, kiwi fruit slices were weighed every 5 min. The kiwi fruit slices were gently wiped with paper towel after soaking.

## 2.2. Drying of osmotic-dehydrated kiwi fruit and kinetic analysis

After osmotic dehydration, the kiwi fruit slices were transferred to a drying oven (WFO-410W, Nakayama Rika, Saitama, Japan) and dried at 80°C for 6 h. During drying, kiwi fruits were weighed every 30 min. Based on the weight changes during drying, moisture content was calculated as the time course of the sample weight and equilibrium dry weight. Drying characteristics were evaluated by several mathematical models. The dimensionless relative moisture content against drying time was plotted as a drying curve. Utilising the drying curves of samples with different osmotic dehydration solutions, kinetic parameters of the most simplified model, known as the exponential model [4], were calculated as follows:

$$MR = (M - M_e) / (M_0 - M_e) \quad (1)$$

$$MR = \exp(-kt) \quad (2)$$

Where MR and M indicates the dimensionless relative moisture content and the certain moisture content,  $M_0$  indicates the initial moisture content,  $M_e$  indicates the equivalent moisture content, k indicates the drying rate constant ( $\text{min}^{-1}$ ) and t indicates the drying time (min). Usually, this model does not provide an accurate simulation of the drying curve for many foods, particularly by underestimating the beginning of the drying curve and overestimating the later stages [5]. Therefore, another exponential model called the Page model was also applied [5,6].

$$MR = \exp(-kt^n) \quad (3)$$

Where n indicates the empirical constant. Equations (2) and (3) were applied to the dimensionless relative moisture content during drying, and the drying rate constant k was calculated using Kaleida Graph 4.0 J (Hulinks, Tokyo, Japan).

## 2.3. Quality analyses of dried kiwi fruit

Several quality factors are important for both consumers and food suppliers; consumers mainly determine product quality based on the colour of dried fruit in a supermarket, while the most important factor for suppliers is the shelf life. We determined the quality of dried kiwi fruits by surface colour and water activity in this study. Colour parameter  $L^*a^*b^*$  (L; lightness, a; green-red, b; blue-yellow) of quarter-cut dried kiwi fruits was measured using a colour metre (ZE2000, Nippon Denshoku Industry. Co. Ltd., Tokyo, Japan). Two-thirds of the cut dried kiwi fruits were fixed in a plastic pan for water activity measurements using

a water activity metre (LabMaster aw, Novasina, Switzerland). All experiments were performed in quintuple, and results are presented as means  $\pm$  standard deviations.

### 3. Results and Discussion

#### 3.1. Colour

The colour of fresh kiwi fruit and dried kiwi fruit with or without (dried control) selected osmotic dehydration was measured (Table 1). Fresh kiwi fruit showed the lowest  $a^*$  value, and fresh and dried control kiwi fruits showed higher  $L^*$  values. Dried samples in which the pH was adjusted to 2.0 showed slightly lower  $L^*$  and  $b^*$  values compared with non-pH-adjusted samples (sucrose, pH 6.0, and glucose, pH 3.8). Dried fruits soaked in citric acid solutions showed the lowest  $L^*$  and  $b^*$  values and the highest  $a^*$  values. Combinations of osmotic dehydration and drying processes led to a decrease in lightness. These results suggest that kiwi fruit's green pigments, such as chlorophyll a and b, melt into the soaking solution during osmotic dehydration and change during the thermal drying process, resulting in a change in the colour of dried kiwi fruits. However, colour changes in dried kiwi fruit soaked in sucrose and glucose solutions were limited, and these products would be more acceptable to consumers.

Table 1. Colour parameters of dried kiwi fruit with saccharide and pH-adjusted sugar solutions

Sample	$L^*$	$a^*$	$b^*$
Fresh	$48.9 \pm 1.6$	$-6.9 \pm 1.0$	$28.4 \pm 1.5$
Dried control (no sugar)	$49.2 \pm 2.9$	$1.5 \pm 0.7$	$30.1 \pm 2.0$
60% sucrose, pH 6.0	$47.0 \pm 2.9$	$1.4 \pm 1.0$	$32.1 \pm 1.8$
60% sucrose, pH 2.0	$45.5 \pm 2.8$	$1.6 \pm 0.8$	$29.5 \pm 1.5$
60% glucose, pH 3.8	$45.6 \pm 3.9$	$1.8 \pm 1.0$	$30.3 \pm 2.7$
60% glucose, pH 2.0	$43.9 \pm 3.0$	$1.6 \pm 1.2$	$29.7 \pm 1.8$
6% citric acid	$37.2 \pm 2.5$	$3.8 \pm 0.9$	$23.9 \pm 2.0$
60% citric acid	$35.0 \pm 2.6$	$7.9 \pm 1.1$	$21.3 \pm 2.2$

#### 3.2. Water activity

The water activity in food products is a well-known index of storability. While the water activity of dried kiwi fruit without osmotic dehydration was 0.61, those of osmotic-dehydrated samples ranged from 0.43 to 0.49 (Table 2). The shelf life of a food product at a given water activity may vary depending on the structure and composition of the food material, and spoilage is a concern. Microbial activity, enzyme reaction, browning reaction and lipid oxidation are strongly dependent on water activity. In this study, the microbial activities, such as those of bacteria, yeast and mould, and enzyme reactions were limited

when the water activity ranged from 0.43 to 0.49. These results indicate that osmotic dehydration with sugar (including pH-adjusted samples) improves the shelf life.

**Table 2. Water activity of dried kiwi fruit**

Sample	Water activity
Dried control (no sugar)	0.61 ± 0.08
60% sucrose, pH 6.0	0.49 ± 0.02
60% sucrose, pH 2.0	0.48 ± 0.01
60% glucose, pH 3.8	0.48 ± 0.01
60% glucose, pH 2.0	0.47 ± 0.01
6% citric acid	0.47 ± 0.03
60% citric acid	0.43 ± 0.04

### 3.3. Kinetic analysis of drying

Based on the weight changes during drying, the moisture content was calculated as the time course of the sample weight and equilibrium weight. Then, the dimensionless relative moisture content against drying time was plotted as a drying curve. The most simplified model was applied to the drying curves. The lowest drying rate constant of dried kiwi fruit was observed in the control (Table 3). In contrast, osmotic-dehydrated samples showed higher values than the dried control (Table 3). The pH-adjusted dried samples had values similar to those of non-pH-adjusted samples. Moreover, dried samples with a citric acid solution showed lower values than those with sucrose or glucose.

Osmotic dehydration with saccharide solutions enhanced drying. However, the soaking solution pH did not have any apparent effect on the drying characteristics. A lower soaking solution pH would destroy the internal structures of kiwi fruit, such as membranes, and once membranes are destroyed during osmotic dehydration and drying processes, the internal structure of kiwi fruit will easily shrink. Therefore, the drying rate constants of lower pH samples did not increase compared with those without a pH adjustment.

**Table 3. Drying rate constants of dried kiwi fruit**

Sample	Drying rate constants (min <sup>-1</sup> )
Dried control (no sugar)	0.0045 ± 0.0001
60% sucrose, pH 6.0	0.0059 ± 0.0001
60% sucrose, pH 2.0	0.0062 ± 0.0005
60% glucose, pH 3.8	0.0062 ± 0.0005
60% glucose, pH 2.0	0.0063 ± 0.0001
6% citric acid	0.0055 ± 0.0001
60% citric acid	0.0058 ± 0.0007

### **3. Conclusions**

We investigated the effects of saccharide additives on dehydration–drying kinetics and the quality properties of dried kiwi fruit. Drying rate constants and water activities of dried kiwi fruits with osmotic dehydration were superior to those without osmotic dehydration. Soaking solutions with a lower pH led to a decrease in lightness. However, soaking solution pH had no significant effect on the water activity or drying kinetics. The combination of sugar and citric acid for a single soaking solution would enable to investigate a novel physicochemical and taste parameters. Further analysis of taste characteristics are essential for the dried fruit industry.

### **Abstract**

*The goal of this study was to prove the feasibility of a conical spouted bed dryer for the drying of wastes of almond tree fruit. The drying operating regimes ranges in spouted beds contactors were determined. The drying tests were conducted in the spouted bed regime under determined experimental conditions. Beds consisting of almond shells were dried at drying air temperatures ranging from room temperature to 140 °C. The drying behaviour was assessed based on the decrease in moisture content of almond shells with the time and the effect of drying air temperature on the drying process was analyzed.*

**Keywords:** *Almond shells wastes; conical spouted beds; biomass wastes; drying*

---

## 1. Introduction

World energy consumption has increased by 28% in 2017 and renewable fuels are the world's fastest-growing energy source, predicting an increase of 2.3%/year between 2015 and 2040 [1]. Biomass is a key renewable resource, which supplies 14% of the world's energy consumption. Since biomass wastes usually have high moisture content, in order to increase the yield of thermal valorization of these wastes, it is advisable to reduce the moisture content previously.

Almond nut production annually generates more than 4,800 dry tons of by-products per 1,000 acres of harvested almond trees [2]. This biomass wastes including shells, hulls, and pruning, composed mainly by cellulose, lignin and hemicelluloses are suitable for energy production. The most common treatments for these wastes are landfills, compostage, recycling and direct burning [3]. However, there is little research of energy uses for waste from almond processing including gasification, pyrolysis, and combustion or co-firing [2]. World production of almonds was estimated about 3.2 million tonnes in 2016, being the United States the largest producer with 2 million tonnes. Spain is the second world's almond producer, with a yearly production around 200 thousand tonnes [4]. Almond shell is the hard layer between the hull and the almond nut, which protects the almond from insects while on the almond tree (*Prunus dulcis*).

Spouted beds technology can be an appropriate alternative for energy exploitation of renewable biomass wastes, with a previous reduction of moisture content of biomass wastes by drying, due to the high mass and energy transfer. Conical spouted beds have been applied for drying biomass wastes such as agricultural wastes [5-6], vineyard pruning wastes [7] sludge wastes [8-11], of yeast [12].

## 2. Materials and Methods

The experimental unit used, Fig. 1, comprises a conical dryer, a blower, two high efficiency cyclones, an electrical preheater and thermocouples. The conical dryer (Fig. 1) made of AISI-310S stainless steel is externally insulated to reduce heat loss, has an angle of 36°, base diameter of 0.03 m and inlet gas diameter to inlet dryer diameter ratio,  $D_o/D_i$ , 1/2, 2/3 and 1. The geometric factors of this dryer are listed in Table 1.

