27 **Abstract**

28 Barley malt production comprises three main steps: steeping, germination, and drying.
29 Ultrasound technology has been widely studied to find ways to improve mass transfer in food
30 processes and, consequently, to reduce process times. So, this study evaluated the effect of
31 temperature and the intermittent application of ultrasound on the steps involved in barley
32 hydration. The barley hydration was carried out at 10, 15, 20, and 25 °C with and without the
33 application of 0.75 W/mL and 1.5 W/mL of nominal power density at 20 kHz. The ultrasonic
34 energy delivered was measured in the same conditions as the steeping process using a
35 calorimetric method, taking distinct differential volume measurements throughout the hydration
36 medium. The ultrasonic energy delivered presented average values of 51.1 W at 750 W and 84.7
37 W at 1500 W nominal power. Ultrasound application increased both water uptake rates and
38 equilibrium moisture content as shown by the Peleg and Weibull-exponential model parameters,
39 with the latter showing better adjustment ($R_{adj}^2 > 0.953$ and $NRMSE < 5\%$). Applying ultrasound
40 also significantly reduced the time required to achieve the conventional moisture level required
41 for barley germination: 29% and 44% at controlled temperatures of 20 °C and 25 °C,
42 respectively.

43 **Keywords:** hydration; malt; high-intensity ultrasound; non-conventional technologies.

52 1. Introduction

53 Barley is the most important grain for the malting industry, widely used for the production of
54 beer, whiskey, barley wines, malt extracts, and other products (Yaldagard et al., 2008). This is
55 mainly due to the technological properties and flavoring characteristics that barley malt can
56 confer to foodstuffs. These attributes are a consequence of a series of reactions that occur during
57 a careful and protracted malting process.

58 In general, the malting process comprises three main steps: steeping or hydration, germination,
59 and drying. During conventional steeping, the grain is soaked in water for 24 to 36 hours in order
60 to increase moisture levels to 40-46% (w.b.) (Brookes et al., 1976). After steeping, the grains
61 take approximately 3 to 6 days to germinate. During hydration and especially during
62 germination, water promotes the transport of gibberellic acid inside the grains which leads to the
63 production of enzymes such as α - and β -amylase. This process causes changes in the structure of
64 the grain, influencing the quality of the malt (Mayolle et al., 2012; Montanuci et al., 2015).
65 Afterwards, the green malt is dried to reduce the water content to 4-5% (w.b.). This interrupts the
66 biochemical reactions and develops the malt's flavor (Samaras et al., 2005). The time-
67 temperature binomial of this last operation is highly dependent on the hydration process, since
68 the sensitivity of the enzymes may change in accordance with the moisture content of the grain
69 (Lewis and Young, 2001).

70 The hydration process is an essential unit operation for dried products like barley, as it defines
71 the product's properties and subsequent uses, such as cooking, extraction, fermenting,
72 germinating, and eating (Patero and Augusto, 2015). Concerning the malt quality, controlling the
73 amount of barley water absorbed is imperative to improving the malting process. However, water
74 absorption by the grain may be influenced not only by factors such as barley composition and
75 grain structure, but also by water temperature during steeping and the specific steeping methods
76 employed (Montanuci et al., 2013).

77 As a way of accelerating grain hydration, high-intensity ultrasound (US) provides a novel
78 technological solution to improve mass transfer processes. This technology has many
79 applications in the food industry (Cárcel et al., 2012; Garcia-Noguera et al., 2010; García-Pérez
80 et al., 2007). Although high-intensity ultrasound already plays an important role in the hydration
81 of seeds and cereals such as beans and sorghum (Ghafoor et al., 2014; Patero and Augusto, 2015)
82 there are still few studies that specifically look at barley steeping (Miano et al., 2015; Yaldagard
83 et al., 2008).

