29 **Abstract**

30 The influence of the amylose:amylopectin ratio on the properties of pea, potato and
31 cassava starch (with a high, intermediate and low amylose-amylopectin ratio,
32 respectively) films and the effect of the incorporation of rice bran of two different
33 particle sizes were studied. The structural, mechanical (elastic modulus, tensile
34 strength and percentage of elongation at break), optical (gloss and internal
35 transmittance) and barrier (water vapour permeability and oxygen permeability)
36 properties of the films were analysed after 1 and 5 weeks under controlled storage
37 conditions (25°C and 53%RH). The properties of the films were affected by both
38 amylose-amylopectin ratio and storage time. The high content of amylose gave rise to
39 stiffer, more resistant to fracture, but less stretchable films, with lower oxygen
40 permeability and greater water binding capacity. Although no changes in the water
41 vapour permeability values of the films were observed during storage, their oxygen
42 permeability decreased. Throughout storage, films became stiffer, more resistant to
43 break, but less stretchable. Rice bran with the smallest particles improved the elastic
44 modulus of the films, especially in high amylose content films, but reduced the film
45 stretchability and its barrier properties, due to the enhancement of the water binding
46 capacity and the introduction of discontinuities (fibre particles) in the matrix.

56

57 **1. Introduction**

58 Conventional plastics are synthetic polymers derived from petroleum whose residues
59 are not easily assimilated in the environment. This fact has led to the increasing use of
60 biodegradable raw materials to obtain biodegradable plastics as an alternative to
61 petroleum-derived polymers in different sectors, such as agricultural, medical or
62 pharmaceutical. Nowadays, the use of films or edible coatings based on biodegradable
63 polymers is increasing because these materials are environmentally friendly (Chen,
64 Liu, Chen, Chen & Chang, 2008, Mehyar and Han, 2004) and exhibit properties which
65 can become similar to those observed in conventional plastics (Jiménez, Fabra, Talens
66 & Chiralt, 2012a; Famá, Goyanes & Gerchenson, 2007; Rindlav-Westling, Stading,
67 Hermansson & Gatenholm, 1998).

68 Materials for biodegradable packaging are classified according to their molecular
69 structure; polysaccharides, proteins and fats are the most widely used (Falguera,
70 Quintero, Jiménez, Muñoz & Ibarz, 2011; Adebisi, Adebisi, Jin, Ogawa & Muramoto,
71 2008; Nam, Scanlon, Han & Izydorczyk, 2007; Mehyar and Han, 2004;
72 Gnanasambandam, Hettiarachchy & Coleman, 1997). Of the polysaccharides, starch,
73 cellulose and their derivatives are very commonly studied as film-forming compounds
74 (Jiménez et al, 2012a; Chen, Liu, Chang, Cao & Anderson, 2009a).

75 Starch is a polysaccharide from cereals (corn, wheat or rice), legumes (pea) and tubers
76 (potato or cassava). It has a granular structure and is composed of two
77 macromolecules: amylose and amylopectin. Amylose is a linear polymer formed by
78 glucose units linked by α -(1,4) whereas amylopectin is a highly branched polymer of
79 glucose units with ramifications in α -(1,6). The amylose:amylopectin ratio depends on
80 the source of starch and this ranges from 15:85 to 35:65, except in waxy starch and
81 high amylose corn starch whose amylose content is about 5% and 50-80% respectively
82 (Liu, 2005) . It is known that both polymers are responsible for the starch crystallization
83 which leads to changes in the mechanical response (increased stiffness) of starch
84 products (Talja, Helén, Roos & Jouppila, 2007).

85 Starch is used to obtain films because of its high availability and great ability to form an
86 odourless, colourless and transparent (Vásconez, Flores, Campos, Alvarado &
87 Gerschenson, 2009) polymer matrix with low oxygen permeability, which is very
88 interesting for food preservation (Jiménez *et al.*, 2012a; Dole, Joly, Espuche, Alric &
89 Gontard, 2004; Han, Seo, Park, Kim & Lee, 2006; Liu, 2005). It is also especially
90 attractive because of its biodegradability and low cost (Han *et al.*, 2006; Chen *et al.*,
91 2008; Lafargue, Lourdin & Doublier, 2007). Nevertheless, starch films present some
92 drawbacks: unstable mechanical properties due to the retrogradation phenomenon and
93 a relatively high water vapour permeability (Lafargue *et al.*, 2007; Chen *et al.*, 2008;
94 Phan The, Debeaufort, Voilley & Luu, 2009; Wu *et al.*, 2010).

95 In starch films, the retrogradation phenomenon over time, can greatly affect not only
96 their mechanical properties but also their barrier capacity. So, the study of changes
97 occurring during their storage is necessary to ensure their functionality at different
98 times after processing. Different authors have studied the development of properties of
99 starch films. Jiménez, Fabra, Talens, & Chiralt (2012b) studied the effect of re-
100 crystallization on physical properties of corn starch films containing fatty acids and
101 concluded that fatty acid incorporation did not notably improve water vapour
102 permeability while the degree of crystallinity of the matrix increased during storage
103 time. In order to improve properties of the starch films different strategies are used by
104 different authors. Da Matta, Silveira, de Oliveira & Sandoval (2011) evaluated
105 mechanical properties of edible films made from wrinkled pea starch rich in amylose
106 combined with xanthan gum and glycerol and they observed that the increase in
107 xanthan gum concentration did not affect the physical and mechanical properties of the
108 films. For potato starch films, Zhang, Thompson & Liu (2011) studied how cellulose
109 fibre and potato pulp affected the properties of thermoplastic starch. The addition of
110 fibre did not affect the film glass transition. Nevertheless, moisture content, surface
111 tension and the hydrophilic character of films increased in line with the fibre content.
112 Souza, Benze, Ferrao, Ditchfield, Coelho, & Tadini (2011) stated that films based on

113 glycerol and clay nanoparticles as reinforcement are an interesting biodegradable
114 alternative as packaging material. Famá, Gerschenson, & Goyanes (2009) also studied
115 the influence of wheat bran on physicochemical characteristics of cassava starch films
116 and concluded that the mechanical properties and water vapour permeability of starch-
117 wheat bran composites improved when the fibre content rose.