The drying air velocity was determined by the air flow rate measured by mass flowmeter, installed at the inlet pipe, and controlled by a computer to an accuracy of  $\pm 0.5\%$ .

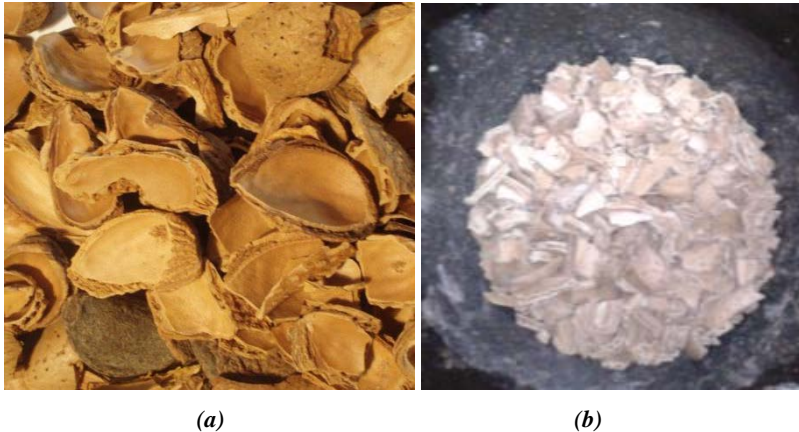

**Fig. 1** Schematics of the experimental plant and of the conical spouted bed dryer with an outline of solid particles movement in the spouted bed regime.

**Table 1.** Geometric factors of the conical spouted bed dryer

Conical spouted bed dryer		
Diameter of the cylindrical section	$D_c$ (m)	0.23
Cone angle	$\gamma$ (deg)	36
Gas inlet diameter	$D_o$ (m)	0.015, 0.02 and 0.03
Diameter of the cone bottom	$D_i$ (m)	0.03
Upper diameter of the stagnant bed	$D_b$ (m)	$D_i + 2 H_o \tan (\gamma/2)$
Height of the conical section	$H_{cone}$ (m)	0.31
Stagnant bed height	$H_o$ (m)	between 0.03 and 0.20
Thickness of the dryer wall	$X_{steel}$ (mm)	2
Thickness of the insulation	$X_{ins}$ (mm)	14

During the drying process, solids were sampled by a suction pump, and the solids moisture content was measured by Mettler Toledo HB43-S Halogen hygrometer. Room temperature, the relative air humidity and air humidity at the inlet and the outlet were measured using Ahlborn MT8636-HR6 thermal conductivity detectors (accuracy  $\pm 2\%$  relative humidity). The drying air temperature was measured by a K-type thermocouple (relative error: the greater  $\pm 0.75\%$  or  $\pm 2.2^\circ\text{C}$ ) located at the inlet to the dryer.

Biomass wastes studied, Fig. 2, were almonds shells. In the industry almonds are washed before peeling. Almonds shells have a density of  $1220 \text{ kg/m}^3$ , particle sizes 5-8 mm and moisture content 25-30 wt%. Bed masses of almond shells used are 100-400 g. Solids moisture content is measured by Mettler Toledo HB43-S Halogen hygrometer (accuracy  $\pm 0.01 \%$ ).

*Fig. 2 (a) Grinded wet almond shells wastes inside the feeder. (b) Grinded dry almond shells wastes inside the conical spouted bed dryer.*

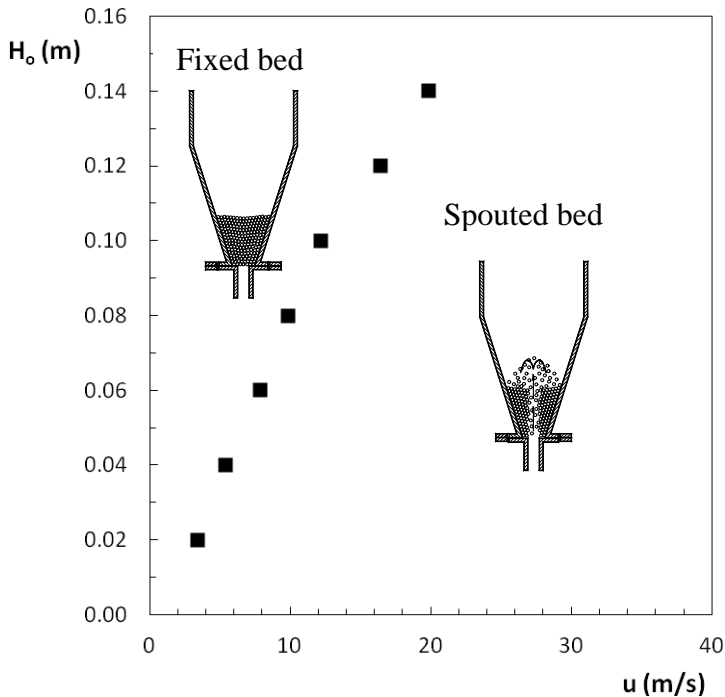

### **3. Results and discussion**

The performance of conical spouted beds for drying of beds formed from almond shells and operation conditions at inlet gas temperature at room temperature and at  $105 \text{ }^\circ\text{C}$  have been established in this paper. Likewise, the evolution of solids moisture content has been measured with the time, and effect of operating conditions on drying time has been analyzed.

In order to prove the feasibility of the conical spouted bed dryer for thermal exploitation of almonds shells, the range of the stable operating regimes of homogeneous beds formed from wastes of almond shells was determined. The minimum air flow rate necessary to achieve the spouted bed regime was characterized by pressure drop fluctuations with a standard deviation less than  $10 \text{ Pa}$  [13]. The experimental values of minimum air velocity corresponding to the spouted bed regime are shown in Fig. 3 for beds consisting of wastes of almond shells with stagnant bed height ( $H_0$ ) in the range of 0.02-0.14 m along with an outline of solid particles in the stagnant bed and in the spouted bed regime for a system taken as example. Starting in the stagnant bed, increasing stagnant bed height, the air velocity necessary to reach the spouted bed regime increases, therefore the velocity operating range over the minimum spouting flow is narrower. The spouted bed regime is

reached in all studied systems, characterized by the vigorous cyclic movement as is shown inside the conical dryer, Fig. 1.

With the aim of determining the drying behaviour of the conical spouted bed dryer, beds consisting of the almond shells waste were dried under different experimental conditions.

**Fig. 3 Operating map of stagnant bed height versus the gas velocity. Experimental system:  $\gamma=36^\circ$   
 $D_o=0.03$  m, almond shells of  $d_s=5.6$  mm.**

The experimental results for the time evolution of the moisture content of almonds shells,  $X$ , from the initial moisture content of 40 wt % (d.b.) to the equilibrium moisture content are plotted in Fig 4 for a bed consisting of 400 g of wet almond shells with drying air temperatures of 25 and 105 °C. The air flow rate, was high enough, so that the outlet air humidity was lower than saturation humidity, resulting in a driving humidity gradient. The drying process was assumed concluded when the difference between two consecutive measurements of solids moisture content did not exceed  $\pm 0.05$  wt%.

At the beginning of the process the decrease in the moisture content is more pronounced, almost proportional, controlled by evaporation of free moisture. At the end of the drying process, variation of almond shells moisture content is asymptotic until the moisture content reaches its equilibrium value.

**Fig. 4** Time evolution of the moisture content of a bed of almond shells. Experimental system:  $\gamma=36^\circ$ ;  $D_o=0.03\text{ m}$ ,  $M=400\text{ g}$ ,  $d_s=5.6\text{ mm}$ , initial moisture content 33 wt % (d.b.),  $u=1.10\text{ u}_{ms}$ ;  $T=25$  and  $105\text{ }^\circ\text{C}$ .

As the inlet air temperature is increased, the solids moisture content decreases faster, with shorter drying time to reach the moisture equilibrium content, which depends on the inlet air temperature and the relative humidity. In drying of almonds shells, as inlet air temperature is increased 80 °C, from 25 to 105 °C, drying time is decreased by around 75% from 60 to 15 minutes.

#### 4. Conclusions

The feasibility of a conical spouted bed equipment for thermal exploitation of almond shells wastes by drying in the spouted bed regime has been proven at low air temperatures. The range of operating regimes beds consisting of almond shells has been determined under different experimental conditions.

The moisture content of almond shells decreases almost proportionally with time from the initial moisture content to equilibrium moisture content, and this diminishing is more noticeable at the beginning of the drying process, at high moisture content. The drying time

to reach the equilibrium moisture content decreases with increasing drying air temperature around 75% with a temperature increase of 80 °C.

### **Abstract**

*The purpose of this study was to determine the effects of convective air-drying at different temperatures (35, 50, 60 and 75°C) on the color of Bifurcaria bifurcata (BB) seaweed powders obtained after milling, the antioxidant activity and polyphenolic and carbohydrate content of the aqueous extracts obtained by ultrasound-assisted extraction. BB seaweed powders exhibited significant color differences between powders obtained from BB dried at 35°C (yellowish-green) and 50–75 °C (brown). High air drying temperature (above 60°C) significantly reduced the total polyphenolic, carbohydrate content and scavenging activity of aqueous extracts of BB.*

**Keywords:** *Phaeophyceae Antioxidant activity Carbohydrates Color Polyphenols*

## 1. Introduction

The safety and toxicity issues related with synthetic antioxidants [1] can explain the increasing interest in natural antioxidants to replace synthetic additives in foods or nutraceuticals. Natural antioxidants are effective in protecting the body against damage caused by Reactive Oxygen Species (ROS) and extending the storage time of food. They have the capability not only to improve oxidative stability but also to provide a wide variety of additional health benefits [2]. They inhibit or prevent the oxidation of a substrate and evolve to protect biological systems against damage induced by ROS.

It has been demonstrated that antioxidant compounds from seaweeds have health benefits such as antimutagenic, anti-viral, amelioration of diabetic complication, bactericides, etc. Some types of polyphenols and tannins (*i.e.* phlorotannins) have strong antioxidant activities, and they are abundant in brown macroalgae [2]. Regarding the potential uses of brown seaweeds, due to their interesting antioxidant properties, it is necessary to study how the processing (including operations such as collection, preservation (drying) and storage, among others) affects the biological activity of certain compounds. Traditionally, seaweeds are sundried for long periods and the final properties can be altered. The current increase of marine algae production rates requires the application of faster and controlled industrial methods. In this sense, in order to overcome the long periods of natural sun drying (days), several alternatives can be useful such as freeze-drying or convective hot air drying, which is the most widely employed method for preserving biological materials, where the air conditions (temperature, relative humidity and velocity) are controlled [3].