84 High-intensity ultrasound is able to enhance mass transfer through mechanisms related to both
85 solid and liquid phases, concerning barley and water respectively, in the specific case of barley
86 hydration. Solids under the effect of acoustic waves might behave like sponges due to a rapid
87 series of alternating contractions and expansions (García-Pérez et al., 2007). The same effect can
88 induce the formation of micro channels inside grain and reduce the resistance to water absorption
89 (Ghafoor et al., 2014). Ultrasound can also promote micro-agitation in solid–fluid interfaces
90 (Liang, 1999), which can reduce the external resistance and increase the water transport into the
91 barley grain.

92 The operating temperature is also an important factor when dealing with grain hydration. Resio
93 et al. (2006) reported faster hydration and a slightly higher moisture content saturation point in
94 amaranth grains when soaked at higher temperatures at a studied range of 30–60 °C, although at
95 the highest temperature the grains are supposed to lose solids to the hydration medium. The
96 temperature dependence of steeping is probably related to a higher agitation state of water
97 molecules at higher temperatures, and this trend was also observed in conventional barley grain
98 steeping at a range of 10–35 °C (Montanuci et al., 2013; Borges et al., 2017). However, the
99 temperature should be controlled when the hydration process is assisted by high-intensity
100 ultrasound in order to prevent the system over-heating and any other undesirable effects on either
101 the malt or the operating conditions.

102 The absorption of part of the acoustic energy into heat, which is proportional to the intensity and
103 attenuation of the ultrasonic waves traveling through the medium, should be investigated to
104 avoid undesirable effects (Raso et al., 1999). Generally, this determination has been made
105 through the measurements of punctual temperature variations during the first periods of
106 ultrasound application in different processes (Polachini et al., 2017; Margulis and Margulis,
107 2003; Chivate and Pandit, 1995). However, the energy is dissipated throughout the liquid and
108 may not reach all of the material of interest. The study by Fan et al. (2017) reinforced the need
109 for information about a specific acoustic field as a function of different positions of the
110 ultrasonic device.

111 Therefore, the present work was intended to provide an alternative approach to obtaining average
112 acoustic energy for whole volume elements using the calorimetric method. Additionally, this
113 study evaluated the effects of high-intensity ultrasound at different controlled temperatures
114 during the hydration process of whole barley kernels, by measuring the water uptake and
115 modeling the rate of water uptake as a function of time, temperature, and ultrasound power
116 intensity. The characterization of this process is essential for the correct design of hydration
117 processes assisted by ultrasound.

118

119 **2. Materials and methods**

120 *2.1. Raw materials*

121 Barley (*Hordeum vulgare*, variety Shakira) kernels, kindly donated by the Agroindustrial
122 Cooperative (Guarapuava, Paraná, Brazil), were used for the hydration experiments. Initial
123 moisture levels were determined using AOAC methods (AOAC, 2005), oven-drying at 105 °C,
124 in three replicates. The initial moisture level was 10.01 ± 0.65 g/100 g (d.b.). The grains were
125 stored in a refrigerated low-humidity room.

126

127 2.2. Ultrasound-assisted hydration experiments

128 The ultrasound-assisted hydration experiments were carried out in the system schematized in
129 Figure 1. Approximately 100 g of barley kernels were placed in a perforated stainless-steel
130 sample holder, inside a jacketed stainless-steel vessel containing 1000 mL of water. Constant-
131 temperature water circulated in the jacket side of the vessel, provided by an ultra-thermostatic
132 circulated water bath (MA-184, Marconi, Piracicaba, Brazil), to control the hydration
133 temperature.

134 A Vibra-Cell VCX-1500 ultrasound processor horn type (Sonics & Materials, Newton, USA),
135 with a 25 mm diameter axial sonotrode operating at 20 kHz frequency and 1500 W maximum
136 nominal power, was used to assist in the steeping treatments. The ultrasonic tip of the sonotrode
137 was axially placed 1.5 cm above the sample in the center of the stainless-steel vessel (Fig. 1).