118 One of the means of improving the barrier and mechanical properties of starch films is
119 through the incorporation of natural fibres from plant origin as fillers. In this sense,
120 Chen *et al.*, (2009a) used pea hull fibre nanoparticles in pea starch films, which
121 improved film transparency, tensile strength, elongation at break and water barrier
122 properties due to the high content of cellulose crystalline regions and the interactions
123 between the nanofibre and the starch matrix. Famá *et al.*, (2009) introduced wheat
124 bran as filler in cassava starch matrices, thus improving their mechanical and water
125 vapour permeability.

126 Bran rice is a by-product of rice which is obtained from rice bleaching and it represents
127 about 10% of the grain weight. Rice bran contains good quality biological proteins, fats
128 and starch. Depending on the variety of rice and the type of processing, rice bran
129 contains about 15-20% fat, 12-16% protein, 23-28% fibre and 7-10% ash (Sánchez,
130 Quintero, & González, 2004). In addition, bran has a high vitamin B and E complex (as
131 α -tocopherol) content (Carroll, 1990).

132 Despite its interesting composition, rice bran is not given the importance it deserves
133 since it is only used in animal food. Nevertheless, in recent years, attempts have been
134 to reappraise it by studying applications in different areas. In this way, rice bran has
135 been evaluated as a source of oil (Nikolosi, Ausman, & Hegstead, 1990), protein
136 concentrates (Gnanasambandam & Hettiarachache, 1995) and as a matrix of edible
137 films (Dias, Müller, Larotonda, & Laurindo, 2010; Adebisi *et al.*, 2008;
138 Gnanasambandam *et al.*, 1997).

139 The aim of this work was to analyse the influence of the amylose:amylopectin ratio on
140 the properties of films obtained from three different (pea, potato and cassava)

141 starches, with different ratios of both polymers and the effect of the addition of rice bran
142 with two different particle sizes, as a film filler. Structural, mechanical, optical and
143 barrier properties of the films were analysed at different storage times (1 and 5 weeks)
144 in order to compare their behaviour and functionality.

145

146 **2. Materials and methods**

147 2.1. Materials

148 Pea (PE) and potato (PO) starch were purchased from Roquette (Lestrem, France) and
149 cassava starch (CAS) obtained from Asia Modified Starch CO; LDT (Kalasin, Thailand).
150 Rice bran obtained from Arrocería Antonio Tomás, S.L. (Sollana, Valencia, Spain).
151 Glycerol, used as plasticizer, was provided by Panreac Química S.A. (Castellar de
152 Vallès, Barcelona, Spain).

153

154 2.2. Amylose-amylopectin ratio

155 Amylose-amylopectin ratio in each starch (pea, potato and cassava) was determined in
156 triplicate, by using an Amylose/Amylopectin Assay Procedure enzymatic kit which was
157 purchased from Megazyme (Wicklow, Ireland).

158

159 2.3. Rice bran particle size

160 To select particle size, rice bran was sieved to obtain two different bran fractions. The
161 smallest particle size fraction that pass through the 100 μm mesh and the coarse
162 fraction contained between mesh 250 and 100 μm were obtained and used for film
163 preparation. The smallest particle bran is named "Fine" (F) and the other bran fraction
164 is called "Coarse" (C).

165 The rice bran particle size, surface weighted mean diameter ($D_{3,2}$, eq 1) and volume
166 weighted mean diameter ($D_{4,3}$, eq 2) were determined in bran aqueous dispersions, in
167 triplicate, with a laser light scattering instrument (Malvern Instruments Ltd,
168 Worcestershire, U.K.). Particle size measurements were taken for two different

169 fractions. To this end, bran fraction was dispersed in aqueous medium and
170 measurements were taken with ultrasonic homogenization to maintain the sample
171 homogeneity.

$$172 \quad D_{4,3} = \frac{\sum n_i d_i^4}{\sum n_i d_i^3} \quad (1)$$

$$173 \quad D_{3,2} = \frac{\sum n_i d_i^3}{\sum n_i d_i^2} \quad (2)$$

174

175 2.4. Compositional analysis of rice bran

176 Moisture content (MC) was determined from sample weight loss when samples were
177 introduced into a convection oven at 100°C for 24 h and, afterwards, equilibrated in
178 desiccators with P₂O₅ for 2 weeks until constant weight.

179 Ash content was obtained by applying the gravimetric method 104/1 of the International
180 Association for Cereal Science and Technology (ICC, 1990). The rice bran was
181 introduced into a muffle "Select-Horn" (J.P. Selecta; Abrera, Barcelona, Spain) at
182 910°C for 15 min.

183 Protein content was obtained by means of the method of analysis 105/2 (ICC, 1994).

184 The crude protein content was obtained by multiplying the nitrogen content, determined
185 by the Kjeldahl procedure, using the factor F=5.95. A digestion unit "Bloc-digest" (J.P.
186 Selecta; Abrera, Barcelona, Spain) and a Kjeldahl distiller "Pro-Nitro M" (J.P. Selecta;
187 Abrera, Barcelona, Spain) were used.

188 Fat content was obtained by using the Soxhlet method 30-20 (ICC, 1967). Samples
189 were firstly dried at 103°C and then the fat was extracted by an oil extractor "Det-
190 GrasasN" (J.P. Selecta; Abrera, Barcelona, Spain).

191 Starch content of the rice bran was determined using the enzymatic Kit "Starch Assay
192 Kit", which was supplied by Sigma (Saint Louis, Missouri, USA).