Several authors studied the effect of different drying techniques on the antioxidant properties of extracts of different seaweeds such as *Sargassum sp.*, *Kappaphycus alvarezii*, *Gracilaria chilensis*, among others [4,5]. However, no studies assessing the effect of drying conditions on phytochemical properties of *Bifurcaria bifurcata* were found in the literature. Consequently, the main objective of this work is to determine the effect of the air drying temperature on color and phytochemical properties of brown seaweed *Bifurcaria bifurcata*.

## 2. Materials and Methods

*Bifurcaria bifurcata* seaweeds previously dried at 35, 50, 60, and 75°C in a hot convective air dryer were milled in order to obtain seaweed powders. Milling was carried out using a centrifugal mill (ZM 200, Retsch GMBH, Germany). The rotor speed was adjusted to 8000 rpm and a standard sieve (500 µm) was employed. The milled systems obtained at different drying temperatures (BB35P, BB50P, BB60P, and BB75P) were stored at 5°C in polyethylene plastic bags under vacuum with a vacuum-packer (Sammic V201, Spain) for further utilization.

Color of obtained powders and their different particle size fractions obtained after sieving (sieves from 40 up to 500  $\mu\text{m}$ ) was determined using a colorimeter (Chroma Meter CR-400, Konika Minolta, Japan). Color was measured by means of CIELab coordinates:  $L^*$  (whiteness ( $L^* = 0$ ) or brightness ( $L^* = 100$ )),  $a^*$  (redness ( $a^* > 0$ ) or greenness ( $a^* < 0$ )) and  $b^*$  (yellowness ( $b^* > 0$ ) or blueness ( $b^* < 0$ )). Moreover, total color difference parameter ( $\Delta E^*$ , Eq. (1)) for each size fractions (i) was estimated and classified according to [6] using as reference (r) the color coordinates of the seaweed powder prior to sieving (whole).

$$\Delta E^* = \sqrt{(L_i^* - L_r^*)^2 + (a_i^* - a_r^*)^2 + (b_i^* - b_r^*)^2} \quad (1)$$

Seaweed aqueous extracts were obtained from the different dried seaweed powders in order to determine the effect of air drying in total polyphenols and carbohydrate content and the antioxidant activity of seaweeds. Samples of powdered seaweed, were processed with an ultrasound sonicator (Hielscher, UIP-1000 hdT, Germany) to enhance the extraction of polyphenols and carbohydrates. All experiments were carried out in batch. The procedure starting with a rehydration step (15 min) before extraction. Then extraction operation took place using a 200 mL beaker at controlled temperature ( $< 35^\circ\text{C}$ ) employing a cold water bath to avoid that high temperatures could affect the antioxidant activity. All extractions were performed using water as solvent. The equipment operated with a frequency of 20 kHz and the irradiation power ( $< 1000 \text{ W}$ ) was regulated in the ultrasound generator at 80% amplitude. The conditions were 4 min of contact time and 30 w·w<sup>-1</sup> of liquid-solid ratio. Finally, obtained extracts were centrifuged at 12400 rpm for 15 min using a high speed laboratory centrifuge (2-15, Sigma, UK), and the supernatant obtained was then filtered by pressure using syringe filters with a pore size of 0.25  $\mu\text{m}$  and used for characterization analysis. All seaweed aqueous extracts were analyzed by means of DPPH scavenging activity, total solids, polyphenols and carbohydrate content.

The quantitative determination of total polyphenols content (TP) was measured as phloroglucinol (PHL) equivalents following a colorimetric method [7]. TP was evaluated in reference to raw seaweed powder sample ( $\text{mg PHL} \cdot (100 \text{ g dry powder})^{-1}$ ,  $\text{TP}_w$ ) and also to total solids content in the extract ( $\text{mg PHL} \cdot (100 \text{ g dry solids})^{-1}$ ,  $\text{TP}_s$ ).

Carbohydrates content of the extracts was determined following a method previously reported [8]. Carbohydrates content was expressed as glucose equivalents (GL) referred to raw seaweed powder sample ( $\text{mg GL} \cdot (100 \text{ g dry powder})^{-1}$ ,  $\text{CHO}_w$ ) and also to total solids content in the extract ( $\text{mg GL} \cdot (100 \text{ g dry solids})^{-1}$ ,  $\text{CHO}_s$ ).

The DPPH scavenging activity assay measures the capacity of a system to react with a free radical agent (2, 2-diphenyl-1-picrylhydrazyl, DPPH). It was employed the method proposed by Brand-Williams [9]. In its radical form, DPPH $\cdot$  shows an absorption peak at

515 nm, but upon reduction by an antioxidant (AH) or a radical species (R·) the absorption disappears. As the reaction takes time to fully develop, for the determination of the DPPH scavenging activity absorbance is measured every 5 min until it reaches the stationary state. Scavenging activity, SA, is evaluated by means of Eq. (2):

$$SA(\%) = \frac{A_0 - A_f}{A_0} \cdot 100$$

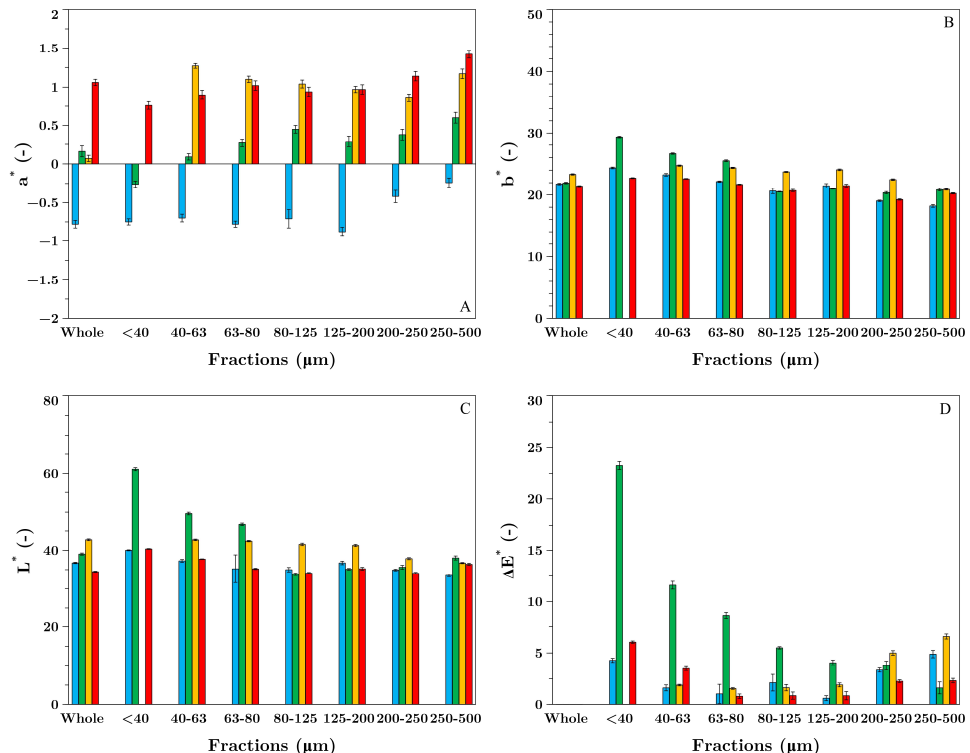

(2)

where  $A_0$  (-) is the absorbance at time 0 and  $A_f$  is the absorbance after one hour.

### 3. Results and Discussion

#### 3.1. Color characterization

The trends for color parameters values of powders from seaweeds dried at 35, 50, 60 and 75°C with the corresponding particle size fractions are displayed in Figure 1.

**Fig. 1**  $a^*$  (A),  $b^*$  (B),  $L^*$  (C) and  $\Delta E^*$  (D) color parameters of *Bifurcaria bifurcata* seaweed powders obtained after drying at different temperatures 35°C (■), 50°C (■), 60°C (■) and 75°C (■).

Specifically,  $a^*$  parameter values increased with increasing drying temperature. It is noticeable that the trend of  $a^*$  changes from green to red with drying temperatures above 35°C. Regarding particle size effect,  $a^*$  increased in general for all assessed seaweed powders.

The effect of drying temperature did not cause relevant changes in  $b^*$  values. All seaweed powders have a yellowness predominance ( $b^* > 0$ ). Regarding color properties of size fractions,  $b^*$  slightly decreased for all systems as mean size increased. Both trends might be related to the presence of still structurally undamaged parts of the seaweed in the biggest particles.

It can be seen that  $L^*$  parameter significantly decreased with increasing particle size up to 200-250  $\mu\text{m}$  for all drying temperatures. Nevertheless, regarding drying temperature effect, no clear trends were observed.

The evaluation of total color difference ( $\Delta E^*$ ) trend showed minimum values at intermediate particle sizes (from 80 to 200  $\mu\text{m}$ ). Particularly, the found color difference can be classified as small  $\Delta E^* = 0.60, 1.60, 1.54,$  and  $0.79$  for BB35P, BB50P, BB60P, and BB75P, respectively, according to [6].

Summarizing, drying temperature effect on color properties of *Bifurcaria bifurcata* seaweed powders modifies from greenness to redness predominance at drying temperatures above 35°C.

## 3.2. Seaweeds extracts

### 3.2.1. Total polyphenols content

Total polyphenols content values (TP) of aqueous extracts from *Bifurcaria bifurcata* dried at different temperatures are shown in Figure 2.

Fig. 2 Total Polyphenols (TP) of aqueous extracts of *Bifurcaria bifurcata* powders formerly dried at different temperatures (35°C (■), 50°C (■), 60°C (■) and 75°C (■)): referred to raw powder (mg

***PHL*·(100 g dry powder)<sup>-1</sup>, *TP<sub>w</sub>* (left) and total solids content in the extract (mg *PHL*·(100 g dry solids)<sup>-1</sup>, *TP<sub>s</sub>* (right).**

It can be observed that *TP<sub>w</sub>* content of *Bifurcaria bifurcata* extracts did not significantly change when drying with air-drying temperatures lower than 60°C. *TP<sub>s</sub>* in the extracts showed the same trend. The fact that both parameters, one referred to raw powder (*TP<sub>w</sub>*) and the other to total solids content in the extract (*TP<sub>s</sub>*) indicates that the significant differences in *TP* can be attributed to the different temperatures employed during drying and not to differences in the extraction yields.