138 After each specific steeping period (1, 2, 3, 4, 6, 8, 10, 14, and 24 hours), the sample holder was
139 removed from the vessel, drained to remove excess superficial water, weighed, and placed back
140 into the hydration vessel in order to determine the water uptake. Ultrasound acoustic waves were
141 continuously applied for 30 minutes every time a sample was placed in the hydration unit, and
142 then interrupted until it was removed for weighing. This resulted in a total of 4.5 hours of
143 ultrasound application during the 24 hours. The water content (X) was calculated by mass
144 balance, with the initial sample mass (m_0), the initial moisture (X_0), and the sample weight (m) as
145 a function of hydration time (t). For this calculation, increases in the weight of the sample were
146 considered to be exclusively due to the mass of water absorbed by the grain. Additionally, the
147 dissolution of soluble solids towards the medium was negligible (Patero and Augusto, 2015).

148 The steeping experiments were carried out at four different temperatures (controlled at 10, 15,
149 20, and 25 °C), in accordance with the upper temperature limits required for barley germination
150 and malting industry practices (Brookes et al., 1976). The influence of high-intensity ultrasound
151 nominal power on barley hydration was evaluated by applying three different levels (0, 750, and

152 1500 W). For each condition, the steeping experiment was carried out in duplicate according to
 153 an experimental factorial design.

154

155 2.3. Ultrasonic energy measurements

156 Prior to the experiments, the ultrasonic energy actually delivered (P_{US}) in the hydration
 157 experiments was determined using the calorimetric method adapted from Cárcel et al. (2012).

158 The ultrasonic energy was obtained for the hydration unit presented in Fig. 2a, in which an
 159 energy balance was applied for the time interval of the application of ultrasound acoustic waves
 160 from time t_0 to t_{US} and average water temperature from T_0 to T_{US} . The temperatures were
 161 measured by means of thermocouples placed in the water and connected to the data acquisition
 162 module (NI 9213, National Instruments, Austin, USA). LabView software (National Instruments,
 163 Austin, USA) was used to record the temperature on a computer (Fig. 1). The temperature inside
 164 the medium was recorded (in triplicate) during the 90 seconds (t_{US}) of ultrasound application
 165 (Raso et al., 1999) in 57 positions (four radial positions, including $r = 0$; six angular positions,
 166 and three axial positions, as showed in Fig. 2b). Temperature recordings were carried out in the
 167 same conditions as the hydration experiments at 10, 15, 20, and 25 °C and high-intensity
 168 ultrasound at 750 and 1500 W nominal power. From the measured temperatures at each point, a
 169 mean volumetric temperature of the hydration water was calculated by Eq. (1) using the
 170 rectangular integration:

$$T = \frac{1}{V} \int T_i dV_i \quad (1)$$

171 Considering that energy exchanges between the hydration water and the jacketed vessel were
 172 negligible for the short time of temperature recording, the accumulated energy accounted for the
 173 acoustic power (P_{US}) by Eq. (2).

$$174 P_{US} = \rho V c_p \frac{dT}{dt} \quad (2)$$

175 As expected, the similar linear profile of temperature versus time was observed in the hydration
 176 medium, and the values of dT/dt were acquired by linear fitting. The thermophysical properties
 177 of the hydration water were obtained using the Eqs. (2) and (3) reported by Carvalho et al.
 178 (2015). These values were considered constant at the mean temperature during heating.

$$\rho = 995.3 - 8.442 \times 10^{-3} T^2 \quad (2)$$

$$c_p = 3.112 + T^{3.406 \times 10^{-3}} \quad (3)$$

179 From the ultrasonic energy (P_{US}) values, the ultrasonic density was also calculated according to
 180 Eq. (4):

$$D_{US} = \frac{P_{US}}{V} \quad (4)$$

181
 182 *2.4. Mathematical modeling for ultrasound-assisted barley hydration*
 183 Two empirical models were used to describe the hydration of barley assisted by ultrasound. The
 184 Peleg model (Peleg, 1988) represented by Eq. (5) describes the kinetics of moisture sorption that
 185 asymptotically approaches the equilibrium:

$$X = X_0 + \frac{t}{k_1 + k_2 t} \quad (5)$$

186 where k_1 is the Peleg model's constant rate, or the inverse of the hydration rate, and k_2 is the
 187 constant of capacity of the Peleg model which is related to the equilibrium moisture content
 188 ($X_{eq} = X_0 + 1/k_2$).