193 Fibre percentage was estimated from the difference between the total percentage of
194 the rest of the analysed components and 100, assuming that starch is the only
195 carbohydrate.

196

197 2.5. Preparation of films

198 For preparation of starch films, three formulations based on distilled water, starch (pea,
199 potato or cassava) and glycerol were prepared. The dispersions contained 2% w/w of
200 starch whereas the plasticizer was added considering a starch:glycerol ratio of 1:0.25,
201 on the basis of previous studies (Jimenez et al. 2012a). In the preparation of starch
202 films containing rice bran as filler, six formulations were obtained by using fine (F) or
203 coarse (C) rice bran and starch (pea, potato or cassava) and glycerol. The film forming
204 dispersions were prepared in the same way and with the same glycerol ratio and bran
205 was afterwards incorporated in a starch:rice bran ratio of 1:0.1.

206 Starch aqueous dispersions were maintained at 95°C for 30 min to induce starch
207 gelatinization. Then, glycerol was added and the dispersion was homogenized using a
208 rotor-stator homogenizer (Ultraturrax D125, Janke and Kunkel, Germany) at 13,500
209 rpm for 1min and 20,500 rpm for 3 min at 95°C under vacuum. For starch films
210 containing rice bran, this was incorporated prior to the homogenization step. The film-
211 forming aqueous dispersions were cast into a levelled Teflon casting plates (15cm
212 diameter) and each film contained 1.5 g of total solids. Films were formed by drying at
213 25°C and 45%RH for 48 h. Then, they were peeled intact from the plates and were
214 conditioned at 53% RH using magnesium nitrate-6-hydrate saturated solution (Panreac
215 química, S.A., Castellar del Vallés, Barcelona, Spain) at 25°C until analysis. Their
216 thickness was measured at six random positions with a Palmer digital micrometer to
217 the nearest 0.0025 mm. All films were analyzed after one or five storage weeks.

218

219 2.6. Characterization of films

220 2.6.1. X-ray diffraction spectra

221 X-ray diffraction spectra were obtained using a Diffractometer D8 Advance (Bruker
222 AXS, 230 V, 50 Hz and 6.5 KVA, Karlsruhe, Germany). For this analysis conditioned
223 samples were cut into squares of 4 cm and mounted on a carbon base. Spectra were
224 obtained at 2θ between 5 and 30, using $K\alpha$ Cu radiation (λ : 1,542 Å), 40 kV and 40 mA
225 with a step size of 0.04982.

226

227 2.6.2. Microstructural properties

228 Microstructural analysis of films was carried out using a scanning electron microscope
229 (SEM) (JEOL®, model JSM-5410, Japan) and an atomic force microscope (AFM)
230 (Multimode 8, Bruker AXS, Inc. Santa Barbara, California, USA) with a NanoScope® V
231 controller electronics. To this end, films were equilibrated in desiccators with P_2O_5 for
232 two weeks to ensure that no water was present in the samples.

233 SEM observations were carried out on the film surface and in their cross section. To
234 prepare the samples, films were frozen in liquid N_2 and cryofractured to observe the
235 cross section. Samples were fixed on copper stubs, gold coated, and observed using
236 an accelerating voltage of 11 kV. Three replicates per formulation were observed.

237 AFM with the PeakForce QNM (Quantitative NanoMechanics) was used to analyse
238 surface film nanostructure. Measurements were taken from small areas of the film
239 surface (20x20 μm) and the resulting data were transformed into 2D image of the Log
240 DMT modulus. Three images were captured per formulation, for samples stored for 1
241 and 5 weeks.

242

243 Measurements were also taken from several areas of the film surface (50 x 50 and 3 x
244 3 mm) using the tapping mode. The resulting data were transformed into a 2D image.

245 Phase Imaging mode derived from Tapping Mode, that goes beyond topographical
246 data to detect variations in composition, adhesion, friction, viscoelasticity, and other
247 properties, including electric and magnetic, was also applied.

248 According to method ASME B46.1 (ASME, 1995), the following statistical parameters
249 related with sample roughness were calculated: average roughness (Ra: average of
250 the absolute value of the height deviations from a mean surface), root-meansquare
251 roughness (Rq: root-mean-square average of height deviations taken from the mean
252 data plane).

253

254 2.6.3. Moisture Content

255 To determine film moisture content, five replicates by formulation were dried in a
256 convection oven at 60°C for 24h, and then they were equilibrated with P₂O₅ until
257 constant weight.

258

259 2.6.4. Water Vapour Permeability

260 The water vapour permeability (WVP) of films was determined following the gravimetric
261 method ASTM E96-95 (1995) by using Payne permeability cups (Payne, elcometer
262 SPRL, Hermelle/sd Argenteau, Belgium) of 3.5 cm diameter. The temperature was
263 25°C and the relative humidity gradient was 53-100%, which was obtained using
264 magnesium nitrate-6-hydrate and pure water, respectively. Cups were introduced into
265 desiccators and these into a temperature-controlled chamber at 25°C. Control of cup
266 weights was performed every 2 h using an analytical balance (± 0.00001 g). The water
267 vapour transmission (WVTR) was determined from the slope obtained from the
268 regression analysis of weight loss data versus time, once the steady state had been
269 reached, divided by the film areas. For each type of film, WVP measurements were
270 replicated four times.

271

272 2.6.5. Oxygen Permeability

273 The oxygen permeability (OP) was obtained by using an Oxtran System (Mocon,
274 Minneapolis, USA) which determined the oxygen permeation. Measurements were
275 taken at 25°C following the standard method (ASTM D3985-05, 2005) at 53% RH. Film

276 samples (50 cm²) were introduced into the equipment to perform the assay. Films were
277 exposed to pure oxygen flow on one side and pure nitrogen flow on the other side. An
278 oxygen sensor read permeation through the film and the rate of oxygen transmission
279 was calculated taking into account the amount of oxygen and the area of sample.
280 Oxygen permeability was calculated by dividing the oxygen transmission by the
281 difference in oxygen partial pressure between the two sides of the film, and multiplying
282 by the average film thickness. At least two replicates per formulation were considered.