Extracts obtained from seaweeds dried at 75°C rendered the lowest *TP* values indicating that air-drying temperature clearly influences *TP* content of the extracts. The use of a hot air-drying technique can lead to thermally-promoted physical and chemical processes *i.e.* structural collapse of cells during drying, textural modifications, migrations of chemical compounds, accumulation of substances in cell membranes and several chemical reactions) during this step, which make difficult the subsequent extraction of phenolic compounds.

### 3.2.2. Carbohydrate content

The effect of drying temperature on carbohydrate content (*CHO*) of extracts can be observed in Figure 3.

**Fig. 3 Carbohydrate content (*CHO*) of aqueous extracts of *Bifurcaria bifurcata* powders formerly dried at different temperatures (35°C (■), 50°C (■), 60°C (■) and 75°C (■)): referred to raw powder (mg GL·(100 g dry powder)<sup>-1</sup>, *CHO<sub>w</sub>* (left) and total solids content in the extract (mg GL·(100 g dry solids)<sup>-1</sup>, *CHO<sub>s</sub>* (right).**

As in the case of *TP* content, air-drying temperatures higher than 60°C significantly decreased *CHO* content. The extracts obtained from BB75 showed the minimum values of *CHO<sub>w</sub>* and *CHO<sub>s</sub>* (2103 ± 143 mg eq. GL/100 g dry powder and 4426 ± 301 mg eq. GL/100 g dry solid, respectively) and the maximum value of *CHO* content was observed for BB35 (2394 ± 167 mg eq. GL/100 g dry powder and 521 ± 363 mg eq. GL/100 g dry solid, respectively). These results might be related to the physical and chemical processes that

may difficult the extraction of carbohydrates, in the same mode than the phenolic compounds. Similarly, to the TP content results, CHO obtained results indicated that their differences should be attributed to the effect of drying conditions (temperature) and not to the differences in the extraction yields, because trends of CHO<sub>w</sub> and CHO<sub>s</sub> values with temperature were similar.

### 3.2.3. Antioxidant activity

The antioxidant activity of aqueous seaweed extracts was evaluated by means of total DPPH radical scavenging activity (SA), Table 1.

**Table 1. Radical scavenging activity (SA) of extracts from *Bifurcaria bifurcata* seaweeds dried at different temperatures.**

Drying Temperature (°C)	SA (%)
35	58.3±2.3 <sup>a</sup>
50	54.7±7.2 <sup>a</sup>
60	55.4±0.7 <sup>a</sup>
75	45.3±2.5 <sup>b</sup>

\*Data are presented as means±standar deviation. Data value of each parameter with different superscript letters in columns are significantly different (P≤0.05).

The effect of air drying temperature was very similar to the previously described for TP and CHO. Air drying temperatures higher than 60°C significantly decreased the SA of *Bifurcaria bifurcata* aqueous extracts. The reduction in TP content and SA at high drying temperatures may be due to several factors: release of phenolic compounds bound to cell wall during drying; thermal degradation by oxidative enzymes; phenolic compounds may rapidly degrade at drying temperatures above 40°C; binding of polyphenols to other substances (proteins) or alterations in their chemical structure [5,10,11].

The observed trend of SA and TP was previously reported in literature by other authors. Tello-Ireland et al. [5] reported a loss of antioxidant activity when drying *Gracilaria chilensis* at high temperatures (70°C) and Gupta et al. [10] a 30% decrease in TP of *Himanthalia elongata* when dried at 40°C in comparison with fresh seaweed.

## 4. Conclusions

Air drying temperature has a clear effect on phytochemical properties of brown seaweed *Bifurcaria bifurcata*. Regarding color properties, temperatures of drying higher than 35°C enhance a change from greenness to redness predominance on the color of the seaweeds powders. In the case of total polyphenolic and carbohydrate contents and scavenging activity of the aqueous extracts, all parameters are significantly reduced when drying at temperatures higher than 60°C. These results clearly define the drying conditions to be employed for this brown seaweed when specific properties of the final powders or extracts are required.

---

### **Abstract**

*In this work the spray drying of the fresh stevia leaves aqueous extract without encapsulating agents was carried out. The effect of the inlet air temperature (160-200 °C) and the feed flow rate (2-3 kg/h) on the total phenolic content, the total flavonoid content and the antioxidant capacity were evaluated using Folin-Ciocalteau, aluminum chloride and DPPH methods respectively. The inlet air temperature had a significant effect on all parameters evaluated that showed a decrease when increasing the inlet air temperature, the feed flow rate had a significant effect on total flavonoids content and the antioxidant capacity, by increasing the feed flow rate the inhibition of the DPPH radical decreased and the total flavonoid content increased. The treatment at 160 °C and 3 kg/h retained highest total flavonoid content and the antioxidant capacity.*

**Keywords:** Phenolic compounds, stevia, spray drying, antioxidant capacity

---

## 1. Introduction

Several families of compounds with nutraceutical and functional properties have been described in the stevia polyphenolic family. These compounds include phenolic compounds<sup>[1]</sup>, flavonoids<sup>[2]</sup> and tannins<sup>[3]</sup>.

Spray drying is a continuous operation technology commonly used to obtain high concentrations of soluble compounds<sup>[4]</sup>. For plant extracts, spray drying has been used to obtain products with high physical, chemical and microbiological stability, low storage costs and long shelf life<sup>[5]</sup>.

This research aimed to evaluate the effect of the inlet air temperature and the feed flow (FF) rate of the spray drying of fresh stevia leaves aqueous extracts on the total phenolic compounds (TPC) and the antioxidant capacity (AA).

## 2. Materials and Methods

### 2.1 Raw material

Fresh leaves of *S. rebaudiana* variety Morita II were collected from an organic crop in Oaxaca, Mexico (Fig.1).

*Fig. 1 Fresh stevia leaves.*

### 2.2 Aqueous extract

Distilled water at 80 °C was added to the fresh leaves in 5:1 v/w ratio, followed by ultrasonic extraction at 25 °C. Afterward, it was left at 25 °C for 48 h in the dark. The extract was filtered using a mesh sieve (pore size 0.149 mm).

### 2.3 Spray drying

A Mobile Minor concurrent flow spray dryer (Niro Copenhagen, Denmark), equipped with a pneumatic pulse rotary atomizer (TS-Minor, M02/B), was used. The atomization rate was set at 23,000 rpm, and the drying air flow was  $84 \pm 2$  kg/h.

## 2.4 Moisture content and total solids

Moisture contents was determined according to the AOAC<sup>[6]</sup> method 934.01. The total solids of the extract, expressed as gram of dry matter per liter ( $g_{dm}/L$ ), was determined according the AOAC<sup>[6]</sup> 990.19 method.

## 2.5 Determination of total phenolic content

Phenolic compounds were extracted with methanol acidified with hydrochloric acid at 1% (v/v). The total phenolic content was analyzed by the Folin-Ciocalteu method, as described by Periche et al<sup>[7]</sup>.

## 2.5 Determination of antioxidant capacity

An 80% methanol solution was used for extraction of antioxidant compounds. The antioxidant capacity (%) was measured with the DPPH method according to Shukla et al<sup>[8]</sup>.

## 2.7 Determination of total flavonoid content

An 80% methanol solution was used for extraction of flavonoids. The aluminum chloride colorimetric method was used, according to Kumazawa et al<sup>[9]</sup>. The absorbance was read at 510 nm. Standard de quercetin was used as references. Flavonoids were expressed as quercetin equivalent per litre (mg QE/mL).

## 2.8 Conversion of concentration units

In order to compare the effect of the drying conditions on the content of total phenolic compounds, the total flavonoid content and the antioxidant activity, the measurement units were expressed on a dry basis, using Eqs. (1) and (2):

$$C_T = \frac{C_C \times V_{ex}}{W_{dl}} \quad (1)$$

$W_{dl}$  was calculated using Eq. (2):

$$W_{dl} = w_{ft}(1 - X_{wb}^f) \quad (2)$$

## 2.9 Statistical analysis

All the analysis were performed on triplicates. A  $2^2$  factorial design, with three central points, was applied to evaluate the effect of inlet air temperature ( $T_{in}$ ) (160 and 200 °C) and FF rate (2 and 3 kg/h) on the total phenolic content, antioxidant activity and total flavonoids content. Data analysis was done using ANOVA, and a response was performed with Statistica software Ver. 7.

### 3. Results and discussion

The concentration of phenolic compounds in the fresh leaves was  $77.00 \pm 0.59$  GAE/g<sub>dl</sub>, which was higher than that reported in other works. Periche et al<sup>[7]</sup> reported an average content of  $44.40 \pm 1.04$  GAE/g<sub>dl</sub> while Lemus-Mondaca et al<sup>[11]</sup> obtained  $0.29 \pm 0.02$  GAE/g<sub>dl</sub>.

The drying process significantly influenced ( $p < 0.05$ ) the phenolic compounds content. In all drying treatment (Table 1) the phenolic compound content decreased when the drying temperature was raised. The powders showed an average phenolic compounds loss of 57%. The FF rate did not have a significant effect on TPC ( $p > 0.05$ ). The results obtained in this work contrast with those obtained by Periche et al<sup>[7]</sup>. (2015), who dried stevia extracts by convection and lyophilized reporting an increased total phenolic content as temperature increases. This inconsistency could be due to direct exposure of the extract of ground fresh stevia leaves to the spray drying conditions. Therefore, the phenolic compounds were more exposed during the spray drying as opposed to when the whole leaf is dried, in which the phenolic compounds are protected in the vacuoles<sup>[12]</sup>.

Table 1. Total phenolic, flavonoids and antioxidant capacity content.