189 The Weibull-type exponential model with three parameters describes hydration processes as
 190 probabilistic events, which may present some variability such as mass gains or losses
 191 (Cunningham et al., 2007; Cunha et al., 1998). It is represented by Eq. (6):

$$\theta = 1 - \exp\left(-\left(\frac{t}{\beta}\right)^\alpha\right) \quad (6)$$

192 where $\theta = (X-X_0)/(X_{eq}-X_0)$, α is the shape parameter, correlated to the process initial rate, and β is
193 the scale parameter which corresponds to the time required for the sample to reach 63% of the
194 equilibrium moisture content.

195

196 2.5. Statistical analysis

197 The models were fitted to the experimental data of water uptake versus hydration time by non-
198 linear regression using the Solver tool of Microsoft Excel® (Microsoft Corporation, Redmond,
199 USA). The parameters were identified using the generalized reduced gradient method (GRC
200 Non-linear) of the same software. The effectiveness of the fit was evaluated using the adjusted
201 determination coefficient (R_{adj}^2), residual plot analysis, and the normalized root mean square
202 error (*NRMSE*) in order to determine the reliability of both models.

203 The influence of temperature and ultrasound nominal power on all ultrasound-assisted hydration
204 treatments was evaluated by the analysis of variance (ANOVA) with a confidence interval of
205 95%, by using the software Minitab v.16.1.1 (Minitab Inc., State College, USA).

206

207 3. Results and Discussion

208 3.1. Ultrasonic energy

209 It is known that some energy could be dissipated during electrical conversion into effective
210 acoustic energy. Therefore, the delivered ultrasonic energy was measured using the calorimetric
211 method concerning the entire medium of hydration to provide a better estimation of the acoustic
212 fields in the entire reactor. This provides important data to make adequate conclusions about the
213 cavitation, not only at a specific point, but for the whole liquid.

214 The linear increase of temperature with sonication time provided values of dT/dt to obtain P_{US} of
215 51.12 W at 750 W and 84.68 W at 1500 W nominal power, as indicated in Fig. 3. The resulting
216 average ultrasonic power density obtained by the relationship between the ultrasonic energy

217 delivered and the volume of water (1000 mL) varied from 0.0495 to 0.0522 W/mL and from
218 0.0829 to 0.0864 W/mL at 750 W and 1500 W, respectively, at the range of temperatures
219 studied. As this work took into account energy transfer throughout the liquid medium (not only
220 at the point of maximum cavitation), relative lower delivered energy was obtained compared to
221 other studies (Polachini et al., 2017; Ozuna et al., 2014). The increase in temperature was less
222 intense as the temperature recordings were taken closer to the reactor wall and away from the
223 sonotrode tip, bringing down the maximum conversion rates that are usually concentrated right
224 below the sonotrode. At the position of maximum increase, temperature increases would result in
225 average acoustic powers of 75.17 W at 750 W and 123.26 W at 1500 W if only this punctual
226 increase is taken into account. However, the resulting actual ultrasonic density was similar or
227 higher than other similar studies involving hydration assisted by bath type ultrasound (Patero and
228 Augusto, 2015; Yildirim et al., 2011), even considering the integral method used to obtain real
229 acoustic power.