283

284 2.6.6. Mechanical properties

285 Mechanical properties were measured with a Universal Test Machine (TA.XT plus,
286 Stable Micro Systems, Haslemere, England) following the ASTM standard method
287 D882 (ASTM, 2001). Force-distance curves were obtained and transformed into stress-
288 strain curves which allowed tensile strength at break (TS), percentage of elongation at
289 break (%E) and elastic modulus (EM) to be obtained. Eight replicates carried out per
290 formulation. Equilibrated film specimens (2.5 cm wide and 10 cm long) were mounted
291 in the film-extension grips (A/TG model) which were set 50 mm apart. The speed of the
292 testing machine during stretching was 50 mm min⁻¹ until breaking.

293

294 2.6.7. Optical properties

295 The opacity of films was determined by applying the Kubelka-Munk theory of multiple
296 dispersion to the reflection spectra (Judd & Wyszecski, 1975; Hutchings, 1999). Internal
297 transmittance (Ti) of the films was quantified using eq. (3). In this equation R₀ is the
298 reflectance of the film on an ideal black background. Parameters a and b were
299 calculated by eqs. (4) and (5), where R is the reflectance of the sample layer backed by
300 a known reflectance R_g. The reflection spectrum on the white and black background
301 was determined from 400 to 700 nm with a MINOLTA spectrophotometer CM.36000d
302 (Minolta Co. Tokyo, Japan). Measurements were performed in the side of film which
303 was in contact with air during drying and each formulation was analyzed in triplicate.

304

305

$$T_i = \sqrt{(a - R_0)^2 - b^2} \quad (3)$$

306

$$a = \frac{1}{2} \left(R + \frac{R_0 - R + R_g}{R_0 R_g} \right) \quad (4)$$

307

$$b = (a^2 - 1) \quad (5)$$

308

309 Gloss measurements were obtained according to the ASTM standard D523 method
310 (ASTM, 1999), using a flat surface gloss meter (Multi-Gloss 268, MINOLTA) at an
311 angle of 60° with respect to the normal to the film surface. Three films of each
312 formulation were measured over a black matte standard plate. Results were expressed
313 as gloss units, relative to a highly polished surface of standard black glass with a value
314 close to 100.

315

316 2.7. Statistical Analysis

317 The analysis of data was performed through variance analysis (ANOVA) using the
318 Statgraphics Plus 5.1. software (Manugistics Corp., Rockville, MD). To discern
319 between samples the Fisher least significant difference (LSD) at the 95% confidence
320 level was used.

321

322 3. Results and discussion

323 3.1. Properties of the starches. Amylose:amylopectin ratio

324 Properties of starch films, such as mechanical behaviour, depend on the
325 amylose:amylopectin ratio since the different behaviour of amylose (AM) and
326 amylopectin (AP) molecules contributes to film properties (da Matta, 2011). The
327 amylose content of pea, potato and cassava starches were 24.9±0.9, 17.9±1.9 and
328 9±2, respectively with an amylose/amylopectin ratio of 1/3.0, 1/4.6 and 1/9.9,
329 respectively. These values reflect an important difference between these starches, pea

330 starch being the richest in amylose and cassava starch the poorest. Although the
331 obtained values are in the reported range for the different starches, differences
332 associated to origin or cultivar could be observed. Mehyar & Han, (2004); Chen et al.
333 (2008); Ma, Chang, & Yu, (2008) and Zhang & Han (2006) reported amylose contents
334 of between 30 and 40 % in pea starch, which is higher than the values obtained. For
335 potato starch the value obtained coincides with the result reported by Talja, Peura,
336 Serimaa, & Jouppila (2008) whereas it was lower than that reported by Alvani, Qi,
337 Tester, & Snape, (2011). (25.2-29.1%). For cassava starch, higher amylose contents
338 (19.7% and 22.5%) were found by Souza et al. (2011). The amylose content will affect
339 the film properties since the phenomenon of recrystallization, which occurs during film
340 formation and storage, has been mainly related with this polymer (Myllärinen, Buleon,
341 Lahtinen, & Forssell, 2002 and Rindlav-Westling et al., 1998). This phenomenon is
342 mainly responsible for changes in the mechanical behaviour (increase in the elastic
343 modulus and decrease in the film stretchability) which make the films excessively brittle
344 (Jimenez et al., 2012a).

345

346 3.2 X-ray diffraction

347 Figure 1 shows the X-ray diffraction spectra of pure starch films, which were
348 equilibrated at 53% RH and 25°C for 1 and 5 weeks in order to analyse the re-
349 crystallization progress in the films. For starch matrices, the crystalline structure was
350 mainly attributed to the spontaneous recrystallization of amylose molecules after
351 gelatinization (Myllärinen et al., 2002; Forssell, Helleman, Myllärinen, Moates, &
352 Parker, 1999 and Rindlav-Westling et al., 1998). This process occurs mainly during film
353 drying when the chain mobility is still high due to the water content. Several authors
354 (Rindlav-Westling et al., 1998) report that drying conditions at high relative humidity, or
355 long drying times, greatly promote amylose crystallization, whereas amylopectin shows
356 a retarded crystallization when the molecular mobility in the system is high enough.

357 After both 1 and 5 weeks of storage, pea starch films exhibited the highest crystallinity,
358 as deduced from the greater intensity of its sharp peaks. On the contrary, the lowest
359 crystallinity was found in cassava starch films, where an amorphous X-Ray diffraction
360 pattern was observed after both storage times. This behaviour can be related with the
361 different amylose:amylopectin ratio and confirms that the crystallization progress in the
362 films was faster as the amylose content increased. This was also observed by other
363 authors in gelatinized starch (García, Martino, & Zaritzky, 2000), whereas for native
364 starch the higher crystallinity in granules is associated with a greater content of
365 amylopectin (Cheetham & Tao, 1998).