Temperature °C	Feed flow rate kg/h	Phenolic compounds mg GAE/g <sub>dl</sub>	Flavonoids mg QE/g <sub>dl</sub>	Antioxidant capacity %
Fresh leaves		$77 \pm 0.59$	$170.45 \pm 0.61$	$93.66 \pm 0.55$
200	2	$40.90 \pm 0.57$	$110.47 \pm 0.48$	$88.68 \pm 0.64$
200	3	$41.48 \pm 0.78$	$117.26 \pm 1.08$	$76.93 \pm 0.30$
160	2	$49.93 \pm 0.91$	$117.10 \pm 0.24$	$86.36 \pm 0.68$
160	3	$47.21 \pm 0.11$	$124.68 \pm 0.58$	$90.13 \pm 0.78$

The flavonoid concentration in the fresh leaves was  $170.45 \pm 0.61$  mg QE/g<sub>dl</sub>. In all drying treatments the flavonoid concentration decreased (Table 1).

For instance, Lemus-Mondaca et al<sup>[12]</sup> reported, in fresh samples, an lower amount of  $0.89 \pm 0.02$  mg QE/g<sub>dl</sub>. The flavonoids concentration was affected by the drying process ( $p < 0.05$ ), showing a decrease with the increase in temperature and an increased when FF decrement. This results could be because flavonoids are sensitive to oxidation and thermal degradation during spray drying<sup>[5]</sup>.

The inlet air temperature and the FF rate significantly impacted ( $p < 0.05$ ) on the antioxidant capacity. The highest antioxidant capacity was observed at the lowest temperature (160 °C)

and the highest FF (3 kg/h). This results were similar to Georgetti et al<sup>[13]</sup> and Krishnaiah et al<sup>[14]</sup> who reported similar behavior for spray-dried soybean extract and *Morinda citrifolia*.

#### 4. Conclusions

Spray drying is an efficient technology for the preservation of the antioxidant compounds of the fresh stevia leaves aqueous extract, even without the use of encapsulating agents. The antioxidant capacity of the final product ranged from 76 to 90%. The treatment at 160 °C and 3 kg/h retained highest total flavonoid content and the antioxidant capacity. Therefore, the aqueous stevia leaves extract could be considered as a natural source of antioxidants, with prospects to be considered as a food complement.

### **Abstract**

*The commercial value of stevia dehydrated leaves is related to the content of glycosides and their appearance. The present work approaches the effect of packed bed drying conditions (temperature, flow rate and solid loading) on glycosides and antioxidants activity of stevia leaves of Morita II variety. Diffusion coefficient was calculated. The drying times ranged between 34 and 160 minutes, the temperature was the most significant factor followed by solid loading and flow rate. Drying increases the concentration of antioxidants, stevioside and reduces rebaudioside A.*

**Keywords:** *drying, packed bed, stevia rebaudiana, glycosides, antioxidants*

---

## **1. Introduction**

Stevia leaves are a source of bioactive compounds, among which are steviol glycosides that confer a high sweetening capacity and antioxidant compounds such as phenols and flavonoids, which has a therapeutic value<sup>[1]</sup>. The commercial value of stevia dehydrated leaves is related to the content of glycosides and their appearance. Some drying methods has been applied on stevia leaves, among shade drying, convective drying with longitudinal-flow at low (30 and 80°C) and high temperatura(100 and 180°C) and liophylization<sup>[2, 3, 4]</sup>. In the traditional process, fresh leaves are spread on a mesh or perforated plate in thin or thick layer and warm air is forced through the layer leaves to remove the moisture. The drying time could be reduced by fluidizing the leaves, but the quality of the final product may decrease. This research aimed to evaluate the effect of the drying conditions (temperature, flow rate and solid loading) of packed bed (PB) of stevia leaves Morita II variety on glycosides and antioxidants content.

## **2. Materials and Methods**

### **2.1. Raw material**

Fresh leaves of *S. rebaudiana* variety Morita II were collected from an organic crop in Oaxaca, Mexico (latitude: 16°19', longitude: 98°23'). Fresh leaves with no mechanical damage, no apparent evidence of fungi or bacteria harm and uniform color were selected.

The dimensions, density, and moisture content of the fresh leaves were measured. The void fraction of the bed was calculated by dividing the density of the bed between the density of the leaves. The thickness was measured with a micrometer. The area of the leaves was measured with image analysis using the ImageJ® version 1.50i program. The density of the leaves was determined using the buoyant force method (YDK 01S kit, Denver Instrument).

The moisture content was determined by the method 934.01 of the AOAC. <sup>[5]</sup>.

### **2.2. Fixed Bed Drying**

The samples were dehydrated in a lab scale fluidized bed dryer with a glass fluidization tube with a height of 50 cm, a diameter of 10 cm and a thick of 0.2 cm. The packed bed drying process was carried out introducing the load of leaves in a perforated plastic basket. The dried air is heated with an electric resistance of 1 kW and the temperature is regulated by a PID controller (Love control, 32DZ). The air flow is regulated with an adjustable AC drive controller using a asynchronous motors (Altivar™ 16 Telemecanique). The drying kinetics were obtained by weighing the fluidization tube and the loading of the stevia leaves in a precision balance (Sartorius ED4202S-CW), considering time intervals determined by the drying conditions (2, 3 or 5 min). The drying was finished when the weight does not change in three consecutive measurements. The effective diffusion coefficient was calculated using

the analytical solution of the Fick equation considering only the first term of the serie and employing experimental data ( $\ln(X-X_f/X_0-X_f)$  vs time), with lineal tendence and a coefficient correlation  $>0.995$ .

### 2.3. Antioxidant compounds.

The measurement of antioxidant capacity ( $C_A$ ), total phenolic content ( $F_T$ ) and total flavonoid content ( $F_L$ ), were determined using the 2,2-diphenyl-1-picrylhydrazyl free radical scavenging activity, the Folin-Ciocalteu method and the aluminum chloride colorimetric method respectively, as detailed by Méndez-Lagunas *et al.* [6]. All the chemical products were purchased in Sigma–Aldrich.

### 2.4. Steviol glycosides compounds.

#### 2.4.1. Chemicals and reagents

Acetonitrile and water (HPLC grade, Sigma Aldrich, USA) were used for the mobile phase preparation. Standard of stevioside and rebaudioside A were purchase in Sigma Aldrich.

#### 2.4.2. Sample preparation

Fresh (0.4 g) or dry (0.1 g) ground leaves were mixed 5 mL de agua. The mixture was sonicated at 44 KHz for 20 minutes at room temperature and centrifuged at 2080 rpm for 5 min. The supernatant was separated from the precipitate. Two consecutive extractions were made to the precipitate. The accumulated volume of the supernatant was measured and stored in amber vials. An aliquot (20  $\mu$ l) of the accumulated of the three supernadant consecutives extractions was used for the quantification of stevioside ( $E_V$ ) and rebaudioside A ( $R_A$ ).

#### 2.4.3. HPLC analysis

An isocratic HPLC method was performed for the determination of steviol glycosides using an ODS Hypersil C18 column (250  $\times$  4.6 mm, particle size 5  $\mu$ m) and a UV detector set at 210 nm. The mobile phase consisted of acetonitrile-water (35:65, v/v) at a flow rate of 1 ml/min. Data analysis was carried out using Chromera software. Calibration curves of stevioside and rebaudioside A were constructed over the range 0.03-0.9 mg/ml. In order to compare the effect of the drying conditions on the  $R_A$  and  $E_V$  concentrations, the units of measure were expressed on the basis of dry matter ( $\text{mg/g}_{\text{dm}}$ ).

### 2.5. Experimental design and statistical analysis

The drying tests were carried out following a 3x2x2 complete factorial experimental design with 3 replicas. The factors studied were temperature, T (40, 50 and 60  $^{\circ}$ C), air flow,  $\bar{u}$ , (2 and 3.5 m/s) and area solid loading,  $\rho_A$  (1.5 and 3  $\text{kg/m}^2$ ).

All the chemical analysis was performed on triplicates. The analysis of variance (ANOVA) was used to evaluate the effect of operating conditions on the drying time, the concentration of antioxidants (antioxidant capacity, total phenols and flavonoids) and the concentration of glycosides (stevioside and rebaudioside A). The software NCSS version 9 was used to perform the statistical analysis.

### 3. Results and Discussions

**3.1. Physical characteristics.** Fresh stevia leaves had a moisture content ( $X_0$ ) of  $0.75 \pm 0.03$   $\text{kg}_w/\text{kg}_{\text{wm}}$ , a thickness of  $2.08 \pm 0.1$  mm, a maximum equivalent diameter of 6.53 cm and a minimum of 2.53 cm. The density of the leaves was  $0.95 \pm 0.031$   $\text{g}/\text{cm}^3$ . The packed bed of 1.5  $\text{kg}/\text{m}^2$  solid loading had a bed height of 3.2 cm, a bulk density of  $60$   $\text{kg}/\text{m}^3$  and a void fraction of 0.93, while the bed of 3.0  $\text{kg}/\text{m}^2$  had a height of 5.2 cm, a bulk density of  $80$   $\text{kg}/\text{m}^3$  and a void fraction of 0.92.

**3.2. Drying kinetics.** Figures 1 show drying curves of packed bed of stevia leaves. The curves are grouped depending on the drying temperature, the air flow and the packing. The drying rate increases with the increase in temperature and air velocity, as well as with the decrease of solid loading. At low air flow the packaging has a greater effect on the drying rate. The drying rate curves have a second-order polynomial tendency.

Fig. 1 Drying curves of leaves of stevia in packed bed.

**Table 1. Effective diffusivity in stevia leaves and drying time of packed bed of leaves.**

T (°C)	$\bar{u}$ (m/s)	$\rho_A$ (kg/m <sup>2</sup> )	t (min)	$D_{\text{eff}} * 10^{10}$ (m <sup>2</sup> /s)
40	2.0	3.0	160	6.73
40	2.0	1.5	130	9.31
40	3.5	3.0	135	9.74
40	3.5	1.5	124	10.65
50	2.0	3.0	87	11.61
50	2.0	1.5	75	16.18
50	3.5	3.0	70	13.26
50	3.5	1.5	60	15.80
60	2.0	3.0	40	18.17
60	2.0	1.5	36	21.74
60	3.5	3.0	36	21.27
60	3.5	1.5	34	21.27

Table 1 shows the diffusivity of water and the drying time to reach a moisture content of 0.10 kg<sub>w</sub>/ kg<sub>dm</sub>. Drying temperature followed by the solid loading and the air flow and the air temperature-solid loading interaction are statistically significant ( $p < 0.05$ ) on drying time. The drying time in trays with longitudinal flow,<sup>[3]</sup> is three times less than with flow through in packed bed. The air temperature is significant ( $p < 0.05$ ) on effective diffusivity. The air flow and the solid loading affect the diffusivity value, however, its effects are less than the temperature.