230 The results indicated that acoustic energy was significantly affected by the intensity of applied
231 nominal power, but not affected by the temperature of the water. The average conversion ratio
232 between the delivered ultrasonic energy and the nominal power (P_{US}/P_N) was 6.82% for 750 W
233 and 5.64% for 1500 W nominal power, showing a reduction in the conversion ratio with the
234 increase in the nominal power. This low conversion ratio is due to high volumes treated with
235 high-action and, consequently, to the presence of many regions of low-action ultrasound. As all
236 these regions were considered in the calculation, the little punctual dT/dt near to the reactor wall
237 caused a decrease in the resulting average dT/dt . The reduction in the yield of conversion can be
238 explained by the higher energy losses to the medium due to attenuation and higher levels of
239 cavitation at higher nominal ultrasonic power. Gogate et al. (2011) stated that, above a certain
240 power limit, a number of cavitation bubbles might cluster near the tip of the sonotrode. This can

241 cause disturbances in this region of the medium, leading to difficulties for energy transfer
242 processes.

243 According to Sala et al. (1995), reaction rates in ultrasound-assisted processes may be reduced as
244 the medium temperature increases due to the exponential increase in vapor pressure and the
245 reducing number of microbubbles formed, resulting in fewer collapses due to cavitation and less
246 energy transmitted. However, Raso et al. (1999) found that the amount of energy delivered by
247 the ultrasound waves can be reduced drastically above 70 °C. This was found to be true in the
248 current study, which observed no influence of temperature on the transmitted energy at a range
249 of temperatures from 10–25 °C. Although temperature might not affect energy conversion into
250 acoustic power, it had a significant positive effect on mass transfer as reported by the grain
251 hydration. This means that the yield of power conversion is not affected if hydration is enhanced
252 by increasing temperature.

253

254 *3.2. Ultrasound-assisted barley hydration*

255 The experimental steeping curves of barley are shown in Figure 4, together with the fitted
256 mathematical models. The increase in temperature and ultrasonic power applied for the total of
257 4.5 hours reduced the time required to reach the necessary moisture levels for the germination of
258 barley seeds by conventional processes (approximately 75 g/100 g d.b.) (Mayolle et al., 2012).
259 After 24 hours, the steeping performed at 10 °C did not reach 75 g/100 g (d.b.) of moisture, even
260 with the application of intermittent high-intensity ultrasound. At 15 °C, the hydration performed
261 without the application of high-intensity ultrasound also failed to reach the necessary moisture
262 level for germination, even after 24 hours (Fig. 4). However, by applying high-intensity
263 ultrasound at 0.0511 W/mL actual volumetric power at a temperature of 15 °C, 24 hours of
264 hydration was enough for the barley seeds to reach the required moisture for germination, while
265 only 20 hours was needed at 0.0847 W/mL actual volumetric power. The steeping conducted at

266 20 °C assisted by 0.0511 W/mL and 0.0847 W/mL of acoustic density showed reductions of
267 29.2% and 37.5% respectively in the amount of time required to reach the right moisture levels
268 without sonication. At 25 °C, the time reduction was even higher: 33.3% and 44.5% quicker with
269 the application of ultrasound at 0.0511 W/mL and 0.0847 W/mL respectively.

270 The results of this study have shown a significant reduction in the amount of time required for
271 barley steeping by applying high-intensity ultrasound. Montanuci et al. (2013) showed that
272 hydrated barley reached 75 g/100 g (d.b.) moisture only at 20 °C or above, when investigating
273 hydration in five cultivars of barley during a period of 32 hours using a mechanically stirred
274 medium (sample and water) at temperatures between 10 and 35 °C. Based on this data,
275 ultrasound can be used as an efficient tool to enhance the mass transfer and reduce the
276 conventional steeping time instead of using energy to heat and/or to maintain the average
277 temperature. At industrial plants which are already supplied with warm water, the time
278 previously required for the hydration phase can be reduced by almost half by using power
279 ultrasound. It is also worth reiterating the statement of Miano et al. (2005) that the ultrasonic
280 treatment is not only capable of reducing the required time for steeping without affecting the
281 germination and vigor of the seeds, but it can also improve the germination rate of the seeds.