366 A typical C-type crystallinity pattern was found in pea starch films. This type of
367 crystallinity is an intermediate form between A and B types, as reported by Carvalho
368 (2008). In this sense, pea starch films showed peaks at 2θ 5.4° (characteristic of B-type
369 polymorphs), 14.8° (characteristic of A-type polymorphs), 16.8° (characteristic of both A
370 and B-type polymorphs) and 19.0° and 21.8° (characteristic of B-type polymorphs).
371 Similar results have been observed by da Matta *et al.* (2011), Wu *et al.* (2010) and
372 Chen *et al.* (2009a). In the case of potato starch films, a typical C-type pattern can also
373 be observed, with peaks at 5.1° , 11.7° and 17.2° of Bragg angle. Nevertheless, the
374 peaks are smaller and less sharp as compared with those obtained in pea starch films,
375 which indicates that the film exhibited a more amorphous character with smaller
376 crystallites (Talja *et al.*, 2008). Cassava starch films were mainly amorphous since no
377 sharp peaks were found, as previously observed by other authors (Chen, Kuo, & Lai,
378 2009b).

379 Comparisons of diffractograms after 1 and 5 storage weeks allow us to conclude that
380 no significant changes in the crystallinity occur throughout the storage period, probably
381 due to the low moisture content of the films which inhibits the chain mobility to form
382 crystalline associations for both amylose and amylopectin polymers. Different authors
383 (Myllärinen *et al.*, 2002) have pointed out that amylose crystallizes very fast during the
384 film formation, whereas the crystallization of amylopectin is a slower process. In the

385 richest amylose starch (pea starch), crystallization had occurred at the first control time
386 (1 week) and probably during the drying period, as reported by other authors
387 (Myllärinen et al., 2002; Forssell, et al., 1999; Rindlav-Westling et al., 1998 and
388 Rindlav, Hulleman, & Gatenholm, 1997). During storage, no notable changes in the X-
389 ray diffraction pattern were observed in any case.

390

391 3.3. Microstructural features

392 SEM and AFM microstructure analyses provide information about the surface
393 morphology and internal microstructure of the films. Figure 2 shows SEM micrographs
394 of the surface and cross section of the different starch films. In general, starch films
395 showed a homogeneous aspect, thus indicating that the gelatinization step was enough
396 to disrupt all the starch granules. Smooth film surfaces were also previously observed
397 by other authors for starch films obtained by casting (Wu et al., 2010; Chen et al.,
398 2009a; Chen et al., 2009b). Nevertheless, in the cross section image, the presence of a
399 heterogeneously-fractured layer on the film surface in the pea starch sample reveals
400 the progress of crystallization in this zone, probably due to the greater molecular
401 mobility associated to the water vapour diffusion near the film surface. The presence of
402 microcracks in cassava starch films is remarkable. This may be due to the electron
403 impact during observation as explained by Jiménez, Fabra, Talens, & Chiralt (2012c),
404 as a result of the lower mechanical resistance of this sample.

405 Figure 3 shows AFM images of pea, potato and cassava starch films, obtained by
406 using PeakForce QNM. Raw data were converted into 2D images and their scale is
407 expressed as Log DMT modulus. Differences in the surface mechanical resistance can
408 be observed in the samples at both 1 and 5 storage weeks. The surfaces of pea and
409 potato starch films are rougher, which indicates the co-existence of crystalline (harder)
410 and amorphous (softer) zones. It is remarkable that these zones are wider in pea
411 starch than in potato starch samples, in agreement with the sharper peaks reflected in

412 the X-ray spectra, associated with bigger crystals. No notable differences were
413 appreciated between 1 and 5 storage weeks.

414 In cassava starch samples, more homogenous, but lower, values of DMT modulus can
415 be observed, due to the more amorphous character of the films. It is remarkable that in
416 these films, a harder surface was detected at 5 storage weeks which reveals that films
417 were significantly hardened (higher values of Modulus) during storage, although no
418 crystallization was detected since the surface appears homogenous. The different
419 behaviour of the starch matrices was coherent with the different amylose:amylopectin
420 ratio, which is associated with a different recrystallization progress during film
421 formation.

422

423 3.4. Moisture content and barrier properties

424 Table 1 shows the moisture content values of the studied films, stored for 1 and 5
425 weeks at 25°C and 53% RH Humidity. The values ranged between 9.9 and 11.4% and
426 pea and potato starch films were the samples which exhibited the highest moisture
427 content, as reported in previous studies (Mehyar & Han, 2004; Kaisangsti,
428 Kerdchoechuen, & Laohakunjit, 2012). This can be associated with the higher degree
429 of crystallization, since crystalline zones bond a greater amount of water than
430 amorphous zones (Myllärinen et al., 2002; Forssell et al., 1999 and Rindlav-Westling et
431 al., 1998). Nevertheless, moisture content significantly ($p < 0.05$) decreased after 5
432 storage weeks, when more homogeneous values of moisture content were obtained for
433 the different films. This development indicates that films equilibrate slowly with the
434 conditioning relative humidity, reaching a value closer to the equilibrium by losing water
435 during storage. The water loss will provoke a greater chain aggregation in the
436 amorphous region which will imply an increase in the film compactness that will affect
437 barrier and mechanical properties.

438 Water vapour permeability (WVP) values define the final application of a film in contact
439 with food systems and they must be as low as possible to avoid water transfer (Ma *et*

440 *al.*, 2008). Table 1 shows WVP values of starch films analyzed at 25°C and a 53-100 %
441 RH gradient. No significant differences between WVP values of the different films were
442 found at the different storage times, in agreement with results found by other authors
443 (Han *et al.*, 2006; Ma *et al.*, 2008). The small changes in sample moisture content and
444 the subsequent increase in the matrix compactness did not affect the water vapour
445 barrier properties of the films.