**3.3. Antioxidant compounds.** The content of phenolic compounds, flavonoids and antioxidant capacity are shown in table 2. The antioxidant capacity of dried stevia leaves is similar with the fresh leaves. The content of phenols and flavonoids is higher in dry leaves than in fresh stevia leaves, however, the drying conditions studied did not have a significant effect. The solid loading could give a difference in antioxidant compound. The increase in polyphenols may be due to the breakdown of cellular constituents of the material, associated with the availability of precursors of phenolic molecules that are derived from the non-enzymatic interconversion between its.<sup>[3, 7]</sup>

**3.4. Steviosides compounds.** The content of rebaudioside A ( $R_A$ ) decreases and the content of stevioside ( $E_V$ ) is increased in dehydrated leaves relative to fresh leaves (Table 3). The degradation of steviol glycosides by hydrolysis has been proposed to explain this behavior<sup>[8]</sup>. A decrease in rebaudioside A may be related to the increase in the content of stevioside. The three variables, temperature, air velocity and charge density, as well as their interactions,

have a significant effect ( $p < 0.05$ ) on the content of  $E_V$  and  $R_A$ . Lower flow rate and higher solid loading give a higher content of  $R_A$ .

60	3.5	3.0	83.68±5.46	44.02±6.02

#### 4. Conclusions

The three variables evaluated (temperature, air flow and solid loading) had a significant effect on the drying time. The order of importance was the temperature, the solid loading and the flow rate.

The drying in packed bed increases the content of phenols and flavonoids of stevia leaves, none of the variables studied was significant in the content of antioxidants, however, the solid loading is a factor that must be taken into consideration; the higher the solid loading, the higher the antioxidant content.

The drying in packed bed reduce the content of rebaudioside A ( $R_A$ ) and increases the content of stevioside (EV) of stevia leaves. The load of solids was a significant factor, the higher solid loading, the higher content of steviosides.

The proposed drying conditions for the conservation of the physicochemical properties in packed bed of the stevia leaves are 50°C, 2 m/s and 1.5 kg/m<sup>2</sup>

### **Abstract**

*In this work the influence of some process variable on drying rate of henna leaves was studied. For this reason, henna leaves were dried (1 m/s) with and without ultrasound application at three temperatures, 40, 50 and 60 °C. As can be expected, the higher the temperature the faster the drying process. Ultrasound application increase drying rate at every temperature tested. Drying kinetics were modeled by using different experimental models. Weibull model provided the best fit for henna leaves drying kinetics.*

**Keywords:** *Ultrasonic; Weibull model; henna leave; temperature.*

---

## 1. Introduction

Henna (*Lawsonia inermis*) leaves (Fig. 1) is an important product consumed widely in Algerian society. This plant is found mainly in the southern region of Algeria and it is available eight months a year. Its height can reach 2-3 m at the end of its life. The dark green oval leaves (2-4 cm long) present high interest not only for cosmetic but also for medicinal issues [1].

Among the methods used to conserve medicinal plants, drying is one of the most extended. The reduction of the moisture content prevents the degradation of this material [2] making possible its use for different applications [1]. The traditional drying of henna by exposition to the sun is being substituting by convective hot air drying. This permits to standardize the production and avoid problems such as contamination with particles (dust) or insects. However, drying can highly affect the quality attributes of henna leaves. Therefore drying kinetics studies can contribute to the better understanding of the process and select the best drying conditions that permits to obtain a high quality product.

*Fig. 1 The fresh leaves of El henna (Lawsonia inermis).*

High intensity ultrasound has been used to intensify drying process. This could permit the use of milder drying conditions that can improve the product quality. Thus, the aim of this work was to determine the drying kinetics of henna leaves at different temperatures and quantify the influence of the application of ultrasound during the process.

## 2. Materials and Methods

### 2.1. Experimental drying

#### 2.1.1. Sample preparation

The henna leaves studied were cultivated and neatly transported by air from the wilaya of Béchar, in the south west of Algeria, to the laboratory of the Analysis and Simulation of Agro-food Process (ASPA) research group, Food Technology Department, Universitat Politècnica de València, Spain. There, they were stored in a refrigerator at  $5 \pm 1$  °C until drying experiments. The moisture content was measured by placing the samples in a vacuum oven at 70 °C and 200 mmHg until constant weight, following standard method n°934.06 [3].

#### 2.1.2. Experimental drying kinetics

Drying kinetics were carried out in an ultrasonically-assisted convective dryer previously described [4,5]. This equipment is a laboratory scale dryer modified to apply power ultrasound, with automatic control of the air temperature and velocity and provided with an automatic sample weighing system.

Fig. 2 Scheme of ultrasonically assisted convective drier [6].

The drying experiments were carried out in triplicate at three different air temperatures (40, 50 and 60 °C) without (Air) and with ultrasound application (Air+US; 21.7 kHz, 20.5 kW/m<sup>3</sup>). In every case, an air velocity of 1 m/s was used. The dehydration process was stopped when samples lost 75% of their initial weight.

## 2.2. Drying kinetics

The evolution of moisture content of samples during drying was determined by weighting the henna leaves after different drying times and the initial moisture content [7]. The equilibrium moisture content of the henna leaves was experimentally obtained by placing the henna samples at the drying conditions for a very long time. This time was enough to have no difference in sample weight for two hour. Then the moisture content of samples was expressed in non-dimensional way by using Eq. 1 [8].

$$MR = \frac{X(t) - X_{eq}}{X_0 - X_{eq}} \quad (1)$$

Where MR is the non-dimesional moisture content or moisture ratio, X(t) is the moisture content after a drying time (kg water/kg dry matter, d.m.), X<sub>0</sub> is the initial moisture content of samples (kg water/kg d.m.) and X<sub>eq</sub> (kg water/kg d.m.) is the equilibrium moisture content.

## 2.3. Mathematical modeling

Given the complexity of the phenomena involved in the drying of a product, it has been proposed mathematical models of different complexity including theoretical and empirical models. Thus, theroretical models can provide parameters, such as diffusivity, than can help to better understand the drying process. On the other hand, empirical or semi-empirical relationships permit to describe the drying curves and quantify the influence of drying conditions on drying rate. [8] Thus, in the case of this work eight different empirical models were used to describe the drying kinetics (Table 1).

**Table 1. Mathematical models applied to the experimental drying kinetics**

Name of model	Model
Newton	$MR = \exp(-kt)$
Page	$MR = \exp(-kt^n)$
Henderson and Pabis	$MR = a \times \exp(-kt)$
Logarithmique	$MR = a \times \exp(-kt) + c$
Tow term	$MR = a \times \exp(-k_0t) + b \times \exp(-k_1t)$
Weibull	$MR = \exp(-t/k)^n$
Diffusion approach	$MR = a \times \exp(-kt) + (1-a) \times \exp(-kbt)$
Wang and Singh	$MR = 1 + a.t + b.t^2$

The parameters of each equation were identified by using the non-linear optimization method of Marquardt-Levenberg (CurveExpert and Origin 6.1 software). To assess the goodness of the fit, the correlation coefficient ( $r$ ) (Eq. 2) and standard error (EST) (Eq. 3) were calculated.

$$r = \sqrt{1 - \frac{\sum_{i=1}^{n_{\text{exp.data}}} (MR_{\text{exp}i} - MR_{\text{cali}})^2}{\sum_{i=1}^{n_{\text{exp.data}}} (MR_{\text{exp}i} - \bar{MR}_{\text{exp}})^2}} \quad (2)$$

$$EST = \sqrt{\frac{\sum_{i=1}^{n_{\text{exp.data}}} (MR_{\text{exp}i} - MR_{\text{cali}})^2}{n_{\text{exp.data}} - n_{\text{param}}}} \quad (3)$$

Where  $MR_{\text{cali}}$  is the calculated value of the non-dimensional moisture content by using the tested model,  $MR_{\text{exp}i}$  is the experimental value of equilibrium moisture content,  $n_{\text{param}}$  is the number of parameters of the particular model and  $n_{\text{exp.data}}$  is the number of experimental points. The mean value of the non-dimensional moisture content ( $\bar{MR}$ ) was calculated as follows:

$$\bar{MR} = \frac{1}{n_{\text{exp.data}}} \sum_{i=1}^{n_{\text{exp.data}}} MR_{\text{exp}i} \quad (5)$$

### 3. Results and discussion

#### 3.1. Experimental drying kinetics

The initial moisture content of henna leaves was 2.33 kg water/kg d.m. Temperature affects the experimental drying kinetics; the higher the temperature the faster the process (Fig. 3). Thus, the time needed to achieve a moisture content of 1 kg water/kg d.m. was 2.64 h at 40 °C, 1.94 h at 50 °C and 1.25 h at 60 °C.

Ultrasound application significantly accelerated drying of Henna leaves (Fig. 4). In this sense, at 40 °C, drying time in experiments carried out with ultrasound was 50 % lower than the needed in experiments carried out without ultrasound application. The influence of ultrasound in drying rate was quite similar at the different temperatures tested.

Fig. 3 Experimental drying kinetics of the *Henna* leaves without ultrasound application .

### 3.2. Modelling

Among the different models tested, the Weibull model gave the best fit, that is, the highest value of  $r$  parameter and the lowest of  $EST$ . The model parameters identified are shown in Table 2. The studied process variables, temperature and ultrasound application, did not significantly affect ( $p < 0.05$ ) the  $n$  parameter. This parameter is related with the product considered.

On the contrary,  $k$  parameter, which is inversely proportional to the drying rate, was affected by both, temperature and ultrasound application. Thus, the higher the temperature, the lower the  $k$  value, which indicates a faster drying.

The application of ultrasound also reduced the identified  $k$  figures, meaning a lower time of drying becoming this influence more important at moderate drying temperature. Thus, at  $50^\circ\text{C}$ , the  $k$  identified in *Air+us* experiments was 27% lower than the identified in *Air* experiments. This difference was 16% at  $50^\circ\text{C}$  and only 7% at  $60^\circ\text{C}$ .