282 Regarding the fitting procedure, the residual plots for the Peleg model and the Weibull-
283 exponential model are presented in Figure 5. In general, both models were well-fitted to the
284 experimental values. The fitting performance can also be verified through the statistical
285 parameters R_{adj}^2 and $NRMSE$ presented in Table 1. The Weibull-exponential model, in particular,
286 was better fitted as it resulted in lower $NRMSE$ and higher adjusted determination coefficients,
287 even presenting more parameters than the Peleg model. The Peleg model showed higher negative
288 values for shorter times and a tendency to increase until reaching a maximum positive value and
289 then decreasing for longer times of hydration. The Weibull-exponential model showed similar
290 behavior, but with residual values lower than the Peleg model. Although these models presented

291 different degrees of accuracy, the interpretation of the respective parameters provides important
292 information.

293 The constant rate parameter values of the Peleg model are in close agreement with the ones
294 published by Montanuci et al. (2013) for five different varieties of barley seeds, which varied
295 from 0.0273 to 0.0670 h·100 g/g (d.b.) at a range of temperatures between 10 and 35 °C without
296 ultrasound. This parameter (k_1), related to the initial rate of hydration, was not significantly
297 influenced by the temperature of the process ($p=0.075$). The application of high-intensity
298 ultrasound reduced k_1 ($p<0.001$), or in other words the application of ultrasound increased the
299 initial rate of hydration. The constant of capacity parameter (k_2) behaved as reported by these
300 same authors. It was affected by temperature and the intensity of the ultrasound applied, in such
301 a way that the higher the temperature combined with the application of ultrasound, the lower the
302 value of k_2 ($p < 0.001$). Moreover, the hydration of other grains such as sorghum assisted by
303 acoustic ultrasonic density of 0.026 W/mL was able to reduce the constant rate (k_1) of the Peleg
304 model from 0.029 to 0.025 h·100 g/g (d.b.) and reduce the capacity constant (k_2) from 0.0286 to
305 0.02574 100 g/g (d.b.) at 25 °C (Patero and Augusto, 2015). The fitting parameters are also in
306 accordance with Ghafoor et al. (2014), who applied ultrasound to the hydration of navy beans at
307 16 °C, describing a reduction in the Peleg model's k_1 from 0.029 to 0.016 h·100 g/g (d.b.) for the
308 control and sonicated processes respectively.

309 Regarding the Weibull-exponential model, the shape parameter (α), related to the initial rate of
310 water absorption, was affected ($p<0.001$) by temperature and the application of high-intensity
311 ultrasound. The parameter increased with rising temperatures and decreased with the increasing
312 ultrasonic power. Similarly, as shown by the Peleg model, applying ultrasound increases the
313 initial rate of water absorption. The scale parameter (β), which represents the time needed to
314 absorb 63% of the total water absorbed at the equilibrium (Cunningham et al., 2007), was not
315 significantly affected by the application of high-intensity ultrasound ($p>0.781$), but decreased as