446 The oxygen permeability (OP) was analyzed at 25°C and 53% RH in films equilibrated
447 under these conditions for 1 and 5 weeks. Table 1 shows the mean values of OP after
448 the different storage times. For pea starch films, similar values have been reported by
449 Mehyar and Han (2004). After one week, the OP values were significantly lower for
450 films with the highest content of amylose (PE), which indicates that this polymer is
451 mostly responsible for the oxygen barrier ability of the films. This coincides with that
452 reported by García *et al.* (2000) for plasticized corn and amylo maize starch films.
453 Likewise, Forssell *et al.* (2002) report that unplasticized amylose films exhibited lower
454 oxygen permeability than amylopectin films, regardless of their equilibration at different
455 relative humidities. Nevertheless, the plasticizer content, in combination with the water
456 content, had a great influence on the oxygen permeability values of starch films. After 5
457 storage weeks, the oxygen permeability values of every film were significantly reduced,
458 coherently with the increase in the matrix compactness, as commented on above. In
459 general, the OP values are very low and, as reported by Shen, Wu, Chen, & Zhao,
460 (2010), one great advantage of starch films is their ability to protect food products by
461 forming an oxygen barrier.

462

463 3.5. Mechanical properties

464 Film properties related to easy film-handling, their fragility or their stretchability, are
465 very interesting from a technological point of view (Jiménez, 2009). Elastic modulus
466 (EM), tensile strength at break (TS) and percentage of elongation at break (%E) are the
467 usual parameters with which to describe the mechanical behaviour of films, and they

468 are closely related to the film microstructure (McHugh & Krochta, 1994). TS and %E
469 represent the film's resistance to elongation and its stretching capacity, respectively,
470 whereas EM is a measure of the stiffness of films. Table 2 shows the mean values of
471 these mechanical parameters for the films after 1 and 5 storage weeks at 25°C and
472 53% RH. The mechanical behaviour of starch films was similar to that reported by other
473 authors for pea starch films (Chen *et al.*, 2008, and Da Matta *et al.*, 2011), potato
474 starch films (Cyras, Manfredi, Ton-That, & Vázquez, 2008) and cassava starch films
475 (Famá, Rojas, Goyanes, & Gerschenson, 2005.and Souza *et al.*, 2011).

476 After one week of storage, the mechanical parameter values were significantly different
477 ($p < 0.05$) for the three matrices. The pea starch films (with the highest amylose content)
478 have the highest values in break strength and stiffness and the lowest in stretchability.
479 On the contrary, cassava starch films (with the lowest amylose content) exhibited the
480 lowest break strength values and the highest in stretchability. This indicates the
481 important role played by crystal formation in the mechanical behaviour of the matrix.

482 After 5 weeks of storage, film stiffness and resistance to break increased for all the
483 films, coinciding with the increase in the matrix compactness promoted by water loss.
484 Nevertheless, the highest relative increase occurs for cassava starch films, which could
485 indicate the formation of very small association zones of amylopectin chains between 1
486 and 5 weeks. In the same sense, although all the films lost stretchability during storage,
487 it was cassava starch films which experienced the greatest losses due to the greater
488 extent of amylopectin association during the storage period. As previously commented
489 on, amylose rich starch crystallizes very fast during film drying and subsequent
490 conditioning, whereas amylopectin rich films crystallize more slowly, which is reflected
491 in the way that the different films develop mechanical behaviour. Nevertheless, it is
492 remarkable that the films that are richest in amylose (pea starch) showed the highest
493 values of stiffness and resistance to break after long storage times, whereas
494 intermediate amylose films (from potato starch) showed the greatest stretchability after
495 5 storage weeks.

496

497 3.6. Optical properties

498 The optical properties of the films, gloss and transparency, are directly related with the
499 film microstructure (previously described) and are affected by the surface and internal
500 heterogeneity of the structure (Jiménez *et al.*, 2012b). According to Hutchings (1999),
501 the above-mentioned parameters are the best optical properties with which to evaluate
502 the appearance of the films. Table 3 shows the mean values of the internal
503 transmittance (Ti) of films measured at 450 nm. The Ti of films is related to their degree
504 of transparency and structural homogeneity: low Ti values are related to a high
505 structural heterogeneity with a greater opacity. Analyses were carried out in films
506 previously equilibrated at 53% RH and 25 °C. After one week of storage, different
507 starch based films did not show any significant differences ($p < 0.05$) as regards the Ti
508 values, these being about 85 %. These coincide with those reported in the case of corn
509 starch films Jiménez *et al.* (2012b). After five weeks, no significant changes in
510 transparency occurred in the films. Table 4 also shows the mean gloss values of starch
511 films, which were measured at after 1 or 5 weeks' storage at 53%RH and at an
512 incidence angle of 60° with respect to the normal to the film surface. At initial time, the
513 gloss values of pea starch films were higher than those corresponding with cassava
514 and potato starch films. The differences observed in the film gloss at initial time
515 remained after 5 weeks of storage, since in no case did any significant changes in
516 gloss occur during storage. The higher gloss of pea starch films could be due to the
517 presence of crystalline structures at surface level, as deduced from the SEM
518 micrographs and the higher surface modulus obtained by AFM.

519 In conclusion, films obtained from pea starch, richer in amylose, are stiffer, more
520 resistant to fracture and glossier and less permeable to oxygen, although less
521 extensible, than starch films with a lower amylose content. All the films become harder
522 and more resistant during storage, and those richer in amylopectin become shorter

523 (less stretchable). The oxygen permeability slightly decreased throughout storage time
524 in every case.