**Table 2. Weibull model parameters identified by fitting to the experimental drying kinetics of henna leaves at different temperature and without (Air) and with (Air+us) ultrasound application. Correlation coefficient (r) and standar error (EST)**

Type of experiment	Temperature (°C)	n	K	r	EST
Air	40	0.900	14434.7	0.9948	0.0208
Air+us	40	1.062	10523.7	0.9985	0.0136
Air	50	1.088	7495.6	0.9979	0.0173
Air+us	50	0.993	6286.0	0.9962	0.0207
Air	60	1.114	4705.3	0.9939	0.0271
Air+us	60	1.171	4391.8	0.9900	0.0322

Henna leaves dried at 40 °C, with or without ultrasound application, kept their green color while samples dried at higher temperature showed a brown color. This fact indicates the limited deterioration of the active product at the lowest temperature tested compared with the highest ones. Therefore, ultrasound application represent an alternative to intensify drying rate during drying at milder tempertures and preserving product quality.

**Fig. 4 The experimental moisture ratio described by the Weibull model of the Henna leaves without and with ultrasound.**

#### **4. Conclusions**

The drying kinetics of henna leaves was affected by both temperature and ultrasound application. The higher the temperature the faster the process. However, the green color of samples, which is a measurement of the quality of final product, was maintained only at the lowest temperature tested, 40°C. The ultrasound application accelerate the drying. Its application at low temperature was an interesting alternative to accelerate the drying maintain the quality.

### **Abstract**

*A quality by design approach was used to investigate the influence of formulation composition and spray drying conditions on physicochemical properties of redispersable lipid based nanosystems loaded with Syzygium aromaticum essential oil. Four critical independent variables were studied: presence or absence of the liquid lipid oleic acid (0% - 1%), of the cationic surfactant CTAB (0% and 1%), inlet drying temperature (60 °C -80 °C), and ratio of the drying aids (ADJ) regarded to total formulation constituents weight (1:1 and 2:1). Results showed the production of spray dried redispersable lipid systems loaded with essential is feasible under very restrict conditions.*

**Keywords:** *Encapsulation; lipid systems; essential oil; spray drying; redispersable.*

---

## 1. Introduction

Currently, significant attention has been addressed towards the use of essential oils (EOs) in food, pharmaceutical and cosmeceutical sectors, mainly due to their broad spectrum of proven biological activities, particularly antifungic, antibacterial insecticide, antiviral, antioxidant, among others.<sup>[1]</sup> EOs are hydrophobic, volatile and odoriferous liquids, produced by the plant secondary metabolism, and consist of complex mixtures of chemicals.<sup>[2]</sup> Several limitations exhibited by the EOs such as the high volatility, insolubility in aqueous systems and propensity to degraded due to environmental factors, would deter they use in more elaborated products. Encapsulation processes can modulate and improve the EO physicochemical properties, thus expanding its potential of use in a high variety of products. In this way, the incorporation of essential oils in lipid systems such as solid lipid nanoparticles (SLNs) and nanostructured lipid carriers (NLCs) can be a promising strategy to modify its physicochemical properties; which might positively alter its stability, volatility, water solubility, bioavailability and biological activity.<sup>[3]</sup> Since the SLNs and NLCs are generally presented in liquid forms; the drying of these systems can furnish a redispersible powdered product with higher shelf-life; which can be reconstituted when exposed to aqueous solution or be used in more refined applications.<sup>[4-6]</sup> The drying process as well as the constituents of the encapsulating composition affects directly the physicochemical product properties, such as product granulometry, microstructure, redispersability capability, retention of bioactive compound, and so on. These characteristics affect strongly the product functionality, stability and other technological and biopharmaceutical properties. Several drying technologies can be used to dehydrated these systems, including freeze drying and spray drying.<sup>[7]</sup> Although spray drying is one of the most used method for drying and encapsulation of thermosensitive materials, its use for drying of emulsions and other lipid systems are barely reported in the current literature.<sup>[8,9]</sup> Most of the lipids and surfactants used to develop these systems (and the EOs as well), are liquid at ambient temperature or present low melting temperatures, turning their dehydration process challenging. On the other hand, *Syzygium aromaticum*, popularly knowed as clove, is an important aromatic plant rich in phenolic antioxidants, and has been used for centuries as a food preservative and pain reliever.<sup>[10]</sup> Clove buds contains an essential oil rich in eugenol, substance usually linked to its biological properties, such as antioxidant, antimicrobial, larvicide, and anti-inflammatory. So, clove EO is a promising active phytopharmaceutical ingredient. Therefore, the aim of this work was to investigate the spray drying of lipid based nanosystems (SLNs and NLCs) loaded with *Syzygium aromaticum* EO, evaluating the effects of formulation composition and spray drying temperature on physicochemical properties of the dried product.

## 2. Materials and Methods

*Syzygium aromaticum* EO (from a clove essential oil producer located in Valença, BA, Brazil), solid lipid Precirol® ATO 5 (glyceryl palmitostearate - Gattefossé, France – Melting point ~56 °C), liquid lipid oleic acid (cis-9-octadecanoic acid - LabSynth, Brazil), anionic surfactant Kolliphor P 188 (Poloxamer® 188 - BASF, Brazil), cationic surfactant CTAB (cetyl trimethylammonium bromide - Sigma-Aldrich, Germany - Melting point 237-243 °C), and reverse osmosis water were the materials used for the development of primary SLNs and NLCs. Arabic gum (AG - Nexira, Brazil), Aerosil® 200 (SiO<sub>2</sub> - Evonik Degussa, Germany), Maltodextrin DE-10 (MD - Ingredion, Brazil), were used as spray drying aid (ADJ). Eugenol and eugenyl acetate with purity of 99.0 % and 98.0 % respectively (Sigma-Aldrich, Germany), HPLC grade solvents (Sigma-Aldrich, Germany), and milliQ® water were used in the quantification of Eugenol (EU) and Eugenyl acetate (ACT) by high performance liquid chromatography with diode array detection (HPLC-DAD).

### 2.1 Preparation of SLNs and NLCs formulations

The preparation of the SLNs and NLCs loaded with *Syzygium aromaticum* EO was conducted by the phase inversion method. Solid lipids were melted at 10 °C above their melting temperature, and mixed with 1 % of the liquid lipid oleic acid (only for NLCs). EO at concentration of 3 % (wet basis) was added to this lipid phase and maintained at same temperature. 3% of Poloxamer 188 and 1% of CTAB (when used) were solubilized in the reverse osmosis water and kept at the same temperature of the lipid phase. Then, the aqueous phase was slowly dispersed in the lipid phase under magnetic stirring, and then submitted to a ultraturrax (UltraTurrax T-18 IKA WORKS, Inc., Wilmington, NC, EUA) at 21.500 rpm during 3 minutes.<sup>[10]</sup> To reduce the particle size of the NLCs, the lipid system was submitted to ultrasonic processing (US), using a VCX-750 (SONICS Vibracell, Newtown, EUA) with a 13 mm probe at amplitude of 45%, during 30 minutes at cycles of 5 minutes on and 2 minutes off.<sup>[11]</sup> The total amount of solid lipid, plus liquid lipid and CTAB were set constant at 10% (wet basis). Hence, the ADJ (SiO<sub>2</sub>:GU:MD - 1:3:6), hydrated overnight, were added to the primary lipid compositions at 1:1 or 2:1 ratio regarded to the total amount of formulation components (dry basis). After a stabilization period of 24 hours, the SLNs and NLCs formed were characterized, to determine the effects of composition constituents on selected physicochemical properties. Differential scanning calorimetry of the formulations prepared (freeze-dried) were conducted in a PerkinElmer calorimeter (mod. Jade-DSC), running from 20 to 250 °C, heating rate at 10 °C/min, and N<sub>2</sub> atmosphere (3.0 kgf/cm<sup>2</sup>) to estimate their melting and crystallization temperatures.

### 2.2 Spray drying of the SLNs and NLCs loaded with *Syzygium aromaticum* EO

The drying runs were performed in a SD05 spray dryer (Lab-Plant UK Ltd, Huddersfield, UK), operating in a concurrent flow regime. First, the system was fed with distilled water to

stabilize the SD temperature and humidity profiles. The outlet gas temperature was measured each 5 minutes to detect the instant when the process attains steady state, after which the feed of encapsulating composition began. Operating conditions were: feed rate 4 g/min, diameter of the atomizer nozzle 1 mm, drying gas flow rate 60 m<sup>3</sup>/h, pressure and flowrate of atomizing air of 3 bar and 17 L/min, respectively; and inlet drying temperatures (T<sub>gi</sub>) of 60 and 80 °C. Solids concentration (C<sub>s</sub>) was set at 26%. Samples of the spray dried powders were reserved, and their physicochemical properties determined.

### 2.2.1 Experimental planning

A 2<sup>4-1</sup> fractional factorial design with addition of a central point<sup>[12]</sup> was used to study the effect of following variables: presence or absence of the liquid lipid oleic acid (OA - 0% - 1%), of the cationic surfactant CTAB (0% and 1%), inlet spray drying temperature (60 °C and 80 °C), and ratio of ADJ regarded to total formulation constituents (1:1 and 2:1 – dry basis). The set of experiments conducted are presented in Table 1 (coded variables). Regression analysis were performed to evaluate the significance of the effects of processing variables on product properties and drying performance.

**Table 1. Processing conditions used according to the 2<sup>4-1</sup> experimental design.**

<b>Run</b>	<b>T<sub>gi</sub></b> (-)	<b>CTAB</b> (-)	<b>OA</b> (-)	<b>ADJ</b> (-)

### 2.2.2 Determination of SD product properties and drying performance

The moisture content, water activity, content and retention of marker compounds were measured for the SD powders. The moisture content was determined by Karl Fischer titration, using a Karl Fischer 870 Titrino Plus (Methrom, Switzerland). The water activity was determined in an Aqua Lab 4Tev<sup>®</sup> water activity meter (Decagon devices, USA) using the capacitance electrode. Results were expressed as mean and deviation of triplicate measurements. The concentrations of eugenol (EU) and eugenyl acetate (ACT) in liquid and spray dried samples were determined by a validated high performance liquid chromatography method (HPLC).<sup>[9]</sup> Retention of EU (R<sub>EU</sub>), and ACT (R<sub>ACT</sub>) were defined as the percentual ratio of the amount of marker compounds in the SD product related to the values in original liquid formulation (dry basis). Particle sizes (dp) and the polydispersity index (PDI) of the liquid and redispersed SD samples were determined by dynamic light scattering (DLS) using

a Zetasizer Nano ZS90 (Malvern, UK). Zeta potential (Z) was measured in the same equipment, using the specific measurement cell. The SD samples were redispersed with reverse osmosis water at the original concentration and stirred for 30 minutes. Then, the original and redispersed samples were diluted to 1:200 (v/v) before the measurements (triplicate assays). Microphotographs of selected SD samples were acquired by scanning electronic microscopy (S.E.M. - Zeiss mod. EVO 50). Product recovery ( $R_{EC}$ ), defined as the percentual ratio of the mass of SD product collected by the cyclone by the total mass fed (dry basis), was used as a measure of spray drying performance. The outlet spray drying gas temperatures were monitored during the drying.