316 the temperature was increased ($p < 0.001$). As the treatments assisted by ultrasound caused an
317 increase in the grain's equilibrium moisture content, the required time to absorb 63% of X_{eq} is
318 supposed to be the same. However, temperature seemed to have a positive effect on the water
319 absorption rate. The resulting parameters are in accordance with the ones reported by Montanuci
320 et al. (2015), who also fitted the experimental data of barley hydration to the Weibull-
321 exponential model. They obtained values from 0.41 to 0.59 for the shape parameter (α) and
322 values of 5.83 to 8.87 h for the scale parameter (β) at the same range of hydration temperatures.
323 The values of equilibrium moisture (X_{eq}) estimated by the Weibull-exponential model were
324 higher than the values estimated by the Peleg model for all experimental conditions. The
325 effectiveness of fit (R_{adj}^2 and $NRMSE$) indicated that the values of X_{eq} estimated by the Weibull-
326 exponential model are more reliable than their Peleg counterparts. Both the increase in process
327 temperature and in the intensity of the applied ultrasound resulted in higher ($p < 0.05$) equilibrium
328 moisture. The observed increase ranged from 5.50% to 14.93%, with greater differences at lower
329 temperatures studied. The main complex mechanism involved in conventional non-stirred barley
330 steeping is water diffusion, which controls grain hydration. However, ultrasound has shown itself
331 to be a promising technology for enhancing water transport and X_{eq} . The alternative compression
332 and expansion cycles act similarly to a sponge, which contracts and expands repeatedly as
333 ultrasonic waves travel through the tissue. This phenomenon can keep the micro-channels free,
334 facilitating mass transfer (Garcia-Noguera et al., 2010; Gafhoor et al., 2014; Patero and Augusto,
335 2015). In addition, the wave propagation can generate micro-channels in the tissue due to the
336 mechanical stress and this can improve the hydration. Nevertheless, further investigation is
337 encouraged concerning the possible effects of high-intensity ultrasonic waves on enzyme
338 formation and germination rates in barley malt production.

339

340 4. Conclusions

341 This study investigated the effect of temperature and high-intensity ultrasound on barley
 342 hydration. The ultrasonic energy delivered was determined using the calorimetric method taking
 343 into account different points of the reactor. The average acoustic power was not significantly
 344 affected by temperature in the range investigated, however reductions (6.82% to 5.64% on
 345 average) in the conversion ratio were observed as the nominal power increased from 750 to 1500
 346 W, possibly due to higher attenuation of the ultrasonic waves at higher intensities. Ultrasound-
 347 assisted barley hydration showed higher water uptake rates at the beginning of the process and
 348 then asymptotic behavior towards maximum moisture levels for longer hydration times,
 349 corresponding to the equilibrium moisture. The water uptake rate and the equilibrium moisture
 350 content increased with the ultrasound power, as showed by the Peleg and Weibull-exponential
 351 models. The Weibull-exponential model presented a better adjustment ($R_{adj}^2 > 0.953$ and
 352 $NRMSE < 5\%$) to the data for barley hydration assisted by ultrasound, although the Peleg model
 353 also represents an alternative as it is so easy to use. Ultrasound application reduced the time
 354 required to achieve the necessary moisture level for barley germination from 29 to 44% at
 355 relatively low temperatures (20 and 25 °C respectively), compared to the treatment without
 356 ultrasound, indicative of an alternative technology for improving barley hydration.

358 Nomenclature

c_p	Water heat capacity	J/kg K
D_{US}	Acoustic density	W/mL
k_1	Constant rate parameter of the Peleg model	h·100 g/g d.b.
k_2	Constant capacity parameter of the Peleg model	100 g/g d.b.
m	Mass of sample	g
m_0	Initial mass of sample	g
$NRMSE$	Normalized root-mean-square error	%
p	p -value	-
P_N	Nominal power of the ultrasound generator	W
P_{US}	Ultrasonic energy delivered	W
R_{adj}^2	Adjusted determination coefficient	-
T	Average temperature of water	°C

t	Time	s, h
T_0	Initial temperature of the water	°C
t_0	Time at the beginning of the first interval	S
T_{US}	Water temperature at the end of the first interval	°C
t_{us}	Time at the end of first interval	S
V	Volume of the hydration unit	m ³
X	Moisture content	g/100 g d.b.
X_0	Initial moisture content	g/100 g d.b.
X_{eq}	Equilibrium moisture	g/100 g d.b.
α	Shape parameter of the Weibull-exponential model	
ρ	Water density	kg/m ³
β	Scale parameter of the Weibull-exponential model	h

Highlights

- > The effect of temperature and input power on barley hydration was studied.
- > A new approach to determine the acoustic fields was reported.
- > Hydration processes were well-fitted to both the Weibull and Peleg models.
- > Ultrasound enhanced both water uptake and equilibrium moisture content.
- > Ultrasound reduced the hydration time required for barley germination by up to 44%.