525

526 3.7. Effect of rice bran addition

527 The two rice bran fractions obtained by sieving were analysed as to the particle size
528 distribution by dispersing them in water to the adequate obscuration rate in the laser
529 diffraction equipment. The bran particle size distribution curves are shown in Figure 4
530 for both the smaller particle fraction (F) and the bigger particle fraction (C). Differences
531 between the particle size distribution of two fractions (F and C) can be observed,
532 although a certain degree of curve overlapping was obtained, since sieving only
533 partially separates the particles by size. In Figure 4, the mean values of the bran
534 particle size in terms of $D_{3,2}$ and $D_{4,3}$ are also shown. The differences between these
535 diameters in a given sample indicate that particle size distributions are wide or that they
536 are irregularly-shaped. On the contrary, similar values are associated with narrow
537 particle size distributions and more spherical particles. As expected, significant
538 differences ($p < 0.05$) between $D_{3,2}$ and $D_{4,3}$ were found for both fine and coarse
539 fractions, thus indicating the presence of irregular particles of very different sizes.
540 Figure 5 shows the SEM micrographs of the powder of both bran fractions. Fraction F
541 contains more spherical particles than fraction C which, in turn, contain composite
542 particles (where components are not released). The composition of both fractions is
543 shown in Table 4. The mean values of the moisture, protein, fat and ash contents were
544 very similar for F and C fractions, but significant differences were found for starch and
545 fibre contents; the fine fraction was richer in starch (twice) whereas the coarse fraction
546 contained more fibre. The obtained composition of the two rice bran fractions coincides
547 with data previously reported by Sánchez *et al.* (2004). The protein content is similar to
548 that reported by Rodríguez (2007), Gnanasambandam *et al.* (1997), whereas Pacheco,
549 Peña, & Ortiz, (2002) obtained a similar fat content. These authors observed that the

550 varietal effect and smoothening method may cause significant differences in the ash,
551 fat, protein, starch and fibre content of rice bran.

552

553 3.7.1. Effect of bran addition on microstructural properties

554 The microstructure analysis allows us to identify the arrangement of some components
555 of the film (mainly those non-miscible with the polymer) and the characteristics of the
556 polymer matrix. The microstructural features are also directly related with the film's
557 physical (mechanical, barrier and optical) properties. Figures 6 and 7 show the surface
558 and cross section micrographs of starch films containing rice bran obtained by SEM.
559 The cross section micrographs of films containing bran fractions show a continuous
560 matrix with similar characteristics to those described for bran-free films, but with some
561 dispersed particles, corresponding to proteins, lipid particles and fibres, incorporated by
562 bran. Dispersed particles also appear at surface level in the film, thus indicating that
563 flocculation and creaming occurred during film drying, leading particles to the film
564 surface. It is remarkable that no starch granules were appreciated in the observed
565 fields, which could be due to their gelatinization during the 4 minutes of hot
566 homogenization with the gelatinized starch dispersions. Fat and proteins could also be
567 well integrated in the matrix as a result of the thermal homogenization. In this sense,
568 the particles observed will be mainly fibre. Large composite particles are sometimes
569 observed (Figure 6), although in relatively low numbers for the fine fraction.

570 The presence of the large particles affected the film thickness. Incorporating bran
571 particles led to some irregularities in the film thickness related with the presence of
572 these very large particles. The mean thickness value of bran-films was $75.2 \pm 1.1 \mu\text{m}$,
573 whereas for films with F and C fractions the values were 75.8 ± 0.8 , and $98 \pm 4 \mu\text{m}$,
574 respectively. The variation coefficients were 1.5, 1.1 and 4.1%, respectively. This
575 indicates that while no differences were observed between bran-free films and those
576 containing the F bran fraction, the C fraction is, not suitable to be incorporated into the
577 films since it causes an irregular film formation with a non-constant thickness.

578

579 Figure 8 shows the surface micrographs of films containing rice bran obtained by AFM
580 using PeakForce QNM. The data were converted into 2D images in terms of Log DMT
581 modulus maps, where the darker colour means lower DMT modulus or soft areas. As
582 can be observed, the incorporation of bran filler implied the appearance of a great
583 number of hard particles on the film surface (white spots), as compared with the
584 polymer background, which indicates that the dispersed material which migrates to the
585 film's surface during the drying step is stiffer than the polymer matrix. The surface
586 characteristics of the continuous matrix remain as in the bran-free films with notable
587 differences between pea, potato and cassava films due to the differing extent of
588 amylose crystallization. Crystalline zones appear lighter, whereas amorphous zones
589 are darker. Differences can be observed between the ratio and size of the hard
590 particles on the film surface of the three different starch films. In pea starch films,
591 smaller, free particles can be observed, whereas bigger aggregates appear in the
592 potato starch films. In cassava starch films, the bran particles are not aggregated, but
593 some very soft small spots appeared, which could be attributed to discontinuities on the
594 film surface probably produced by the loss of particles, generating a surface void. This
595 can also occur in the other films, but due to the natural surface roughness it was not
596 easily appreciated.

597 The fact that there are differences in the particle distribution at surface level indicates
598 that differing degrees of flocculation and creaming occurred during film drying, which
599 depends on the viscosity of the aqueous medium induced by starch. In this sense, pea
600 starch, which has the highest amylose ratio, can form gel during film drying, thus
601 inhibiting the particle migration. Cassava starch did not form gel, but the solutions
602 exhibit very high viscosity. The potato starch film-forming dispersion is probably the
603 one that shows the poorest stabilizing properties, thus promoting particle flocculation
604 and migration towards the film surface.

605

606 3.7.2. Effect on barrier properties.