### 3. Results and discussion

Nine distinct lipid compositions were produced according to the experimental planning (Table 1). After 24 hours, the compositions were characterized through determination of dp, PDI, Z, and the contents of eugenol (EU) and eugenyl acetate (ACT). The pH and electrical conductivity of compositions ranged from 4.23 to 4.93 and from 359.0 to 1,068.2 ( $\mu\text{S}/\text{cm}$ ), respectively (data not shown). The amount of marker compounds in the liquid compositions are linked to the ADJ ratio; decreasing conversively with this composition variable.

#### 3.1 Effects of processing variables on product properties and drying performance

The moisture content of the SD product varied slightly with processing variables, reaching a mean value of  $5.3 \pm 0.4$  (% w/w d.b). The water activity ( $a_w$ ) of the SD powders ranged from 0.357 to 0.578. Values of water activity lower than 0.5 are desired to avoid microbial spoilage of dried powders, resulting in longer shelf-life.<sup>[13]</sup> Most of SD powders reach water activity below this value, except compositions F4 and F6 that show  $a_w$  of  $0.578 \pm 0.003$  and  $0.568 \pm 0.003$ , respectively, although none of the variables studied showed statistical significant effect on  $a_w$ . The physicochemical properties (EU, ACT,  $R_{EU}$ ,  $R_{ACT}$ , dp, PDI and Z) of the SD product and of the redispersed samples were submitted to a regression analysis (Table 2). Table 2 shows similar effects of processing variables on the responses EU, ACT,  $R_{EU}$ ,  $R_{ACT}$ , with  $R^2 \geq 0.95$ . The increase in  $T_{gi}$  leads to a decrease in these responses ( $\alpha \leq 0.05$ ), perhaps due to the increase of drying energy available, which can contribute to the increase of volatilization of EO constituents. The effect of ADJ on EU and ACT are expected (dilution effect), but its effects on  $R_{EU}$  and  $R_{ACT}$  were in an opposite direction to the normal reasoning, seemingly due to the interactions between ADJ and the main lipid formulation constituents (CTAB, OA, poloxamer 188, and precirol). The addition of OA in the lipid systems increased EU, ACT,  $R_{EU}$ ,  $R_{ACT}$ , as expected for NLCs, compared to SLN, but this effect only show statistical significance for ACT ( $\alpha \leq 0.05$ ). Surfaces responses of EU as a function of CTAB and ADJ for SLNs and NLS are presented in Fig. 1 ( $T_{gi} = 60^\circ\text{C}$ ). Spray dried products with 7% of EU were formed at selected processing conditions.

**Table 2. Regression coefficients and their statistical significance for selected process responses.**

FACTORS	PROCESS RESPONSES							
	EU (mg/g)	ACT (mg/g)	R <sub>EU</sub> (-)	R <sub>ACT</sub> (-)	dp (nm)	PDI (-)	Z (mW)	R <sub>EC</sub> (%)
Mean	35.836*	2.910*	34.96*	44.88*	1680.7*	0.54*	-29.33*	46.67*
T <sub>gi</sub>	-8.309*	- 0.448*	-8.14*	- 6.70**	66.6	0.05**	1.567	-3.45
ADJ	- 11.334*	- 0.790*	- 3.86**	- 4.86**	-77.1	0.00	-0.367	-2.48
CTAB	8.586*	0.388*	9.61*	7.56*	-43.2	- 0.06**	3.892**	3.32
OA	1.516	0.160* *	1.37	2.56	-313.1	0.05**	-1.642	1.48
R <sup>2</sup>	0.956	0.959	0.984	0.973	0.258	0.918	0.725	0.715

\* Effect significant at  $\alpha \leq 0.01$  - \*\* Effect significant at  $\alpha \leq 0.05$

Fig. 2 shows graphs comparing data of dp, PDI and zeta potential of the original lipid systems with the corresponding values for redispersed SD samples. It can be seen that nanosized liquid SLNs and NLCs were engineered (F1 to F4), with small polydispersity index (PDI) and adequate |Z|. Significant increase of the droplets size for formulations containing CTAB were observed, perhaps due to interaction between the negatively charged<sup>[14]</sup> Arabic gum with the cationic lipid CTAB. This interactions were strong enough to invert the zeta potential of the CTAB primary lipid systems (without ADJ),<sup>[11]</sup> from highly positive values (+32.97 to +44.03 mW) to negative (from  $-30.8 \pm 0.1$  to  $-21.0 \pm 1.0$ ), linked to ADJ amount and OA addition. Therefore, a previous scrutiny of the charges of the composition constituents is highly recommended to reduce the likelihood of occurrence of unwanted interactions. The graphs also show good redispersion properties of SD powders; although some compositions exhibit dp slightly higher than the initial value, except for F6 to F8 products (containing CTAB). The redispersed SD powders with CTAB (F5 to F9) showed a reduction of PDI comparatively to initial composition. Similar values of [Z] were observed for the redispersed SD product and the original liquid lipid systems. These results give robust evidences that our initial goal, the production of redispersible SLNs and NLCs loaded with *Syzygium aromaticum* OE, is feasible. Fig. 3 shows S.E.M. micrographs of selected spray dried SLNs and NLCs; showing predominance of spherical somewhat wrinkled particles. The addition of OA caused a slight decrease in dp (Figs. c and d). Structural changes in the SLNs and NLCs are linked to their thermal and crystalline properties. DSC analysis show small differences in temperatures and enthalpies of fusion and crystallization, linked to systems composition (data not shown).

Fig. 4 shows the experimental results of R<sub>EC</sub> as a function of the outlet SD temperature. The solid line shows linear fit of the experimental data, indicating a tendency of decrease of R<sub>EC</sub> conversely with T<sub>gs</sub>. Traced lines shows the mean values of melting and crystallization

temperatures of lipid compositions. Drying at temperatures at left side of these lines show positive effects on  $R_{EC}$ .

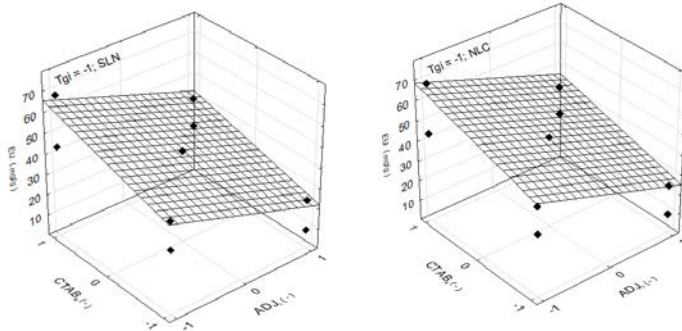

Fig. 1 Effects of CTAB and ADJ on Eugenol content in spray dried SLN and NLC ( $T_{gi} = 60$  °C).

Fig. 2. Comparison of particle size ( $dp$ ), Polidispersity index ( $PDI$ ) and zeta potential ( $|Z|$ ) of the original liquid lipid system and of the redispersed SD product (respectively, open and solid columns).

Fig. 3. S.E.M. images of the SD powder. a: SLN ( $T_{gi} = 60$  °C, ADJ = 1:1; CTAB = 0%); b: SLN ( $T_{gi} = 80$  °C, ADJ = 1:1; CTAB = 1%); c: NLC ( $T_{gi} = 80$  °C, ADJ = 1:1; CTAB = 0%); d: NLC ( $T_{gi} = 60$  °C, ADJ = 1:1; CTAB = 1%).

Fig. 4.  $R_{EC}$  as a function of  $T_{gs}$

## 4. Conclusions

The properties of the nanosized lipid systems loaded with EO are affected by processing conditions. EU and ACT in SD products depend on drying temperature and formulation constituents. R<sub>EU</sub> was higher (~50-60%) for systems with CTAB and OA, at lower SD temperature. Dried SLNs and NLCs are easily redispersed, indicating the potential of this technology.

---

### **Abstract**

*Mexican plum (*Spondias purpurea* L.) is a fruit with high nutritional content. Freeze and tray drying increases its shelf life, however non-reversible changes may occur. Properties as rehydration capacity and texture are considered as a measure of the injury to the material caused by drying. In this sense, the objective of this research was to evaluate the texture profile of dehydrated plum during rehydration and compare it with properties of raw plum. Freeze drying provided a product with less tissue damage reflected in the high rehydration capacity and texture characteristics very close to original unlike those dehydrated by hot air.*

**Keywords:** *Mexican plum; rehydration; texture profile analysis.*

---

## **1. Introduction**

Mexican plum (*Spondias purpurea* L.) is a fruit with qualities and potential for many different applications in the food industry. Nevertheless, the plums are mainly commercialized in local markets and have an incipient postharvest management with few methods for postharvest conservation currently in place [6]. Drying techniques, as freeze drying and tray drying, can be an excellent alternative to make their shelf-life longer and commercialization easier. It allows conversion of perishable materials into stabilized products by lowering water activity to appropriate levels, thus preventing microbial spoilage and quality deterioration [7].

Freeze drying prevents undesirable shrinkage and produces materials with high porosity, good nutritional quality, superior texture, aroma, flavor and color retention [10]. In contrast, tray drying is the most widely employed method for preserving food materials because of its simplicity and low cost that demands small investments for industries. It is commonly used for drying fruits and vegetables using hot air as a carrier of heat [12].

Despite advantages of preserving foodstuffs, drying methods may cause many non-reversible physical and chemical changes in the material such as color, nutritional value, shrinkage, texture etc. [3] Thus, rehydration can be considered as a measure of the injury to the material caused by drying and treatments preceding dehydration [5]. According to Farahnaky and Kamali the ultimate objective of rehydration process is to obtain a product with textural properties similar or close to original [4].