607 The moisture content of pure starch films ranged from 9.9 to 11.4 (Table 2). The
608 incorporation of rice bran provoked an increase in the film's moisture content as can
609 be observed in Table 1, mainly in films containing coarse fraction. This not only
610 indicates that the addition of fibre leads to an increase in the water retention capacity of
611 the films, as suggested by Zhang *et al* (2011), but also that the introduction of mineral
612 content (ashes) implies an increase in the water retention capacity of the matrix,
613 especially from intermediate relative humidity. After 5 storage weeks, the moisture
614 content significantly decreased ($p < 0.05$) in all the films, as was observed for bran-free
615 films, which suggests their slow equilibration with the storage chamber relative
616 humidity.

617 WVP, analyzed at 25°C and a relative humidity gradient 53 - 100%, are shown in Table
618 1. Whereas these values at initial time ranged between 5-6 g mm/ kPa h m² for starch
619 films without bran, in films containing rice bran these were significantly higher ($p <$
620 0.05), mainly for the films with the largest particles. This can be explained by the
621 greater water content in the films, which plasticizes the matrix, as well as by the
622 presence of large particles whose induced tension in the matrix can provoke
623 associated channels that constitute preferential paths for mass transport. On the
624 contrary, Famá *et al.* (2009) reported that wheat bran incorporation in cassava starch
625 significantly reduced the WVP, although they use particles with a lower size range:
626 between 75 and 125 µm. The low particle size is essential as a means of improving the
627 film matrix properties.

628 The influence of particle size on WVP values can be clearly observed in Table 1.
629 Coarse fibres significantly increased WVP as compared with fine fibres, regardless of
630 the type of starch. In this case, large particles seriously interrupt the continuity of the
631 films, thus creating large channels for water diffusion. After 5 weeks of storage, the
632 values of WVP slightly changed, but without any clear tendencies, depending on the
633 starch type and bran fraction. Nevertheless, whereas WVP values tend to decrease

634 with time in films with fine particles, in line with the moisture content reduction in the
635 matrix, they tend to increase in films with the largest particles and a greater fibre
636 content.

637 The OP of films containing bran (Table 1) follows the same tendency as observed for
638 bran-free films, increasing when the amylose content in the starch decreases.
639 Nevertheless, for fine bran, fibres provoked a slight increase in the oxygen permeability
640 of starch films, which can be due to increases in the films' water content. The
641 incorporation of coarse rice bran gives rise to films with micro-cracks, associated to the
642 tension in the dried film provoked by the largest particles. In these cases, it was not
643 possible to measure the OP and this also contributed to the anomalous values of the
644 WVP. After 5 storage weeks, the mean values of OP significantly decreased, as
645 observed in bran-free matrices, due to the reduction in moisture content.

646

647 3.7.3. Effect on mechanical properties

648 Table 2 shows the values of the mechanical parameters of the films with bran fractions
649 after 1 and 5 weeks of storage. The incorporation of rice bran did not significantly affect
650 the elastic modulus of potato and cassava starch films, but significantly increased the
651 elastic modulus of pea starch films. The film resistance to fracture was not significantly
652 affected by the addition of bran, although film extensibility was notably reduced, mainly
653 for the coarse fraction in potato and cassava starch films. In pea starch films, the
654 stretchability reduction is less appreciable due to their very low initial values. These
655 results are coherent with those reported by Famá *et al.* (2009) for cassava starch films
656 reinforced with wheat bran.

657 The effect of storage time is quite similar to that observed for bran-free films. The
658 elastic modulus increased in all cases, except pea starch films, where bran particles
659 partially inhibit the increase in the elastic modulus that occurred in bran-free films. This
660 may be due to the smaller water loss which occurred during storage when the films
661 contained bran. Film resistance to break increased in every case during storage,

662 except pea starch films where it diminishes, in agreement with that commented on
663 above. Film stretchability also decreases in all cases, the values being very similar for
664 all the films after 5 storage weeks. The presence of discontinuities in the matrix,
665 associated to bran particles, affected the matrix cohesion forces, giving rise to very
666 brittle matrices.

667

668 3.7.4. Effect on optical properties

669 Ti values of starch films containing bran fibres are shown in Table 3. As expected, bran
670 addition contributed to reduce film transparency due to the presence of a dispersed
671 phase that leads to light scattering. Nevertheless, as observed in bran-free films, the
672 transparency of films containing bran particles was not affected ($p > 0.05$) by the type
673 of starch, nor by the bran particle size. Similar results were found by Famá *et al.*
674 (2009). These authors also compared the yellow index (YI) of cassava starch samples
675 with different wheat bran contents and observed that YI values rose as the bran
676 content increased.

677 Table 3 also shows mean gloss values of starch films containing rice bran. Bran
678 addition decreased the film gloss with respect to the bran-free ones, except in potato
679 starch based films, where gloss was very low, even without added bran. The effect of
680 bran addition on gloss values was greater when coarse particles were added, in
681 agreement with their greater particle size which largely contributes to the increase in
682 the surface roughness and the subsequent gloss loss.

683

684 **4. Conclusions**

685 Properties of starch films were greatly affected by the amylose-amylopectin ratio.
686 Amylose-rich films form amylose crystalline regions during film drying which give rise to
687 stiffer, more resistant to fracture, but less stretchable films, with lower oxygen
688 permeability and more water binding capacity. All the films develop throughout storage
689 time, mainly due to water loss which leads to more compact matrices: stiffer, more

690 resistant to fracture and less extensible, with lower oxygen permeability, but without
691 changes in water vapour permeability. Rice bran with lower particle size ($D_{4,3} = 57\mu\text{m}$)
692 improved the elastic modulus of the films, especially in high amylose content films (pea
693 starch), but reduced the film stretchability and worsened barrier properties, due to the
694 enhancement of the water binding capacity of the films and the introduction of fibre
695 discontinuities in the matrix. So, the hygroscopic character of the filler was a drawback
696 to the improvement of the film properties. The reduction of the filler particle size is
697 necessary to minimize the negative effect of large particles.
